ASPERULA ODORATA. The herb of this plant contains cumarin, aspertannic acid (?), rubichloric acid, citric acid, and probably catechu.

ASPHALT. *Compact Bitumen, Mineral Pitch, Jew's Pitch, Bitumen Judaicum, Judenpech, Erdpech, Bergpech, Goudron minéral.*—A smooth, hard, brittle, black, or brownish-black, resinous mineral, having a conchoïdal fracture, and a streak lighter than the broken surface with which it is made. Specific gravity 1 to 1·68. Odour bituminous, becoming stronger by friction. Melts at about 100° C., easily takes fire, and burns with a bright, but very smoky flame. Like all bituminous substances, it is a product of the decomposition of vegetable matter, consisting chiefly of hydrocarbons, with variable quantities of oxygen and nitrogen, and yields by dry distillation a small quantity of ammoniacal water, a peculiar empyreumatic oil, and a residue of charcoal mixed with variable quantities of inorganic matter. It dissolves partially in alcohol, more easily in oils both fat and volatile; it is also dissolved by alkalis and alkaline carbonates.

Asphalt is found in most parts of the world, sometimes pure, sometimes associated with various minerals. The name *earthy* or *crude asphalt* is applied to various rocks more or less impregnated with bitumen. Pure asphalt is found on the shores of the Dead Sea, issuing from the earth in the liquid state at the bottom, and rising to the surface, where it forms solid lumps, which are thrown upon the shore. In Trinidad there is a lake of bitumen 1½ mile in circumference, cold and solid near the shore, but gradually increasing in temperature and softness towards the centre. Asphalt is also found, more or less pure, in Cuba, South America, and various parts of Europe.

At Seyssel, near the Rhone (Dépt. de l'Ain), it forms a deposit 2500 ft. long and 800 ft. broad, yielding about 1500 tons annually. At Bechelbrunn and Lobsann, in the Lower Rhine, a viscid bituminous mass is found, called *graisse de Strasbourg*, together with a ferruginous sandstone, containing about 12 per cent. of bituminous matter. At Bastennes and Dax, in the Département des Landes, there is a siliceous sand, impregnated with about 6 per cent. of bitumen. In the Val de Travers, Neufchâtel, there is a cretaceous formation, strongly impregnated with asphalt, which is used for building purposes. In the British Isles, asphalt is found at the Poldice mine in Cornwall; near Matlock in Derbyshire; at Haughmond Hill in Shropshire; and at the Hotwells near Bristol; also in limestone near Glasgow; in freestone near Edinburgh; in the sandstone of Caithness; and generally throughout the Orkneys.

Asphalt is separated from the minerals with which it is associated, either by boiling with water, which causes the bitumen to run out in the melted state, or by the action of hydrochloric acid, which dissolves carbonate of calcium and leaves the asphalt, or with oil of turpentine, which dissolves out the bitumen.

The following table contains the results of analyses of various kinds of asphalt: *a* is asphalt from Coxitambo inPeru; *b* from Bastennes; *c* from Pont-du-Château, Auvergne; *d* from the Abruzzi near Naples; *e* from Pontnavey; *f* from Cuba:

	100·00	100·00	100·00	100·00	100·00	100·00	100·00

According to Boussingault (Ann. Ch. Phys. [2] lxiv. 141), asphalt or compact bitumen is a mixture of two definite substances, viz. *asphaltene*, which is fixed and soluble in alcohol, and *petrolene*, which is oily and volatile. The greater part of the latter may be volatilised by distilling the asphalt with water.

Petrolene (from the asphalt of Bechelbrunn) forms, when dried over chloride of calcium and rectified, a pale yellow oil having a faint taste and bituminous odour. Specific gravity 0·891 at 21° C. Does not become solid at 12° C. It stains paper, and burns with thick smoke. Boils at 280°, forming a vapour of specific gravity 9·415. It contains, according to Boussingault, 87·2 per cent. carbon and 12·1 hydrogen, agreeing nearly with the formula $C^{20}H^{32}$, which for a condensation to 2 vols. gives the vapour-density 9·5.

Asphaltene is obtained pure by heating asphalt for 48 hours to 250° C., whereby the petrolene is completely volatilised. It is a black solid substance, having a strong lustre and conchoïdal fracture. It becomes soft and elastic at about 300° C., decomposes before it melts, and burns like a resin. It gives by analysis 74·2 per cent. C, and 9·9 H, whence Boussingault deduces the formula $C^{40}H^{32}O^{6}$. Gerhardt prefers $C^{20}H^{32}O^{3}$, and suggests that asphaltene may be formed by the oxidation of petrolene.

Asphalt-oil.—Asphalt yields by dry distillation, a yellow oil consisting of hydrocarbons mixed with a small quantity of oxidised matter. It begins to boil at 90° C. but the boiling point gradually rises to 250°. The portion boiling between 90° and 200° has a specific gravity of 0·817 at 15° C.; that which boils between 200° and 250° has a specific gravity of 0·868 at 15° C. Both portions gave by analysis about 87·5 per cent. carbon, 11·6 hydrogen, and 0·9 oxygen, which is nearly the composition of oil of amber. (Völckel, Ann. Ch. Pharm. lxxxviii. 139.)

Asphalt-oil, treated with nitric acid, is transformed into a resin, having the odour of musk and the taste of bitter almonds. On treating the oil with strong sulphuric acid, part dissolves, while the rest floats on the surface. This latter, when decanted, washed with potash, and rectified, yields an oily mixture, whose boiling point ranges from 90° to 250° C., and density from 0·784 to 0·867 at 15° C. Subjected to fractional distillation at intervals of 20° or 30° C., it yields a number of oils gradually

---

* Ann. Ch. Phys. [2] lxxiii. 422. † Ann. Min. xv. 523. ‡ Dingl. polytechn. J. lxviii. 201.

increasing in density, but agreeing very nearly in composition, the mean result of their analysis being 87·5 per cent. carbon, and 12·5 H, a proportion agreeing with the formula $n\mathrm{C}^7\mathrm{H}^6$. It agrees also with Boussingault's analysis of petrolene. All these oils have nearly the same odour, are insoluble in water, but very soluble in alcohol and ether. Strong sulphuric acid scarcely attacks them. They are insoluble in strong nitric acid, and on boiling the liquid, the nitric acid volatilises, and there is formed a very small quantity of a heavy yellow oil.

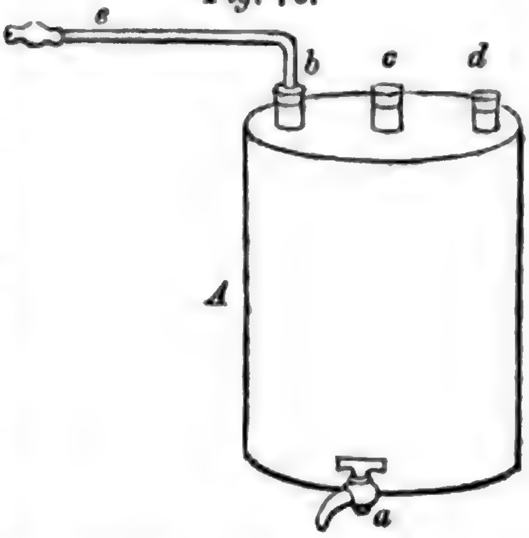
Asphalt was used by the ancient Egyptians in embalming, and appears to have been employed in the construction of the walls of Babylon. It is now used, mixed with sand, chalk, ground sandstone, &c., for pavement, for making water-tight tanks and covers, as a coating for tubes of glass and iron used for conveying gas or water, and for various other purposes of like nature.

Artificial or *Gas-tar Asphalt* is a mixture of sand, chalk, or lime-stone, with the thick pitchy residue obtained by evaporating off the more volatile portions of gas-tar. The mineral substance must be strongly heated to expel moisture and adhering air, the presence of which would prevent the pitch from penetrating thoroughly into the pores of the mineral, and added to the pitch while in the melted state. The pitch should also be very strongly heated, but not enough to char it. This artificial asphalt is used in the same way as the natural asphalt, for pavements, tanks, &c.

ASPHODELUS. The bulbs of *Asphodèle de Sardaigne*, of *Asphodelus racemosus*, and other species of the same genus, are said to contain a fermentable substance from which alcohol may be prepared. According to Landerer, an excellent glue may be obtained from the bulbs of *A. racemosus* and *A. fistulosus* by washing them with water, drying them thoroughly in a stove, grinding them to coarse powder, and mixing the powder with water.

ASPIRATOR. An apparatus first devised by Brunner for drawing a stream of air through a tube or other vessel. The simplest form of it is a cylindrical vessel *A* (*fig.* 76), of zinc or tin plate to hold water, having a cock *a* near the bottom, and three apertures closed with corks *b*, *c*, *d* on the top. *b* is connected with the vessel through which the stream of air is to be drawn; *c* is for the insertion of a thermometer, and *d* to pour in water. The vessel *A* being filled with water, the apertures *c* and *d* closed, and the *cock a* opened, the water runs out; and as air can only enter by the bent tube *e*, inserted into the opening *b*, a stream of air is drawn through the apparatus with which the other end of this tube is connected, the volume of air thus drawn through being exactly equal to that of the water which runs out at *A*. Instead of the metal cylinder, a glass vessel may be used, having a stopcock at the lower part of its side.

Fig. 76.



Regnault, in his analysis of air, used a cylindrical metal vessel with conical terminations, and having at the bottom, a stopcock to which was attached a short glass tube bent upwards, so that the small column of liquid which remained in it when the vessel was emptied of water might prevent air from entering at the bottom The advantage of the conical terminations is that the vessel can be more completely filled and emptied, and the volume of water which runs from it, more exactly measured.

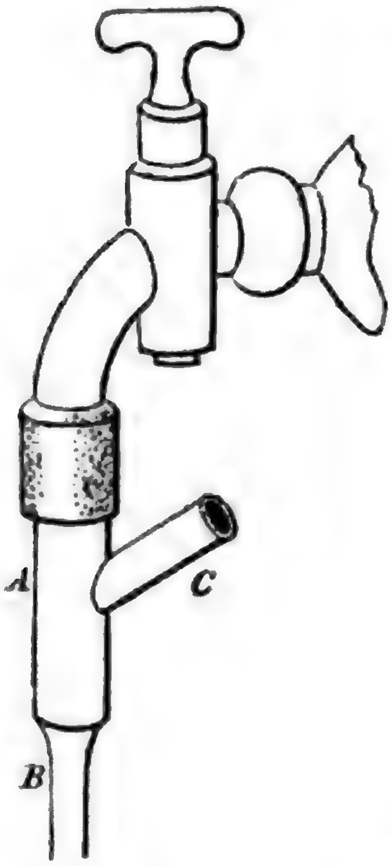
In all these forms of aspirator, the refilling of the vessel with water is very troublesome, especially when large quantities of air are to be drawn through. To obviate this inconvenience, an aspirator has been contrived by Brunner, consisting of two equal cylindrical vessels placed one above the other and communicating by tubes which can be opened or closed, so that, when the water has run from the upper to the lower vessel, the apparatus, turning for the purpose on a horizontal axis, may be inverted so as to bring the empty vessel to the bottom, and the full one to the top; the water may then be again made to run without the trouble of refilling.

Mohr's aspirator has the form of an ordinary gasometer, consisting of two cylindrical vessels, the inner of which, of rather smaller diameter than the outer, is closed at top, and inverted in the outer which contains water. The inner vessel is balanced by a weight passing over a pulley, as in the large gasometers used at gas-works. The vessel through which the air is to be drawn is connected with the inner vessel by a bent tube passing through the outer vessel near the bottom and terminating within the inner vessel.

A simple apparatus, serving both for aspirator and perspirator is described by Dr. F. Guthrie (Phil. Mag. [4] xv. 64).

An aspirator which works by a constant stream of water and does not require any filling or emptying of vessels, has been contrived by M. W. Johnson (Chem. Soc. Qu. J. iv. 186). The principle of this apparatus is the same as that of the water-blast used in the Hungarian mines. The apparatus consists of a small hollow cylinder *A*, of brass or glass, open at both ends, and connected with the vessel through which the air is to be drawn, by the lateral tube *C*. A straight glass tube *B* is fitted to the lower end of the cylinder *A*, and the upper end of that cylinder is attached by a caoutchouc tube to a water-tap supplying a constant stream. On opening the tap, the water, as it runs down, carries the air in the cylinder *A* along with it and the air in the lateral tube *C* is then driven in by the external pressure. In this manner, a stream of air is made to pass from *C* to *A* as long as the water is running. It is best not to open the tap to the full. For a cock $\frac{3}{8}$ of an inch in diameter, the cylinder *A* may be 2 in. long and $\frac{3}{4}$ in. wide; *B* 1 in. long and $\frac{3}{8}$ in. wide; *C* also 1 in. long and $\frac{3}{8}$ in. wide. The volume of air drawn through this aspirator is not equal to that of the water which runs away. With the tube *B*, 8 in. long and $\frac{3}{8}$ in. wide, Johnson found that, for every cubic foot of air drawn in, only 0·69 cub. in. of water was expended. It is clear, therefore, that this form of aspirator cannot be used when the volume of air drawn in is to be exactly measured. In that case one of the aspirators before described must be used. When only small quantities of water are run out, it is sufficient to receive the water in a graduated measure and determine its volume directly. When a large aspirator is used and has to be filled several times, its capacity must be previously determined by filling it with water from a flask of known capacity.

Fig. 77.



This volume of air determined by direct measurement of the water run out, must of course be reduced to the standard pressure and temperature, 0° C. and 760 mm., the coefficient of expansion for each degree centigrade being 0·003665. A correction is also required for the quantity of aqueous vapour in the air, which is saturated with moisture. To determine the alteration of volume thus produced, we must look in the tables of the tension of aqueous vapour for the tension corresponding to the observed temperature. Let this tension expressed in millimetres of mercury be f; also let h denote the height of the barometer, t the temperature in centigrade degrees; v the observed and v' the corrected volume of the air: then

$$v' = v . \frac{h - f}{760} . \frac{1}{1 + 0{\cdot}003665 . t}$$

ASSACOU or **USSACU.** The Brazilian name for the *Hura brasiliensis Martius*, a euphorbiaceous tree, the bark and sap of which contain an acrid very poisonous principle. The thickened sap and the decoction of the bark exert an emetic action, produce ulcerating pustules on the skin, and are used as a remedy for elephantiasis. The natives also use them to prepare poisonous drinks, against which no antidote is known. (Mérat and Gilbert, Pharm. Centr. 1849, p. 30.)

ASSAMAR. (From *assare* to roast, and *amarus* bitter.) This name was given by Reichenbach to the peculiar bitter substance produced when gum, sugar, starch, gluten, meat, bread, &c. are roasted in the air till they turn brown. Reichenbach (Ann Ch. Pharm. xlix. 3) prepares it by roasting thin slices of bread till they become black-brown, treating the pulverised product with absolute alcohol, evaporating to a syrup, again treating with alcohol, &c. till a residue is obtained completely soluble in alcohol. The alcoholic solution is then mixed with ether, which precipitates a peculiar brown substance; the decanted liquid is evaporated; and the residue carefully heated till it is dry. Völckel (Ann. Ch. Pharm. lxxxv. 74) prepares assamar in a similar manner, from the brown tarry liquid obtained by the dry distillation of sugar or caramel, after neutralising the acid contained in the liquid with carbonate of sodium, and evaporating.

Assamar, according to Reichenbach, is a yellow transparent solid; but according to Völckel, it is a reddish-yellow syrupy liquid, which does not solidify till it begins to decompose. It is extremely hygroscopic, and dissolves in water in all proportions. When heated, it melts (Reichenbach), becomes more fluid, and at 100° C., decomposes and becomes darker in colour, after which it no longer dissolves completely in water (Völckel). The aqueous solution is neutral, and reduces nitrate of silver when heated. Assamar is dissolved by potash, and acids precipitate from the solution, a body of different composition. Völckel assigns to assamar the formula $C^{24}H^{12}O^{12}$; but it is doubtful whether the substance so-called is a definite compound, or has ever been obtained in the pure state.

ASTER-TRIPOLIUM. *Sea Starwort.*—The ash of this plant, which grows in salt-marshes, is very rich in chloride of sodium. The several parts of the plant gathered towards the end of September, were found by Harms (Ann. Ch. Pharm. xciv. 247) to yield ash of the composition and amount given in the following table:

	Root-leaves.	Stems.	Stem-leaves.	Flowers.
Ash per cent	14·9	8·7	16·2	9·4
Containing, in 100 pts., after deducting charcoal and sand:				
Carbonic acid (anhyd.)	3·4	3·3	4·2	3·7
Sulphuric acid (anhyd.)	2·7	1·8	4·1	10·5
Phosphoric acid (anhyd.)	2·0	0·6	1·7	10·8
Silica (anhyd.)	0·6	0·5	0·8	1·0
Chloride of sodium	65·5	68·5	60·2	30·0
Chloride of potassium	3·7	14·1	—	—
Soda	—	—	14·0	1·4
Potash	13·6	2·5	6·1	25·4
Lime	5·0	4·5	4·8	7·2
Magnesia	2·2	2·2	1·7	5·7
Sesquiphosphate of iron	1·1	2·1	2·3	4·0
Manganaso-manganic oxide	trace	trace	trace	trace

ASTRACAMITE. A native sulphate of magnesium and sodium, $SO^4MgNa.2H^2O$ occurring in white, opaque, prismatic crystals, together with ordinary sulphate of magnesium, in the bitter salt-marshes on the eastern side of the mouth of the Volga.

ASTRALITE. A glass flux resembling aventurin, but containing crystals of a cuprous compound, which by reflected light exhibits a dichroitic iridescence of dark red and greenish-blue. To prepare it, a mixture of 80 pts. of silica, 120 lead-oxide, 72 carbonate of soda, and 18 anhydrous borax, is fused either with 24 pts. of scale oxide of copper, and 1 pt. of scale oxide of iron, or with 5 pts. of lime, 26 scale oxide of copper, and 2 scale oxide of iron. The mixture is fused in a hessian crucible, at the heat of an ordinary air-furnace, and left to cool slowly in the furnace. The first mixture melts more easily than the second, and yields larger crystals. The dichroitic iridescence is particularly beautiful on cut and polished surfaces. (Pettenkofer, Abhandl. d. naturw. techn. Commission bei d. Akad. d. Wiss. zu München, p. 134.)

ASTROPHYLLITE. A variety of mica found at Brevig in Norway. It contains silica, alumina, ferric oxide, magnesia, potash, soda (a trace), ferrous oxide, manganous oxide, lime, and about 3 per cent. of water. The amount of iron is unusually large. Fluorine is absent. Before the blowpipe it melts easily, and with intumescence. Colour pinchbeck-brown, varying to nearly a golden-yellow in the thinner parts. The crystals are often united in beautiful stellate and floral groups: hence the name. (Scheerer, Berg- u. hüttenmannische Zeitung, 1854, s. 240.)

ATACAMITE. A native oxychloride of copper, originally found in the desert of Atacama in Peru, and since observed in other localities, viz. in some silver mines in Peru, in the districts of Huasco Bajo and Aconcagua in Chili, in the lavas of Vesuvius, and in the mines of Schwarzenberg in Saxony. According to the analyses of Klaproth, J. Davy, Ulex, and Mallet, it contains $CuCl.3CuHO$, or $CuCl + 3(CuO.HO)$. Berthier (Rammelsb. Handw. i. 55), found in a specimen from Cobija, twice the amount of water given by the above formula. F. Field (Chem. Soc. Qu. J. vii. 194), deduces from his analysis of a specimen from Copiapo in Chili, the formula $CuCl + 3CuO + 5HO$, or $CuCl.3CuHO.H^2O$. It forms small rhombic crystals, varying in colour from leek to emerald green, and generally aggregated in crystalline groups. According to Monteiro (Phil. Mag. [4] xiii. 470), it occurs at Serra do Bembe near Ambriz, on the west coast of Africa, in small translucent crystals, $\infty P . \breve{P}\infty$, on malachite and quartz. It dissolves easily and completely in acids, and in ammonia. It is used for the extraction of copper.

ATHAMANTA OREOSELINUM. The root and seeds of this plant contain a peculiar bitter substance, not yet examined, together with athamantin (see next article). The leaves contain, not athamantin, but a bitter principle and a volatile oil, which is obtained by distilling the herb with water. This oil has the composition of oil of turpentine, $C^{10}H^{16}$; it smells like elder, has a density of 0·841, and boils at 163° C. With hydrochloric acid gas, it forms an uncrystallisable liquid, which is colourless after distillation, lighter than water, and boils at 190° C. It does not appear to be related, in composition or properties, either to athamantin or to oil of valerian, which is produced by the decomposition of the latter. (Schnedermann and Winckler, Ann. Ch. Pharm. li. 336.)

ATHAMANTIN. $C^{24}H^{30}O^7$. (Gm. xii. 101; Gerh. iv. 269.)—A substance existing in the root and seeds of *Athamanta oreoselinum*, and other species of the same genus. It was first obtained in an impure state by Winckler (Buchn. Repert. xxvii. 169), afterwards prepared pure and more completely examined by Schnedermann (Ann. Ch. Pharm. li. 315). It is extracted by treating the roots and seeds with alcohol. The solution, if not too concentrated, yields the athamantin, by spontaneous evaporation, in crystals, which may be purified by pressure and recrystallisation. It forms colourless, fibrous, silky crystals, or sometimes rectangular prisms with truncated summits; has a rancid soapy odour, and a slightly bitter acrid taste. It is insoluble in water, and melts in it at the boiling heat, in drops which sink to the bottom of the vessel. It dissolves readily in alcohol and ether, and the solutions are not precipitated by metallic salts. It melts between 60° and 80° C. It does not volatilise undecomposed, although it can sustain a tolerably high temperature without decomposition. By dry distillation, it yields valerianic acid and other products.

Melted athamantin absorbs hydrochloric acid gas, and appears to enter into combination with it, but on raising the temperature to 100° C., decomposition takes place, and the athamantin is resolved into valerianic acid and oreoselone:

$$\underbrace{C^{24}H^{30}O^7}_{\text{Athamantin.}} = \underbrace{2C^5H^{10}O^2}_{\substack{\text{Valerianic}\\ \text{acid.}}} + \underbrace{C^{14}H^{10}O^3}_{\text{Oreoselone.}}$$

When hydrochloric acid gas is passed into an alcoholic solution of athamantin, the products formed are oreoselone and valerate of ethyl. Sulphurous acid acts on athamantin like hydrochloric acid, a crystalline compound being formed at first, and soon afterwards oreoselone, valerianic acid, and sulphurous acid gas. Concentrated sulphuric acid dissolves athamantin and decomposes it in like manner. Athamantin heated with caustic potash, yields valerate of potassium, and a white amorphous substance, which appears to be a hydrate of oreoselone. Lime-water and baryta-water act in the same manner, but more slowly. (See OREOSELONE and PEUCEDANIN.)

Trichlorathamantin, $C^{24}H^{27}Cl^3O^7$, is a light yellow resinous body, produced by mixing an alcoholic solution of athamantin with water, and cautiously adding dilute chlorine-water, till the liquid smells slightly of chlorine. A corresponding bromine-compound appears to be formed by treating athamantin with bromine-water.

Trinitrathamantin, $C^{24}H^{27}(NO^2)^3O^7$, is formed, together with other substitution-products, by the action of cold fuming nitric acid on athamantin. Precipitated by water, it is a yellow pulverulent substance, scarcely wetted by water, easily soluble in alcohol, ether, and ammonia, slightly in dilute nitric acid. (Geyger, Ann. Ch. Pharm. cx. 359.)

ATHANOR or **ACANOR.** *Piger Henricus*, *Fourneau des paresseux*.—A kind of furnace, which has long since fallen into disuse. The long and tedious operations of the ancient chemists rendered it a desirable requisite, that their fires should be constantly supplied with fuel in proportion to the consumption. The athanor furnace was peculiarly adapted to this purpose. Beside the usual parts, it was provided with a hollow tower, into which charcoal was put. The upper part of the tower, when filled, was closely shut by a well-fitted cover; and the lower part communicated with the fire-place of the furnace. In consequence of this disposition, the charcoal subsided into the fire-place gradually as the consumption made room for it; but that which was contained in the tower was defended from combustion by the exclusion of a proper supply of air. U.

ATHAR or **ATTAR.** The Indian name of volatile oil of roses.

ATHERIASTITE. The name given by Weibye to a mineral from Arendal, bearing an external resemblance to scapolite. In composition it appears to be related to epidote, as will be seen by the following comparison of its analysis by Berlin (Pogg. Ann. lxxix. 302) with that of epidote from Arendal by Scheerer (*ibid.* xcv. 503).

	Atheriastite.	Epidote.
Silica	38·00	37·59
Alumina	24·10	20·73
Ferric oxide	6·22	16·57
Lime	22·64	22·64
Magnesia	2·80	0·41
Water	6·95	2·11
	100·71	100·05

Berlin does not state whether the iron in atheriastite is present as a ferrous or as a ferric compound; but it is probably all in the form of ferric oxide. (Scheerer, Handw. d. Chem. 2^{te} Aufl. i. 405.)

ATLAS ORE. See Malachite.

ATLAS SPAR. See Satin Spar.

ATMERYTHRIN. The name given by Kane (Compt. rend. ix. 656) to a product which volatilises in red vapours, and condenses in reddish-green laminæ, in the dry distillation of litmylic acid (erythrolitmin) and litmic acid (a mixture of azolitmin and spaniolitmin), with lime.

ATMIDOSCOPE. An instrument invented by Babinet (Compt. rend. xxvii. 529) to measure the rate of evaporation.

ATMOSPHERE. The gaseous envelope which surrounds any solid or liquid body is called an atmosphere (ἀτμὸς smoke, σφαῖρα globe); thus we speak of the atmosphere of oxygen which spongy platinum attracts to its surface, or of the reduction of a metal in an atmosphere of hydrogen. The term atmosphere is, however, especially employed to designate the gaseous matter which encircles the solid and liquid portions of the earth's surface, forming the air or earth's atmosphere.

Of the existence of matter above the visible crust of the globe we have striking evidence in the resistance offered to bodies moving near the earth's surface and in the effects produced by wind; but the most direct proof that the air is attracted by the solid and liquid portions of the earth's body, or that the air has weight, is afforded by the fact that a vessel filled with air weighs more than the same vessel from which the air has been removed, and that a closed vessel filled with air weighs less in the atmosphere than it does in a vacuum. That the air possesses weight was suspected even before the time of Aristotle; but Galileo, in 1640, was the first who gave the right explanation to the fact observed by the Florentine pump-makers, that they were unable to raise water by a suction-pump more than 32 feet, and supposed by them to show that nature had a "horror vacui." Galileo's explanation was beautifully verified by his pupil Torricelli, who argued that, if the atmospheric pressure supports a column of water 32 feet in height, it must support a column of mercury, which is nearly fourteen times heavier than water, of about 30 inches in height; and thus the first barometer was constructed, the empty space above the mercury in the tube being called, from its discoverer the, *Toricellian vacuum*.

The atmosphere, then, having weight, or obeying the laws of gravitation, forms a part of the earth's body, and accompanies the solid and liquid portions in their axial and orbital motions. The height to which the atmosphere extends above the earth's surface is not the same at all points, since, owing to the increase of the attractive force at the poles and its diminution at the equator, and to the action of the centrifugal force, as also to the increase of temperature, the atmosphere presents, like the earth's solid body, the form of a spheroïd, whose polar is considerably shorter than its equatorial diameter. The absolute height to which the atmosphere extends above any point on the surface of the earth has not been determined with any degree of certainty: for, as air is an expansive fluid, and the volume which a given quantity of air occupies is directly dependent upon the pressure and temperature to which it is exposed (in accordance with the known laws regulating the expansion and contraction of gases), the density of the atmosphere is not uniform, but diminishes as the distance from the earth's surface increases: the exact point at which the atmosphere terminates is thus very difficult to determine. That there is, however, a limit of the earth's atmosphere is rendered certain from the fact, ascertained by the observations of the occultations of stars or satellites, that our moon and most of the planets are destitute of an atmosphere like ours, which could not be the case if the terrestrial air were diffused throughout space. Dr. Wollaston supposed that a gas cannot expand beyond a certain limit, and Faraday has shown that in the case of the vapour of mercury such a limit really exists: hence there can be no doubt that there is a definite limit to the atmosphere; and, from calculations of the time during which the twilight extends to the zenith, it appears that the atmosphere reaches, in a state of sensible density, to the mean height of from forty to forty-five miles above the earth's surface.*

Barometric observations at various heights above the sea-level prove conclusively that Galileo's theory of atmospheric pressure is correct. The first of these barometric measurements, made on the Puy-de-Dôme by Pascal's advice in 1648, showed that the column of mercury supported by the atmosphere sinks as the distance from the earth's surface increases; thus, at the sea-level, the mean height of the barometric column is 760 millimetres (29·92 English inches), whereas in Potosi, at a height of 13,220 feet, the mercury sinks to a mean level of 471 millimetres. The average weight, then, of the atmosphere at the level of the sea is, in our latitudes, that of a column of mercury 760 mm. in height, or equal to a pressure of 103·33 kilogrammes on a square decimetre (nearly 15 pounds on a square inch). This weight, the human body, in common with all substances existing at the bottom of the ocean of air, has to carry; and although it may at first sight appear remarkable that the animal frame should be able without discomfort to bear a pressure amounting to several tons, yet it is certain that not only is this the case, but that our bodies are arranged so that we cannot exist without this pressure; and as an effect of the weight of the air, it has been shown by the brothers Weber, that the human thigh-bone is, in certain positions of the body, retained in its place, together with the ball and socket hip-joint, only by atmospheric pressure; it is well known also that persons remaining for any length of time at great heights above the earth's surface are inconvenienced by hæmorrhage from the nose, eyes, and mouth, owing to the small blood-vessels, unsupported by the atmospheric pressure, being unable to withstand the forcible propulsion of the blood through the system.

The relation according to which the density of the air diminishes in ascending, is easily deduced from the well-known law of Mariotte, that the density of a gas is directly proportional to the pressure to which it is subject; whence it follows that, alterations of temperature and variations in the force of gravity at different heights not being considered, the density diminishes in a geometrical ratio, as the height increases in an arithmetical ratio. It has been found by experiment that, when the barometer stands at a height of 760 mm. it is necessary to ascend 10·5 metres in order to effect a fall of 1 millimetre in the barometric column, or to bring the mercury to stand at 759 mm., or at $760 \cdot \frac{759}{760}$ mm. Now we may assume, without appreciable error, that the air throughout this space of 10·5 metres is of equal density; at a height, then of 10·5 metres the pressure is $760 \cdot \frac{759}{760}$: hence the air in the next 10·5 metres has only a density of $\frac{759}{760}$ of what the lower layer had; and therefore, in ascending through the second 10·5 metres, the barometer does not fall 1 millimetre, but only $\frac{759}{760}$ of a millimetre, so that at a height of twice 10·5 metres, the barometer will stand at $760 \cdot \frac{759}{760} - \frac{759}{760} = 760 \cdot \left(\frac{759}{760}\right)^2$; and as the density of the third layer of 10·5 metres is $\frac{759}{760}$ times less than that of the second, the barometer at the height of three times 10·5 metres, will be $760 \cdot \left(\frac{759}{760}\right)^2 - \left(\frac{759}{790}\right)^2 = 760 \cdot \left(\frac{759}{760}\right)^3$, and so on. If, then, at two places the barometer stands respectively at $B = 760 \cdot \left(\frac{759}{769}\right)^n$ and $B' = 760 \cdot \left(\frac{759}{760}\right)^m$, their difference in elevation is $10{\cdot}5\,\text{m} \times (n - m)$; hence, from these two equations the difference in height, H, between these two points expressed in metres is

$$H = 18363\,(\log B - \log B')$$

or in English feet

$$H = 60246\,(\log B - \log B').$$

By means of this formula, we find that the pressure is diminished to half its original amount, and therefore the air expanded into double its original volume, at a height of 5528 metres or 18,136 ft. above the level of the sea, and that at a height of twice 5528 metres, the pressure is reduced to ¼ of its original amount, and so on.

The mean temperature of the atmosphere, like its density, is not equal throughout the mass, but diminishes as the distance from the earth's surface increases, so that, at a certain height above the sea-level, different for different latitudes, we arrive at a

---

* In order to give an idea of the relation between the earth's diameter and the height of the atmosphere, it may be stated, that if we represent the earth by a globe of 1 foot in diameter, the atmosphere will be represented by a layer of air $\frac{1}{15}$ of an inch in height.

line above which the mean temperature of the air does not rise higher than the freezing point, and this line is called the level of perpetual snow. This regular diminution of temperature in the higher regions of the atmosphere is to be attributed mainly to two causes: 1st, to the fact that the air absorbs but a small portion of the heating rays of the sun in their passage to the earth, the lower zones of the atmosphere being heated by contact with the warmer solid and liquid crust of the globe; and, secondly, to the increase of latent heat which all gases undergo on rarefaction, producing a diminution in temperature. Besides this regular alteration of mean temperature of the various zones of air above the earth, the various portions of the atmosphere exhibit great and constant variation in temperature, owing to the unequal heating effects produced by the sun on the earth in various latitudes and at various times. The mean temperature of any place, and therefore of the air above that place, is the resultant of the amount of heat received from the sun, and that lost by radiation. These two controlling causes are, however, never constant, either in the same or in different places, and hence the temperature is continually varying. The chief factor representing the change of temperature, is the height to which the sun rises above the horizon, and the intensity with which any point on the earth's surface is heated, is proportional to the cosine of the sun's zenith-distance at that point; thus, in the torrid zone, the sun's zenith-distance varies from 0° to 33°·5, or the cosine from 1 to 0·917, whilst in the temperate and frigid zones the cosine of the angle varies from 0·930 to 0·367, and from 0·731 to 0. We see from these numbers that, although many other circumstances, such as duration of day and night, and the thickness of atmosphere through which the sun's rays have to pass affect the temperature, the warm climate of the torrid zone is not subject to such variations as occur in the other portions of the globe. The height at which the mean atmospheric temperature sinks below 0° C., or the height of the snow-line, in different latitudes, is determined by many circumstances besides those already mentioned, as, for instance, the geographical relations of the country, neighbourhood of large masses of water, &c.; thus the snow-line on the northern slope of the Himalaya is found at a height of 15,600 ft., whilst on the southern slope it reaches only 12,200 ft. above the sea. Still the general descent of the line of perpetual snow with increase of latitude is, notwithstanding these local irregularities, plainly seen; thus, under the equator, the snow line is not reached until 15,207 ft., whereas, under the latitude of 60°, it is found at 3818 ft., and in latitude 75°, at only 1016 ft. above the sea-level.

In passing through the atmosphere, a portion of the solar rays is absorbed, the amount of this absorption depending upon the thickness of the layer of air through which the rays pass. Pouillet (Pogg. Ann. xlv. 25 and 481) concluded, from his own experiments, that when the sun is in the zenith and the atmosphere clear, the amount of the sun's heat which is absorbed by passing through the air, varies from 18 to 25 per cent. of the quantity which enters the atmosphere.

The light of the sun is also partially absorbed and reflected in its passage through the air, and, according to Clausius (Pogg. Ann. lxxii. 294), out of 1000 rays of direct sunlight entering the atmosphere, 750 reach the earth direct, whilst 186 are reflected as diffuse light, and 64 are absorbed. For the more refrangible chemically active rays, Bunsen and Roscoe have lately determined the amount of atmospheric absorption and reflection: for the numerical results of these experiments the reader is referred to the article on the Chemical Action of Light. Besides suffering absorption and reflection, every ray of light which enters the atmosphere otherwise than perpendicularly to the limiting surface, undergoes refraction, or is bent out of its course in the direction of the denser medium, so that, as we see the object in the direction of the tangent to the curve as it enters the eye, all celestial objects appear higher than they really are. According to the experiments of Biot and Arago, the refractive index, from the absolute vacuum into air at 0° C. and 0·76 m. pressure of mercury, is 1·000294; and hence the refractive power of the air is equal to 0·000588.*

Owing to the unequal heating effect which the sun produces on the various portions of the earth's surface, either from general or local causes, the temperature of the atmosphere varies in every part of the globe, and in the same part undergoes continual change, thus producing the motion of masses of air which we call wind. Winds are invariably caused by the ascent of a heated mass of air, and the motion of a colder mass to fill up the space thus left vacant; the former of these gives rise to currents in the higher regions of the atmosphere, whilst the latter produces the horizontal currents which we observe at the surface of the earth. Winds may either be confined to very narrow limits, as for example the sea and land breezes seen on every coast, or they may extend over a large portion of the globe, as is the case with the trade winds. The former are caused by local circumstances depending upon the unequal heat-absorb-

---

* *If the index of refraction be = n, the refractive power is n^2-1. See* LIGHT.

ing and radiating power of the sea and land, whilst the latter depend upon the unequal distribution of temperature throughout the globe, being caused by the rise of hot air from the equatorial zones, inducing horizontal currents to stream in from the colder polar regions. These polar currents would, if the earth were at rest, move directly south and north to the equator; but, owing to the earth's axial motion from west to east, they pass continually over latitudes having a velocity of rotation greater than that of the current, which therefore acts as a resistance towards the east, or as a north- or south-east wind.

Composition of the Atmosphere.

It was not until the year 1774 that the true composition of the atmosphere was pointed out by **Lavoisier**. Before this time, the air was spoken of as one of the four elements, together with fire, earth, and water; and it was only during the few years preceding this date that the vague impressions of speculative philosophers were exchanged for the careful observations of Priestley and Scheele, whose discovery of oxygen had paved the way for the knowledge of the exact composition of the atmosphere. In November 1774, having the advantage of acquaintance with Priestley's previous discovery of the vital air procured from red precipitate, Lavoisier announced to the world that the atmosphere consists of two gases, one of them being essential to life, and the other incapable of supporting respiration or combustion. These two gases he named *oxygen* (ὀξὺ, acid, and γεν to give rise to) and *azote* (α privative, and ζωὴ, life) or *nitrogen*, and he found that the first of these gases occupies about one-fifth by bulk of the atmosphere, the other occupying the remaining four-fifths. Besides these two gases, which form by far the largest portion of the atmosphere, many other substances occur in the air, which although present in comparatively small quantities, play so important a part in the action of the atmosphere on our globe that they cannot be regarded as accidental constituents: these substances are, *aqueous vapour*, *carbonic acid*, *ammonia*, and *organic decomposing matter*. The atmosphere also contains traces of very many other bodies which may be considered as foreign or accidental constituents, such as nitric acid, sulphurous acid, carbonic oxide, hydrocarbons and minute solid particles which are seen floating about in the air by the light of a sunbeam.

Since the time of Priestley, Scheele, and Lavoisier, the determination of the quantitative composition of the atmosphere has been made the subject of experiment by many of the most eminent chemists of the present century; but in spite of these numerous investigations, the relative distribution of the component gases of the atmosphere is still but imperfectly known.

At the commencement of this century, there was much difference of opinion amongst scientific men as to the true composition of the atmosphere: Prout, Döbereiner, and Thomson considered the atmosphere to be a chemical compound of 20 volumes of oxygen, and 80 volumes of nitrogen, whilst **Dalton** (Manchester Memoirs, 2 Ser. vol. i. p. 244) contended that the atmosphere is a mere mechanical mixture, but supposed that the relative amounts of the two gases varied according to their specific gravities at different heights above the earth's surface, the oxygen increasing in quantity the nearer the sea-level was approached, and the amount of nitrogen becoming larger as the distance from the surface of the earth increased.

That the determination of the amount of **oxygen** which air in different localities contains, should have excited the interest of men of science as soon as the discovery of the true composition of the air was made, does not seem remarkable, when we bear in mind the direct dependence of all life upon this element, and the great influence which even slight alterations in the amount of atmospheric oxygen might produce on the animal life subjected to this change, and hence Eudiometry (εὔδιος, good, εὐδία, serene air, and μετρεῖν, to measure), or the mode of measuring the quality of the air, quickly became a new and important branch of chemical analysis. At first sight it appeared not unlikely that the unequal development of animal life on the various parts of the globe, would effect considerable alterations in the composition of the air in different localities; and this idea was borne out, not only by the well-known fact of the unhealthiness of the air of certain districts, such as crowded towns, marshes, and the like, but also by the earliest determinative experiments, which showed variations in the composition of air of various localities amounting to nearly 10 per cent. Thus Fontana determined the quantity of oxygen contained in air by absorption with nitric oxide, and obtained results showing from 18 to 25 per cent.; whilst Scheele, on absorbing the oxygen with sulphide of potassium, or by a mixture of sulphur, iron, and water, found from 25 to 33 per cent. of that gas present in air. Other experimenters, however, and among them Dalton, Gay-Lussac, Davy, and Boussingault found, on employing other analytical methods, that the amount of the atmospheric oxygen varied but very slightly in different situations, and that the non-accordance of the results formerly obtained was owing to errors of experiment, caused by the use of imperfect methods. The quantity of oxygen found by Dalton in English air was from 20·7 to 28 per cent., and Gay-Lussac and Humboldt found that Paris air contained from 21·1 to 20·9 per cent., whilst Davy in London obtained from 20·8 to 21·1 per cent.; Thomson in Glasgow, 21·1; and Kupffer, in Kasan, 21·1 per cent. of oxygen. Experiments made by Dalton himself on the composition of mountain air, did not tend to confirm his theory as to the diminution of the relative quantity of oxygen at great heights; and further experience showed that Dalton's views, although theoretically correct for an atmosphere of mixed gases at rest, are not applicable to the air in motion: for Gay-Lussac and Thénard analysed the air which the former savant collected in his celebrated balloon ascent at a height of 7000 metres, and they found that the oxygen amounted to 21·6 per cent. agreeing exactly with an analysis of the air of Paris, made in the same way at the same time, both differing, however, owing to a common error of experiment, from the exact result of later observers. Although from these experiments we can draw the important conclusion that, within certain very small limits, the air has throughout its mass a constant composition as regards oxygen, still the observational errors of these earlier investigators were large, and it was evidently necessary that the composition of the atmosphere should be determined with all the precision that modern science could bestow. The more recent labours of Dumas and Boussingault, Regnault, Bunsen, and Lewy, have attained this end by help of methods in which the maximum error is reduced to $\frac{1}{5000}$.

The analysis of air may be conducted in two ways. Either by measuring the volumes of the component gases, or by determining their weight. The details of the former, or the eudiometric method, are fully described in the article on ANALYSIS OF GASES, and this is the method adopted, with slight variations, by Regnault, Bunsen, and Lewy, whilst the determination by weight has been employed by Dumas and Boussingault.

For the purpose of carrying out the analysis of air, these two French chemists [Ann. Ch. Phys. [3] iii. 257], employed an apparatus in which air previously freed from aqueous vapour, carbonic acid, and ammonia, by passing through U-tubes containing sulphuric acid and potash, was passed through a weighed tube containing metallic copper kept at a red heat, and then entered an exhausted balloon, the weight of which had been accurately determined. The difference of weight of the tube before and after the experiment, was due to the oxygen; that of the balloon, to the nitrogen of the air which passed into the apparatus. This process, conducted with every possible precaution, showed the composition of the atmosphere to be:

	Percentage of oxygen by Weight.	
1841.	Small balloon.	Large balloon.
27th April	22·92	22·92
28th „	23·03	23·09
29th „	23·03	23·04
	22·993	23·016

or 100 parts by weight of air, are composed of 23 parts of oxygen, and 77 parts of nitrogen. From this composition by weight, the composition by volume of the air can be determined when the specific gravity of the oxygen = o and that of the nitrogen = n are given: for $\frac{23}{o} + \frac{77}{n} = \frac{100}{1}$. Dumas and Boussingault found, on employing the specific gravities as obtained by Berzelius and Dulong, that the sum was not 100 but 99·76; hence they concluded that these specific gravities must be incorrect, and determined them again, obtaining o = 1·1057, and n = 0·972, from which the composition by volume of the atmosphere was found to be

$$\begin{array}{lcr} \text{Oxygen} & = & 20{\cdot}81 \\ \text{Nitrogen} & = & \underline{79{\cdot}21} \\ & & 100{\cdot}02 \end{array}$$

The near approximation of these numbers to the truth, has since been proved by the very exact experiments of Regnault (see Regnault's work on Steam, p. 151; or Pogg. Ann. lxxiv. p. 202), who has shown that one litre of air at 0° C. and 0·76 m. pressure, freed from moisture, carbonic acid, and ammonia, weighs 1·293187 grms., whilst one litre of oxygen, under like circumstances, weighs 1·429802 grms., or has a specific gravity of 1·10563, and 1 litre of nitrogen at 0° C. and 0·76, weighs 1·256167 grm., or has a specific gravity of 0·97137. In accordance with these results, Boussingault found in air which he collected in South America, the following percentage volumes of oxygen:

Air from Santa Fé de Bogota,	at a height of	2650 m.	above sea-level	20·65 p. c. O.
„ Ibaqué	„ „	1323	„ „	20·70 p. c. O.
„ Mariquita	„ „	548	„ „	20·77 p. c. O.

The eudiometric determinations of Bunsen and Regnault are on the whole to be preferred to any method of analysis of the air by weight, not only from their greater accuracy, but from the simplicity of the apparatus employed, and the ease with which small samples of air collected at various times and in different localities can thus be analysed.

Bunsen (Gasometry, p. 71), in a series of analyses of air made on fourteen different days in January and February 1846, amongst which the maximum amount of oxygen was 20·97 per cent. and the minimum 20·84 per cent., found a mean of 20·93 per cent. of oxygen.

Regnault (Ann. Ch. Phys. [3] xxxvi. 385) has analysed a very large number of samples of air collected in various quarters of the globe in a uniform manner, according to instructions given by him. The method of analysis employed rarely gave a difference of 0·02 per cent. on the same sample of air. In more than one hundred analyses of air collected in or near Paris, Regnault found a maximum amount of 20·999 vols. of oxygen, and a minimum of 20·913 or a mean of 20·96. This difference of 0·086 per cent. is, according to Regnault, too large to be accounted for by experimental errors.

9 samples from Lyons, Montpelier, Normandy gave from	20·918 to 20·966	p.c. of O.
30 samples collected in Berlin contained . . .	20·908 „ 20·998	„
10 „ „ Madrid „ . . .	20·916 „ 20·982	„
23 „ from Geneva and Chamounix . . .	20·909 „ 20·993	„

Of seventeen samples of air collected in Toulon Roads and other parts of the Mediterranean, fifteen gave similar results of 20·912 to 20·982 per cent. oxygen, whilst two samples collected from Algiers harbour contained only 20·42 and 20·395 per cent. This abnormal result cannot be accounted for, but a similar phenomenon was observed by Lewy.

5 samples taken on the voyage from Liverpool to Vera Cruz gave	20·918 to 20·965	p. c. of O.
2 samples from Ecuador in S. America contained .	20·96	„
2 „ the summit of Pichincha, higher than Mont Blanc	20·949 to 20·988	„

Eleven samples collected in the Asiatic seas from 1848 to 1850, all except two, gave normal results. On the 1st February 1849, the air in the Bay of Bengal contained only 20·46 and 20·45 per cent. oxygen, and on the 8th March 1849 the air from above the Ganges, collected during foggy weather, in presence of much decomposing animal matter, temperature 35° C., when cholera was commencing, contained from 20·390 to 20·387 per cent. of oxygen.

Air collected by Captain Sir James Ross in the Arctic seas gave the normal composition from 20·86 to 20·94 per cent. oxygen. The conclusion which Regnault draws from all these determinations, is that the atmosphere shows perceptible, though very small, alterations in the amount of oxygen at different times and in different places. This variation ranges from 20·9 to 21·0 per cent., but from special unknown causes in tropical countries, the amount of oxygen may sink as low as 20·3 per cent. Bunsen's analyses of the air in Iceland confirm these views.

Lewy (Ann. Ch. Phys. [3] xxxiv. 1) has also published a series of analyses of air collected from various parts of the globe. The relative amounts of oxygen and nitrogen were determined by Regnault's eudiometric process, and the maximum difference between the composition of the same sample of air analysed at different times was $\frac{1}{10000}$. The air of Paris contained, in a mean of three experiments, 21·014 per cent. of oxygen, that of Havre 20·888 per cent., whilst that collected on the Atlantic gave 20·961 and 21·061 per cent., and in South America, 20·995 and 21·022 per cent. of oxygen. Hence we can positively state that no greater difference exists between the composition of the atmosphere as regards oxygen and nitrogen in different latitudes (some few special cases excepted), than is found in the same place at different times.

Frankland (Chem. Soc. Qu. J. xiii. 22) has lately determined the composition of air collected by himself at different elevations on Mont Blanc, viz. at the Grands Mulets, at the summit, and at Chamounix. The conclusion which Frankland draws from his experimental numbers is, that as far as the nitrogen and oxygen are concerned, the composition of these samples of air falls within the limits of variation noticed by former experimenters.

That the air is a mechanical mixture and not a chemical combination of oxygen and nitrogen is seen from the following facts: 1. The amounts of oxygen and nitrogen in the air do not present any simple relation to the combining proportions of these elements, and are moreover variable. 2. On mixing oxygen and nitrogen gases in the proportion in which they occur in air, no contraction or evolution of heat is observed, and the mixture acts in every way as air. 3. When air is dissolved in water, the proportion between the oxygen and nitrogen in the dissolved air is quite different from that in the undissolved air, this difference occurring in strict accordance with the laws of the absorption of gases in liquids (see Gases, Absorption of). When water is saturated with air at any temperature below 30° C., 100 volumes of the dissolved air contain 34·19 vols. of oxygen and 65·09 vols. of nitrogen, whilst the undissolved air contains 21·1 per cent. of oxygen and 78·9 per cent. of nitrogen. Were the air a chemical combination of oxygen and nitrogen, such a separation by solution would be impossible.

The other constituents of the atmosphere, viz. the aqueous vapour, carbonic acid, ammonia, and decomposing organic matter, alter in amount at various times and in different places, much more considerably than the oxygen and nitrogen.

The humidity of the air is affected by many circumstances, such as temperature, distance from masses of water, and configuration of the land over which it lies. The amount of aqueous vapour which any volume of air can take up depends entirely upon the temperature of the air, and is represented by the tension and corresponding density of the vapour of water in vacuo for that temperature; thus at 10° C. the tension of aqueous vapour is 9·47 mm. of mercury, and the corresponding density 0·00000974, or 1 cubic metre of air at 10° C. is saturated when it contains 9·74 grms. of water in the form of vapour. It seldom happens, however, that the air contains its saturating quantity of moisture, and the amount varies extremely with the conditions before mentioned; thus, on the coast of the Red Sea, during a simoon, the air was found to contain only $\frac{1}{13}$ part of the aqueous vapour required to saturate it, whilst in our moist climate, the air is often saturated with watery vapour. The following table shows the relative humidity, *i. e.* the existing percentage on the saturating quantity, as found by Kämtz in Halle, as a mean of several years' observations:

Jan.	Feb.	March.	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.
85·0	79·9	76·4	71·4	69·1	69·7	66·5	61·0	72·8	78·9	85·3	86·2

Hence we see that in Halle the air is most humid in December and driest in August.

The determination of the aqueous vapour contained in the atmosphere may be made, either by leading a known volume of air through weighed tubes containing some hygroscopic substance, as sulphuric acid or chloride of calcium, or by means of hygrometers of various construction, for the description of which the article Hygrometry must be consulted.

The carbonic acid or anhydride contained in the air varies also considerably in amount, though by no means to so large an extent as the aqueous vapour. Many methods are employed for ascertaining the quantity of carbonic acid present in the atmosphere. The most certain method is to absorb the carbonic acid from a known volume of air by passing the air, freed from aqueous vapour and ammonia, through weighed tubes containing caustic potash. Saussure (Pogg. Ann. xix. 391), Brunner (Pogg. Ann. xxiv. p. 569), Pettenkofer (Chem. Soc. Qu. J. x. p. 292), Smith (Chem. Soc. Qu. J. xi. p. 196), and Frankland (Chem. Soc. Qu. J. xiii. 27), have all proposed different methods, for the explanation of which we must refer to the original papers.

From very numerous observations made by Saussure, Brunner, Lewy, and others, it appears that air in the open country contains quantities of carbonic acid varying from 3 to 10 volumes in 10,000 of air. As an average number, it has been found that 4 vols. in 10,000 represent the usual composition of the air as regards carbonic acid. In some few peculiar cases, a much larger proportion of carbonic acid has been found (as noticed by Lewy in S. America at Bogota); but these abnormal results are explained by local circumstances, as neighbouring volcanic emanations or burning forests. The air collected above the ocean showed a small variation in carbonic acid between day and night; that collected in the day contained 5·4, whilst that collected during the night contained 3·3 carbonic acid in 10,000 volumes of air. This observation is easily accounted for by the increase of the coefficients of absorption with the diminution of temperature occurring during the night. Air above the land also slightly changes its amount of carbonic acid at various seasons of the year and times of the day, in dependence upon different meteorological alterations, but as yet experiment has not decided the nature of this dependence. At a certain elevation above the earth's surface, the air, according to Saussure and Schlagentweit, contains more carbonic acid than is found in the lower belts of the atmosphere; this increase, which however is not large, probably arises from the decrease of vegetation in the higher atmospheric regions. In the air of crowded towns or of closed inhabited spaces (such as dwelling-rooms, &c.), the carbonic acid often rises to ten times the normal quantity, owing to inefficient ventilation.

Although the relative amount of 4 vols. of carbonic acid in 10,000 vols. of air appears to be a very small one, yet the absolute quantity of carbon thus contained in the atmosphere is very large, exceeding indeed all that is contained on the earth's surface in the solid form, in the bodies of plants and animals, and that found under the earth's solid crust in the coal formations. The question of change in the composition of the earth's atmosphere as regards carbonic acid is one of vital interest to all forms of terrestrial life: for whilst forming the staple nutriment of the vegetable world, carbonic acid, when present in certain quantities, acts as a violent poison on the higher orders of animal life; nor is the limit at which this gas begins to be hurtful to the animal, very far removed from the quantity which at present exists in the atmosphere: for we find that Leblanc and Péclet assign a limit of five in 1000 (ten times the normal quantity), whilst Reid and Arnott give a much lower limit to the non-injurious effect of this gas. Whether the atmosphere is now slowly undergoing, or has in past ages undergone, any perceptible change in the amount of its carbonic acid, is a question to which, owing to the absence of certain and accurate data, we are as yet unable to give any very satisfactory answer. We do, however, know that there are a great number of causes continually at work, some of which tend to increase the amount of atmospheric carbonic acid, whilst there are others which tend to effect a diminution in this constituent. Whether the resultant of these various counteracting influences is such as to keep, during future ages, the carbonic acid exactly at the present amount, it is, with our present knowledge, impossible to say; but from the remarks which follow, it will be seen that if any alteration occur, it must proceed with extreme slowness.

The principal causes which tend to increase the atmospheric carbonic acid are: (1) The respiration of animals. (2) Combustion of vegetable carbonised material. (3) Exhalations of carbonic acid caused by volcanic and other intra-terrestrial agencies. It would appear that the quantity of carbonic acid escaping from volcanic vents, mineral springs, and other inorganic sources into the atmosphere is much larger than that produced by the two causes first named. According to the calculations of Poggendorff (naturally but very rude approximations to the truth), it seems that, taking the amount of carbonic acid evolved by volcanic action to be ten times larger than that given off by every kind of combustion of carbonised material, the quantity of carbonic acid at present contained in the atmosphere would be doubled in 386 years, supposing, of course, that no causes of diminution of were acting. That such causes of diminution are, however, continually at work we know. They consist mainly in (1) the decomposition of carbonic acid, *i. e.* reduction of carbon and regeneration of oxygen, which living vegetables effect in sunlight. (2) The fixation of carbonic acid as carbonate of lime by the vital action of certain animalculæ, giving rise to coral reefs and islands, and the whole of the vast limestone deposits. (3) The fixation of carbonic acid by inorganic chemical processes.

The immense extent to which these actions, particularly the second one, have gone and are still going on, appears to justify the opinion that if any change in the amount of the atmospheric carbonic acid occur at all, it is more probably a diminution than an increase. Any conclusions which we can draw from geological facts, seem rather to support this opinion: for it is more likely that the air contained a larger amount of carbonic acid during the deposition of the enormous carboniferous system when the vegetation must have been so luxuriant and profuse, and when few, if any, air-breathing animals existed, than less than at present. Still, we have no right positively to assume that the air at the time of the deposition of the coal and limestone contained more carbonic acid than now: for we know nothing of the length of time during which these formations were in progress.

From the foregoing remarks, it is seen that a continual circulation of the atmospheric carbon takes place; the animal gives off the waste portion of its body mainly as carbonic acid, and thus deteriorates the atmosphere, which would soon become unfit for his further use, if the vegetable world did not absorb the poisonous gas, at once retaining the carbon in the solid form, fit for the subsequent nourishment of the animal, and exhaling the oxygen wherewith the higher organism again removes his spent materials.

Having described the causes effecting possible variation of the atmospheric carbonic acid, it is almost needless to consider any change which the oxygen may undergo, for the atmosphere becomes unfit for the sustenance of animal life from the presence of a small quantity of carbonic acid, long before the oxygen is materially diminished. If, however, the carbonic acid is slowly decreasing, it may be interesting to inquire how long our supply of oxygen will last us. Such a speculation has been answered, as satisfactorily as the circumstances admit of, by Dumas and Boussingault. These chemists calculated that if the whole of the earth's atmosphere were put into a balloon and suspended from one end of a balance, it would require 581,000 cubes of copper, each having a side of 1 kilometre (1093 English yards) in length, to be suspended at the other end to equalise the balance. Of this total weight, the oxygen would be represented by 134,000 cubes. Assuming, from the best data, that a man consumes a kilogramme of oxygen per day, taking the population of the earth to be 1000 millions, and supposing that the oxygen taken up by animals and by putrefactive processes is four times as large as that consumed by human beings, and supposing further, that the oxygen given off by plants only covers the expenditure of oxygen effected by other causes not mentioned, it appears, even in this exaggerated case, that an amount of oxygen three times as large as that consumed in one century by the whole number of animals existing on the earth, is represented by 15 or 16 of the copper cubes, each having a side of 1 kilometre in length, or the alteration effected in a century is less than $\frac{1}{8000}$ of the total quantity of oxygen, and is therefore altogether inappreciable by our most exact determinative methods. (See Dumas and Boussingault (1841) Ann. Ch. Phys. [3] iii. 257, 288.)

As regards the ammonia and the organic impurities contained in the atmosphere, we still labour under the disadvantage of insufficient experimental data. The great difficulty in the estimation of these constituents, lies in the very minute quantities which are contained in the atmosphere. This difficulty is seen when we compare some of the statements put forward of the amount of atmospheric ammonia; thus Horsford (Ann. Ch. Pharm. lxxiv. 243), found in 1 million parts of air, 47·6 parts of ammonia, whilst Bineau (Ann. Ch. Phys. xlii. p. 462) found in the same quantity of air, from 0·04 to 0·1 part of ammonia. Between these extremes, we have numerous experiments in which every variation in the quantity of atmospheric ammonia has been found. Although, from the great differences in the numerical results (maximum 135; minimum 0·1 parts of carbonate of ammonia), probably arising, partly from errors of analysis and partly from real variations in the contained quantity, it is impossible to fix upon any number as giving the average composition, still it is certain that the atmosphere always contains ammoniacal salts, and that rain (the first portions more than the latter portions), hail, snow, and dew, all contain appreciable quantities of ammonia.

The atmospheric ammonia plays a very important part in vegetation: for it is mainly if not altogether, from the ammoniacal salts contained in the air, that plants obtain the nitrogen which they require for the formation of seed and other essential parts of their structure. Whether plants are at all able to assimilate the free nitrogen of the atmosphere, must, in spite of the numerous researches on the subject, be considered doubtful. George Ville has for some time asserted, founding his assertion on a large number of elaborate experiments, that plants can absorb and assimilate the free atmospheric nitrogen. Boussingault, on the contrary, from his own extensive investigations, *denies* Ville's conclusions, affirming that it is from nitrogenous compounds alone that plants can assimilate the nitrogen. The commission of the French Academy, which was deputed to examine the question under the direction of Chevreul, reported in Ville's favour, although some doubt as to the estimation of the ammonia contained in the distilled water used, was expressed. Still more lately Lawes, Gilbert, and Pugh, have investigated the subject with great care, and find that plants growing in an atmosphere and on a soil free from ammonia or combined nitrogen in other forms, do not contain more nitrogen than the seeds from which they grow. In the state of uncertainty in which such contradictory statements leave us, we may, however, be certain of one fact in which all the experiments agree, namely, that whether or not plants can assimilate small quantities of free nitrogen, it appears that plants growing in air perfectly free from ammonia, do not flourish to anything like the same extent as plants living in an ammoniacal atmosphere.

Concerning the remaining constituents, and especially the organic putrescent matters, our present knowledge is even less satisfactory or positive than is the case with the ammonia. Within a very recent period, we were unacquainted with any method for determining the presence of organic putrescent matters; and even the very important and ingenious method lately proposed by Dr. R. Angus Smith (Chem. Soc. Qu. J. xi. p. 196) requires much extension and general application before we can arrive at a knowledge of the exact qualitative distribution of the organic impurities. Smith's method (for the details of which we must refer to the paper), depends upon the reducing action which solid, liquid or gaseous organic putrescent matter effects on permanganate of potassium. The strength of the test-solution is determined by adding it to a solution of sugar of known composition, until the colour of the permanganate remains permanent; and the same reaction performed with the air under examination, shows the quantity of contained organic matter. In this way, Smith has detected great differences between the air of various localities. The air from high country ground was found to contain 1 grain of organic matter in 200,000 cubic inches of air, whilst the air from a cesspool contained the same quantity of organic matter in 60 cubic inches of air. In a sanitary, as well as in a purely scientific point of view, it is difficult to over-estimate the importance of this simple method for determining the organic impurities which air contains; and if future research confirm its applicability to all cases, it will prove an invaluable instrument in the hands of the physician and the sanitary reformer.

Besides the constituents already mentioned, air contains minute quantities of **nitrates**, **hydrocarbons**, **sulphurous** and **sulphuric acids**, and according to some chemists, iodine, but this has been lately denied. Ozone also occurs in the atmosphere in very small amounts, varying, however, extremely with the situation and meteorological conditions of the place. (See OZONE.)

The atmosphere of the ocean, as well as of the masses of fresh water occurring on the earth's surface, is subject to the same changes from the existence of animal and vegetable life, as the earth's gaseous atmosphere. The relative proportion between the gases dissolved in the water is fixed in accordance with the law of absorption, and many important and interesting conclusions, such as the relative increase of dissolved oxygen, or diminution of temperature, enabling mammalia to live in the polar but not in the tropical seas, can be drawn from an application of these laws to the atmosphere of the sea. The equilibrium between the constituents of the dissolved atmosphere kept up by animal and vegetable life, is well illustrated by the vivaria now so common, which were first introduced by Mr. Warington.

The air of towns and close-inhabited spaces, becomes, as has been stated, often overcharged with carbonic acid and other impurities. The amount of carbonic acid present in dwelling-rooms, &c., has been made the subject of experiment by Leblanc (Ann. Ch. Phys. [3] v. 223; xxvii. 373), Pettenkofer (Chem. Soc. Qu. J. x. 292); Roscoe (Chem. Soc. Qu. J. x.); and Smith (Chem. Soc. Qu. J. xi. 196). The main results may be stated to be: (1) that in rooms which are not thoroughly ventilated, the amount of carbonic acid may rise from 1 to 7 volumes in 1000 of air; (2) that in well ventilated rooms, the amount of carbonic acid should not rise above 0·8 in 1000; (3) that in ordinary dwellings, or even in school- or barrack-rooms, the carbonic acid is diffused uniformly throughout the space, in whatever parts of the room the exit for deteriorated air is placed, though in the exaggerated case of crowded theatres, the air at the highest part of the building was found to contain more carbonic acid than the air at the level of the stage. For other interesting details, we must refer to the original papers, or to the article on VENTILATION. H. E. R.

ATOMIC VOLUME. *Specific volume; Equivalent volume; Molecular volume.* — The atomic or specific volume of a body is the space occupied by a quantity of it proportional to its atomic weight, and is therefore expressed by the quotient of the atomic weight divided by the weight of a unit-volume, that is by the specific gravity:

$$\text{Atomic volume} = \frac{\text{atomic weight}}{\text{specific gravity}}$$

It must not, however be supposed that the atomic volumes represent the relative volumes of the actual material atoms of different bodies. For, regarding any substance, solid, liquid, or gaseous, as an aggregate of material particles capable of moving amongst themselves, it is impossible to suppose these particles to be in actual contact and to fill up the entire volume of the body; we must suppose them to be separated by certain intervals: consequently the specific gravity, and therefore also the specific volume of the body, will depend, partly on the relative weights of these atoms, partly on the number of them contained in a given space, and therefore on the magnitude of the interstitial spaces. Unless, therefore, the spaces are either infinitely small in comparison with the magnitude of the atoms themselves, or bear the same proportion thereto in all bodies, it is impossible to determine the relative volumes of the actual material atoms: for we have no means of ascertaining the proportion between the size of the atoms and of the intervening spaces in each particular case. The atomic volume of bodies must therefore be understood, as the spaces occupied by aggregates of atoms (including the interstitial spaces), whose weights are proportional to the atomic weights of the bodies.

As the atomic weights, or multiples thereof, represent the proportions in which bodies combine by weight, so likewise do the atomic volumes or multiples thereof indicate the proportions in which they unite by volume, thus: the atomic volume of iodine being $\frac{127}{4 \cdot 95} = 25 \cdot 7$, and that of silver $= \frac{108}{10 \cdot 4} = 10 \cdot 2$, we infer that 25·7 vols. iodine unite with 10·2 vols. silver to form iodide of silver, AgI.

The numbers representing the atomic volumes of bodies vary according to the units of atomic weight and specific gravity chosen, and according to the particular values assigned to the atomic weights. Thus, if the atomic weight of hydrogen be equal to 1, that of chlorine = 35·5, and of sulphur = 32, the atomic weight of hydrochloric acid (HCl) will be 36·5, and that of sulphydric acid (H^2S) = 34. Now the specific gravity of hydrochloric acid gas referred to air as unity is 1·264, and that of sulphydric acid is 1·177. Hence we have:

$$\text{Atomic volume of HCl} = \frac{36{\cdot}5}{1{\cdot}264} = 14{\cdot}44$$

$$\text{,, ,,} \quad H^2S = \frac{34}{1{\cdot}177} = 14{\cdot}44$$

If, on the other hand, we adopt hydrogen as the standard of specific gravity for gases, that of hydrochloric acid is 18·25, and that of sulphydric acid is 17, in each case half the atomic weight. On this hypothesis, therefore, the atomic volumes of both gases are expressed by the number 2. Again, if common ether be represented by the formula $C^4H^{10}O$ [C = 12, H = 1, O = 16], its atomic weight is 74; and, its specific gravity in the gaseous state being 37 (referred to hydrogen), its atomic volume in that state is $\frac{74}{37} = 2$, and in the liquid state (specific gravity at 0° referred to water), its atomic volume is $\frac{74}{0{\cdot}737} = 100{\cdot}41$. But if ether be represented by the formula C^4H^5O [$C = 6$, $H = 1$, $O = 8$], then its atomic volume in the gaseous state will be $\frac{37}{37} = 1$, and in the liquid state $\frac{37}{0{\cdot}737} = 50{\cdot}205$. The atomic volumes of gases and vapours are calculated from the specific gravities referred either to hydrogen or to atmospheric air; those of solids and liquids from the specific gravities referred to water as unity.

Atomic Volumes of Gases.

According to the system of atomic weights adopted in this work, equal volumes of different elementary gases are supposed to contain, for the most part, equal numbers of atoms of their respective elements, so that the atomic weight of each body in the gaseous state is the weight of a volume of the gas equal to that of a quantity of hydrogen whose weight is taken as unity; in other words, the atomic weights of the simple gases are expressed by the same numbers as their specific gravities referred to hydrogen as unity. This is sometimes expressed by saying that an atom of each elementary gas occupies *one* volume. The only exceptions to this law are presented by phosphorus and arsenic, whose densities in the gaseous state are double of what they should be if they followed the law; and by selenium and tellurium, whose vapour-densities have not yet been ascertained with certainty. Sulphur-vapour was formerly supposed to have a density three times as great as that which the general law just stated requires, but recent experiments have shown that it conforms to the general law.

The atoms or molecules of compound bodies in the gaseous state occupy, for the most part, *twice* the volume of an atom of hydrogen or other simple gas; in other words, the number of molecules of a compound gas contained in a given space is half the number of atoms of hydrogen which would be included in that same space. Consequently, the specific gravity of a compound gas or vapour referred to hydrogen as unity is equal to half the atomic weight. Thus, the atomic weight of hydrochloric acid (HCl) is 36·5, and its specific gravity referred to hydrogen is 18·25; the atomic weight of ammonia (NH^3) is 17, and its specific gravity referred to hydrogen is 8·5. (For the further development of this law, and for certain exceptions to it, real and apparent, see the article ATOMIC WEIGHTS.)

The mode of stating these laws of gaseous atomic volume, must of course be modified according to the system of atomic weights chosen. On that which has hitherto been most generally adopted ($H = 1$, $O = 8$, $S = 16$, &c.), some of the elementary gases, viz. chlorine, iodine, bromine, nitrogen, and mercury are supposed to have atomic volumes equal to that of hydrogen, while oxygen, sulphur, phosphorus, and arsenic have atomic volumes only half as great. The former are generally called *two-volume* gases, and the latter *one-volume* gases, the volume of oxygen being taken as the unit. On the same system, the molecules of most compound bodies in the gaseous state are said to occupy *four* volumes.

Atomic Volumes of Liquids and Solids.

1. **Of Elementary Bodies.** The following table contains the atomic volumes of those solid and liquid elements whose densities have been determined with accuracy. The numbers in the third column are the quotients of the atomic weights divided by the specific gravities referred to water as unity:

Substance.	Atomic weight.	Atomic volume.	Specific gravity (water = 1).
Aluminium . .	13·75	5·3	2·5—2·67, Wöhler; 2·67, Deville.
Antimony . .	120·3	17·9	6·72, Marchand and Scheerer; Kopp.
Arsenic . . .	75	13·3	5·63, Karsten; 5·67, Herapath.
Bismuth . .	210	21·2	9·80, Marchand and Scheerer; 9·78, Kopp.
Bromine . .	80	25·8	*Liquid:* 3·19, Pierre; 2·99, Löwig.
Cadmium . .	56	6·5	8·69, Stromeyer; 8·45, Kopp.
Calcium . .	20	12·6	1·58, Bunsen.
Carbon . . .	12	3·4	*Diamond:* 3·52, Brisson.
		5·2	*Graphite:* 2·32, Karsten; 2·27, Regnault.
Chlorine . .	35·5	26·7	*Liquid:* 1·33, Faraday.
Chromium . .	26·2	3·8	7·01, Bunsen and Frankland.
Cobalt . . .	29·5	3·5	8·49, Brunner; 8·51, Berzelius.
Copper . . .	31·7	3·6	8·95, Marchand and Scheerer; 8·93, Kopp.
Glucinum . .	4·7	2·2	2·1, Debray.
Gold . . .	196	10·2	19·34, G. Rose; 19·26, Brisson.
Iodine . . .	127	25·7	4·95, Gay-Lussac.
Iridium . . .	99	4·5	21·80, Hare.
Iron . . .	28	3·6	7·84, Broling; 7·79, Karsten
Lead . . .	103·6	9·2	11·39, Karsten; 11·33, Kopp.
Lithium . .	7	11·9	0·59, Bunsen.
Magnesium . .	12	6·9	1·74, Bunsen; 1·70. Kopp.
Manganese . .	27·6	3·5	8·03, Bachmann; 8·01, John.
Mercury . .	100	7·4	*Liquid:* 13·60, Regnault, Kopp.
Molybdenum . .	46	5·3	8·62—8·64, Buchholz.
Nickel . . .	29·5	3·4	8·60, Brunner; 8·82, Tupputi.
Palladium . .	53	4·6	11·80, Wollaston.
Phosphorus . .	31	16·8	*Yellow:* 1·84, Schrötter; 1·83, Kopp.
		15·8	*Red:* 1·96, Schrötter.
Platinum . .	99	4·6	21·5, Wollaston, Berzelius.
Potassium . .	39·2	45·6	0·86, Gay-Lussac and Thenard.
Rhodium . .	52	4·7	11·0, Wollaston; 11·2, Cloud.
Selenium . .	79	18·4	*Amorphous:* 4·28, Schaffgotsch.
		16·4	*Granular:* 4·80, Schaffgotsch.
Silicon . . .	28	11·2	*Graphitoïdal:* 2·49, Wöhler.
Silver . . .	108	10·2	10·4, Karsten, 10·57, G. Rose.
Sodium . . .	23	23·7	0·97, Gay-Lussac and Thenard.
Strontium . .	43·8	17·2	2·54, Bunsen.
Sulphur . .	32	15·2	*Trimetric:* 2·07, Marchand and Scheerer, Kopp.
		16·2	*Monoclinic:* 1·98, Marchand and Scheerer.
Tellurium . .	128	20·6	6·24, Berzelius; 6·18, Löwe.
Tin . . .	118	16·2	7·29, Karsten; 7·30, Kopp.
Tungsten . .	92	5·3	17·2, Allen and Aiken; 17·5—18·3, Wöhler.
Uranium . .	60	3·3	18·4, Péligot.
Zinc . . .	32·5	4·6	7·13, Kopp; 7·1—7·2, Bolley.

The numbers in the third column of this table, do not exhibit the simplicity of relation which exists between the atomic volumes of gaseous bodies. There are, indeed, several causes which interfere with the existence, or at least with the observation, of such simple relations between the atomic volumes of solid and liquid elements. In the first place, the densities of three of them, viz. mercury, bromine, and chlorine, are such as belong to them in the liquid state, whereas the densities assigned to all the others have been determined in the solid state. In solids, moreover, the density is greatly affected by the state of aggregation, whether crystalline or amorphous, and in dimorphous bodies, each form has a density peculiar to itself. Further, as solids and liquids are variously affected by heat, each having a peculiar rate of expansion, and that rate being different at different temperatures, it is not to be expected that their atomic volumes should exhibit simple relations, unless they are compared at temperatures at which they are similarly affected by heat. Even gases are found to exhibit abnormal atomic volumes if compared at temperatures too near the points at which they pass into the liquid state. In liquids, the simplest relations of atomic volume are found at those temperatures for which the tensions of the vapours are equal (Kopp); and in solids, the melting points are most probably the comparable temperatures. Now the specific gravities of most of the solid elements in the preceding table, have been determined at mean temperatures (as at 15°·5 C.), which, in the case of potassium, sodium, phosphorus, and a few others, do not differ greatly from the melting points, but in other cases, as with gold, platinum, iron, &c., are removed from the melting points by very long intervals. In spite, however, of these causes of divergence, the atomic volumes of certain analogous elements are very nearly equal to each other: viz. those of selenium and sulphur; of chromium, iron, cobalt, copper, manganese and nickel; of molybdenum and tungsten; of iridium, platinum, palladium and rhodium; and of gold and silver.

2. **Of Liquid Compounds.** The relations between the atomic volumes of liquids, have been investigated chiefly by H. Kopp (Ann. Ch. Pharm. xcvi. 153, 303, c. 19). The atomic volumes of liquids, as already observed, are comparable only at temperatures for which the tensions of their vapours are equal, as at the boiling points. If the atomic weights are compared with the densities at equal temperatures, no regular relations can be perceived; but when the same comparison is made at the boiling points of the respective liquids, several remarkable laws become apparent. The density of a liquid at its boiling point cannot be ascertained by direct experiment; but when the density at any one point, say at 15·5° C., has been ascertained, and the rate of expansion is also known, the density at the boiling point may be calculated. (See EXPANSION.)

Table A. contains Kopp's determinations of the atomic volumes of several liquids containing carbon, hydrogen, and oxygen, at their boiling points. The atomic weights are those of the hydrogen scale. The *calculated* atomic volumes in the fourth column are determined by a method to be presently described; the *observed* atomic volumes are the quotients of the atomic weights divided by the specific gravities at the boiling referred to water as unity.

TABLE A.

Atomic Volumes of Liquids containing Carbon, Hydrogen, and Oxygen.

	Substance.	Formula.	Atomic Weight.	Atomic Volume at the Boiling Point.	
				Calculated.	Observed.
Type HH.	Benzene	C^6H^6	78	99·0	96·0... 99·7 at 80° C.
	Cymene	$C^{10}H^{14}$	134	187·0	183·5...185·2 „ 175
	Naphthalin . . .	$C^{10}H^8$	128	154·0	149·2 . . „ 218
	Aldehyde	C^2H^4O	44	56·2	56·0... 56·9 „ 21
	Valeraldehyde . .	$C^5H^{10}O$	86	122·2	117·3...120·3 „ 101
	Bitter almond oil . .	C^7H^6O	106	122·2	118·4 . . „ 179
	Cuminol . . .	$C^{10}H^{12}O$	148	188·2	189·2 . . „ 236
	Tetryl	C^8H^{18}	114	187·0	184·5...186·8 „ 108
	Acetone	C^3H^6O	58	78·2	77·3... 77·6 „ 56
Type HH.O.	Water	H^2O	18	18·8	18·8 . . „ 100
	Wood-spirit . . .	CH^4O	32	40·8	41·9... 42·2 „ 59
	Alcohol	C^2H^6O	46	62·8	61·8... 62·5 „ 78
	Amylic alcohol . .	$C^5H^{12}O$	88	128·8	123·6...124·4 „ 135
	Phenylic alcohol . .	C^6H^6O	94	106·8	103·6...104·0 „ 194
	Benzylic alcohol . .	C^7H^8O	108	128·8	123·7 . . „ 213
	Formic acid . . .	CH^2O^2	46	42·0	40·9... 41·8 „ 99
	Acetic acid . . .	$C^2H^4O^2$	60	64·0	63·5... 63·8 „ 118
	Propionic acid . .	$C^3H^6O^2$	74	86·0	85·4 . . „ 137
	Butyric acid . . .	$C^4H^8O^2$	88	108·0	106·4...107·8 „ 156
	Valerianic acid . .	$C^5H^{10}O^2$	102	130·0	130·2...131·2 „ 175
	Benzoic acid . . .	$C^7H^6O^2$	122	130·0	126·9 . . „ 253

TABLE A (*continued*).

	Substance.	Formula.	Atomic Weight.	Atomic Volume at the Boiling Point.	
				Calculated.	Observed.
Type HH.O.	Ethylic ether	$C^4H^{10}O$	74	106·8	105·6...106·4 at 34 °C.
	Acetic anhydride	$C^4H^6O^3$	102	109·2	109·9...110·1 „ 138
	Formate of methyl	$C^2H^4O^2$	60	64·0	63·4 . . „ 36
	Acetate of methyl	$C^3H^6O^2$	74	86·0	83·7... 85·8 „ 55

	Oxalate of ethyl	$C^6H^{10}O^4$	146	161·0	166·8...167·1 „ 186
	Succinate of ethyl	$C^8H^{14}O^4$	174	205·0	209·0 . . „ 217

A comparison of the numbers in this table, leads to the following results: —

1. *Differences of atomic volume are in numerous instances proportional to the differences between the corresponding chemical formulæ.* — Thus, liquids whose formulæ differ by $n . CH^2$, differ in atomic volume by $n . 22$; for example, the atomic volumes of formate of methyl, $C^2H^4O^2$, and butyrate of ethyl, $C^6H^{12}O^2$, differ by nearly $4 . 22$. Acetate of ethyl, $C^4H^8O^2$, and butyrate of methyl, $C^5H^{10}O^2$. whose formulæ differ by CH^2, differ in atomic volume by nearly 22. The same law holds good with respect to liquids containing sulphur, chlorine, iodine, bromine, and nitrogen (see Tables B, C, D). Again, by comparing the atomic volumes of analogous chlorine and bromine compounds, it is found that the substitution of 1, 2, or 3 atoms of bromine for an equivalent quantity of chlorine, increases the atomic volume of a compound by once, twice, or three times 5. This will be seen by comparing the atomic volumes of PBr^3 and PCl^3; C^2H^5Br and C^2H^5Cl, &c. (Table C.)

2. *Isomeric liquids belonging to the same chemical type have equal atomic volumes.* — The atomic volume of acetic acid, $\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}O$ is between 63·5 and 63·8; that of formate of methyl, $\left.\begin{matrix}CHO\\CH^3\end{matrix}\right\}O$ is 63·4; the atomic volume of butyric acid, $\left.\begin{matrix}C^4H^7O\\H\end{matrix}\right\}O$ is between 106·4 and 107·8; that of acetate of ethyl, $\left.\begin{matrix}C^2H^3O\\C^2H^5\end{matrix}\right\}O$ is between 107·4 and 107·8.

3. *In liquids of the same chemical type, the replacement of hydrogen by an equivalent quantity of oxygen* (that is to say, of 1 pt. of hydrogen by 8 pts of oxygen), *makes but a slight alteration in the atomic volume.*—This may be seen by comparing the atomic volumes of alcohol, C^2H^6O, and acetic acid, $C^2H^4O^2$; of ether, $C^4H^{10}O$, acetate of ethyl, $C^4H^8O^2$, and anhydrous acetic acid, $C^4H^6O^3$; of cymene, $C^{10}H^{14}$, and cuminol, $C^{10}H^{12}O$. The alteration caused by the substitution of O for H^2 is always an increase.

4. *In liquids of the same chemical type, the replacement of 2 at.* H *by 1 at* C (1 pt. by weight of hydrogen by 6 parts of carbon) *makes no alteration in the atomic volume.* —Such, for example, is the case with benzoate of ethyl, $C^9H^{10}O^2$, and valerate of ethyl, $C^7H^{14}O^2$, and with the corresponding benzoates and valerates in general; also

with bitter-almond oil, C^7H^6O, and valeraldehyde, $C^5H^{10}O$; also with phenylic alcohol, C^6H^6O, and vinic ether, $C^4H^{10}O$.

In liquids belonging to different types, the same relations are not found to hold good. Moreover, the types within which these relations are observed, are precisely those of Gerhardt's classification (see CLASSIFICATION). Further, when liquid compounds are represented by rational formulæ founded on these types, their atomic volumes may be calculated from certain fundamental values of the atomic volumes of the elements, on the supposition that the atomic volume of a liquid compound is equal to the sum of the atomic volumes of its constituent elements. In this manner the calculated atomic volumes in the fourth columns of tables A, B, C, D are determined. It must be understood however that these values are based upon somewhat doubtful assumptions respecting the atomic volumes of the elements, and are regarded by Kopp merely as approximations to the truth.

Since the addition of CH^2 to a compound increases the atomic volume by 22, this number may be taken to represent the atomic volume of CH^2; moreover, since C may take the place of H^2 in combination, without altering the atomic volume of the compound, it follows that the atomic volume of C must be equal to that of H^2; and therefore the atomic volume of C $= \frac{22}{2} = 11$, and that of H^2 also equal to 11, or that of H = 5·5. Further, as the substitution of O for H^2 produces a slight increase in the atomic volume of a compound, the atomic volume of O must be rather greater than 11; and it is found that, by assuming the atomic volume of O, when it takes place of H^2 (that is to say, in a radicle, as when acetyl, C^2H^3O, is formed from ethyl, C^2H^5), to be equal to 12·2, results are obtained agreeing very nearly with those of observation. But when oxygen occupies the position which it has in water, $\frac{H}{H}O$, its atomic volume is smaller. The specific gravity of water at the boiling point is 0·9579; hence its atomic volume at that temperature is $\frac{18}{0 \cdot 9579} = 18 \cdot 8$; now the 2 atoms of hydrogen occupy a space equal to 11; hence the volume of the oxygen is 7·8. The same value of the atomic volume substituted for O in the formula of the several compounds belonging to the water-type, in which it occupies a similar place, that is to say, outside the radicle, gives results agreeing nearly with observation. That a given quantity of a substance should occupy different spaces, under different circumstances, is a fact easily explained, when it is remembered that the particles of a body cannot be supposed to be in absolute contact, but are separated by certain spaces, which, increase or diminish according to the temperature of the body, and according as it is in the solid, liquid, or gaseous state.

From these values of the atomic volumes of the elements, carbon, hydrogen, and oxygen; viz.

Atomic volume of C . . . . = 11
" " H . . . . = 5·5
" " O (within the radicle) . . . . . = 12·2
" " O (without the radicle) . . . . . = 7·8

the calculated values of the atomic volumes of liquids, in the fourth column of Table A are deduced. The method of calculation may be understood from the following examples:

Benzene, $C^6H^6 = C^6H^5.H$.

Atomic volume of C^6 . . . . = 66
" " H^6 . . . . = 33
" " benzene . . . . = 99

Aldehyde, $C^2H^4O = C^2H^3O.H$.

Atomic volume of C^2 . . . . = 22
" " H^4 . . . . = 22
" " O (within the radicle) . . . . = 12·2
" " aldehyde . . . . = 56·2

Alcohol, $C^2H^6O = \left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O$.

Atomic volume of C^2 . . . . = 22
" " H^6 . . . . = 33
" " O (without the radicle) . . . . = 7·8
" " alcohol . . . . = 62·8

Acetic acid, $C^2H^4O^2 = \left.\begin{matrix} H \\ C^2H^3O \end{matrix}\right\} O.$

Atomic volume of C^2 . . . . = 22
„ „ H^4 . . . . = 22
„ „ O (within the radicle) . . . = 12·2
„ „ O (without the radicle) . . . = 7·8
„ „ acetic acid . . . . . . = 64·0

Acetic anhydride $C^4H^6O^3 = \left.\begin{matrix} C^2H^3O \\ C^2H^3O \end{matrix}\right\} O.$

Atomic volume of C^4 . . . . = 44
„ „ H^6 . . . . = 33
„ „ O^2 (within the radicle) . . . = 24·4
„ „ O (without the radicle) . . . = 7·8
„ „ acetic anhydride . . . . . . = 109·2

Oxalate of methyl, $C^4H^6O^4 = \left.\begin{matrix} C^2O^2 \\ (CH^3)^2 \end{matrix}\right\} O^2.$

Atomic volume of C^4 . . . . = 44
„ „ H^6 . . . . = 33
„ „ O^2 (within the radicle) . . . = 24·4
„ „ O^2 (without the (radicle) . . . = 15·0
„ „ oxalate of methyl . . . . . . = 117·0

Liquids containing Sulphur.—Sulphur enters into combination in various ways; sometimes taking the place of oxygen in the type HH.O (as in mercaptan); sometimes taking the place of carbon within a radicle (as in sulphurous anhydride) SO.O, compared with carbonic anhydride CO.O; sometimes replacing oxygen within a radicle (as in sulphide of carbon), CS.S, compared with carbonic anhydride. In the first and second cases, the atomic volume of sulphur-compounds may be calculated by attributing to sulphur, (S = 32), the atomic volume 22·6, those of the other elements remaining as above; in the third case, the atomic volume of sulphur appears to be greater; viz. 28·6.

Ex.—*Mercaptan,* $C^2H^6S = \left.\begin{matrix} C^2H^5 \\ H \end{matrix}\right\} S.$

Atomic volume of C^2 . . = 22
„ „ H^6 . . = 33
„ „ S . . = 22·6
„ „ mercaptan . = 77·6

Sulphide of carbon, CS^2 = CS.S.

Atomic volume of C . . = 11
„ „ S (within the radicle) . = 28·6
„ „ S (without the radicle) . = 22·6
„ sulphide of carbon . = 62·2

TABLE B.—*Atomic Volumes of Liquid Sulphur-compounds.*

Chloride of sulphur . .	SCl	67·5	. .	45·7 . . ,, 140
Chloride of phosphorus .	PCl^3	137·5	. .	93·9 . . ,, 78
Bromide of phosphorus .	PBr^3	271	. .	108·6 . . ,, 175
Chloride of silicon . .	$SiCl^4$	170	. .	121·6 . . ,, 59
Bromide of silicon . .	$SiBr^4$	348	. .	144·0 . . ,, 153
Chloride of arsenic . .	$AsCl^3$	181·5	. .	94·8 . . ,, 133
Chloride of antimony .	$SbCl^3$	235·5	. .	100·7 . . ,, 223
Bromide of antimony .	$SbBr^3$	369	. .	116·8 . . ,, 275
Chloride of tin . .	$SnCl^4$	260	. .	132·4 . . ,, 115
Chloride of titanium . .	$TiCl^4$	92	. .	126·0 . . ,, 136

The compounds PCl^3 and $AsCl^3$, have nearly equal atomic volumes: whence it may be inferred that phosphorus, and arsenic, in their liquid compounds, have equal atomic volumes. The same conclusion may be drawn regarding tin and titanium since the atomic volumes of $SnCl^4$ and $TiCl^4$ are nearly equal.

Nitrogen-compounds.—In compounds belonging to the ammonia type, the atomic volume of nitrogen is 2·3. This result is deduced from the observed atomic volume of phenylamine C^6H^7N, which is 106·8. Now the atomic volume of $6C + 7H = 6 . 11 + 7 . 5·5 = 104·5$, which number, deducted from 106·8, leaves 2·3 for the atomic volume of nitrogen.

The atomic volume of cyanogen deduced from the observed atomic volume of cyanide of phenyl, $CN.C^6H^5$, or C^7H^5N, is nearly 28. Thus:—

$$\begin{array}{lllr} \text{Atomic volume of} & C^7H^5N & = & 121·6 \\ ,, \quad\quad ,, & C^6H^5 & = & \underline{93·5} \\ ,, \quad\quad ,, & CN & = & 28·1 \end{array}$$

A similar calculation, founded on the observed atomic volume of cyanide of methyl, C^2H^3N, gives, for the atomic volume of cyanogen, the number 26·8. The atomic volume of liquid cyanogen determined directly at 37° or 39° C. above its boiling point, is between 28·9 and 30·0. As a mean of these values, the atomic volume of cyanogen may be assumed to be 28; and with this value the atomic volumes of the liquid cyanides are calculated. Thus, for

Oil of mustard (sulphocyanate of allyl), $C^4H^5NS = \left.\begin{matrix}CN\\C^3H^5\end{matrix}\right\}S$.

Atomic volume of C^3H^5 . . . . = 60·5
" " CN . . . . = 28·0
" " S (without the radicle) = 22·6
" " oil of mustard . . = 111·1

The atomic volumes of compounds containing the radicle NO^2, are calculated on the hypothesis that the atomic volume of that radicle is 33, which agrees nearly with the observed atomic volume of liquid peroxide of nitrogen. Thus: the atomic volume of nitrite of amyl, $C^5H^{11}NO^2$ = at. vol. of C^5H^{11} + at. vol. of $NO^2 = 115·5 + 33 = 148·5$.

TABLE D.—*Atomic Volumes of Liquids containing Nitrogen.*

Substance.	Formula.	Atomic Weight.	Atomic Volume at the Boiling Point.

From the preceding observations and calculations, it appears that the atomic volume of a compound depends, not merely on its empirical, but likewise on its rational formula; in other words, not merely on the number of atoms of its elements, but further on the manner in which those atoms are arranged. Now a compound may have more than one rational formula, according to the manner in which it decomposes; and hence it might appear that the calculation of atomic volumes must be attended with considerable uncertainty, inasmuch as the atomic volumes of certain elements, as oxygen and sulphur, vary according to the manner in which they enter into the compound. Aldehyde, for example, may be represented either as $\left.\begin{matrix}C^2H^3\\H\end{matrix}\right\}O$, or as $\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}$; and, as the atomic volume of oxygen is 12·2 or 7·8, according as it is within or without the radicle, the atomic volume of aldehyde will be 56·2 if deduced from the type HH, and

---

* Between 44° and 50° above the boiling point.

† Between 37° and 39° above the boiling point.

‡ About 55° above the boiling point.

§ 27° above the boiling point.

51·8 if deduced from the type HH.O. But the atomic weight of aldehyde, and its specific gravity at a given temperature are invariable; it cannot therefore have two different atomic volumes. It must be remembered, however, that, in speaking of a compound as having several rational formulæ, we consider it rather in a dynamical than in a statical point of view; as under the influence of disturbing forces, and on the point of undergoing chemical change. But if, on the other hand, we regard a compound in its fixed statical condition, as a body possessing definite physical properties, a certain specific gravity, a certain boiling point, rate of expansion, refractive power, &c., we can scarcely avoid attributing to it a fixed molecular arrangement, or, at all events, supposing that the disposition of its atoms is confined within those limits which constitute chemical types. It is found, indeed, that isomeric liquids exhibit equal atomic volumes only when they belong to the same chemical type. If this view be correct, the relation between the atomic volumes of elements and compounds, may often render valuable service in determining the rational formula which belongs to a compound in the state of rest. Thus of the two atomic volumes just calculated for aldehyde, the number 56·2, deduced from the formula $C^2H^3O.H$, agrees with the observed atomic volume of aldehyde, which is between 56·0 and 56·9, better than 51·8, the number deduced from  $\left.\begin{matrix}C^2H^3\\H\end{matrix}\right\}O$. This result leads to the conclusion that the aldehydes belong to the hydrogen type rather than to the water type.

There are many groups of liquid compounds, irrespective of isomerism or similarity of type, the members of which have equal or nearly equal atomic volumes. The following table exhibits the calculated atomic volumes of several of these groups:

Water . . .	H^2O	18·8	Ether . . .	$C^4H^{10}O$	106·8
Ammonia . . .	NH^3	18·8	Tetrylic alcohol .	$C^4H^{10}O$	106·8
			Phenylic alcohol .	C^6H^6O	106·8
Bromine . . .	Br^2	55·6	Tetrylamine . .	$C^4H^{11}N$	106·8
Cyanogen . . .	$(CN)^2$	56·0	Phenylamine . .	C^6H^7N	106·8
Aldehyde . . .	C^2H^4O	56·2	Butyric acid . .	$C^4H^8O^2$	108·0
Cyanide of methyl .	C^2H^3N	55·5	Acetate of ethyl .	$C^4H^8O^2$	108·0
Bromide of methyl .	CH^3Br	55·3	Acetic anhydride .	$C^4H^6O^3$	109·2
			Chloral . . .	C^2HCl^3O	108·1
Alcohol . . .	C^2H^6O	62·8	Dichlorinated chloride of ethyl . .	$C^2H^3Cl^3$	106·9
Acetic acid . .	$C^2H^4O^2$	64·0			
Formate of methyl .	$C^2H^4O^2$	64·0	Monochlorinated chloride of ethylene .	$C^2H^3Cl^3$	106·9
Cyanate of methyl .	C^2H^3NO	63·3			
Ethylamine . .	C^2H^7N	62·8	Bromide of phosphorus . . .	PBr^3	108·6
Sulphide of carbon .	CS^2	62·3			
Iodide of methyl .	CH^3I	65·0			
			Valeraldehyde . .	$C^5H^{10}O$	122·2
Acetone . . .	C^3H^6O	78·2	Cyanide of tetryl .	C^5H^9N	121·5
Cyanide of ethyl .	C^3H^5N	77·5	Bitter almond oil .	C^7H^6O	122·2
Sulphocyanate of methyl . . .	C^2H^3NS	78·1	Cyanide of phenyl .	C^7H^5N	121·5
Sulphide of methyl .	C^2H^6S	77·6	Sulphide of ethyl .	$C^4H^{10}S$	121·6

These groups exhibit an approach to the uniformity of atomic volume which is observed in the gaseous state.

Berthelot has adduced a number of examples, showing that when a liquid compound is formed by the union of two other liquids, whose specific volumes are denoted by A and B, with elimination of x atoms of water, the specific volume of the compound is nearly $= A + B - xC$ (the atomic volume of water being denoted by C). Berthelot's observations, however, were made at medium temperatures, not at the boiling points of the liquids (Ann. Ch. Phys. [3] xlviii. 322).

Schröder, *ibid.* i. 552; lii. 269, 282; cvi. 226; cvii. 113.—Filhol, Ann. Ch. Phys. xxi. 415.—Playfair and Joule, Chem. Soc. Mem. ii. 477; iii. 54, 199; Chem. Soc. Qu. J. i. 121.—H. Schiff, Ann. Ch. Pharm. cvii. 64; cxii. 88.—Gm. i. 67—86.)

The most general relation that has been observed between the atomic volumes of of solid compounds is, that *isomorphous compounds have equal atomic volumes*, in other words, their densities are proportional to their atomic weights. Such is the case, for example, with carbonate of strontium (strontianite) and carbonate of lead (witherite).

Formula.	At. Weight.	Sp. Gr.	At. Volume.
Sr^2CO^3	147·6	3·60	41·0
Pb^2CO^3	267·4	6·47	41·4

If the crystalline forms are only approximately similar, the atomic volumes also are only approximately equal, the difference being less as the angles of the two crystalline forms are more nearly equal, and their axes more nearly in the same ratio. An alteration of atomic volume, such as is often produced by the introduction of one element into a compound in place of another, is attended with a corresponding alteration of crystalline form. The atomic volume may likewise be altered without any change in the composition of the body, viz. by change of temperature, and this also produces in most cases, as Mitscherlich has shown, a corresponding alteration in the magnitude of the angles. In crystals of the regular system, however, variation of temperature produces no alteration either in form or in atomic volume.

In dimorphous compounds, each modification has a density, and therefore also an atomic volume, peculiar to itself.

The equality, exact or approximate, of the atomic volumes of isomorphous compounds, has been traced by Hugo Schiff, through several classes of salts, especially in the sulphates of the general form, $M^2SO^4.7H^2O$ (*vitriols*), in the double sulphates of the magnesian class, $\left.\begin{matrix}K;\ NH^4\\ M\end{matrix}\right\}SO^4.3H^2O$, and in the alums. The atomic volumes of these compounds are given in the following table:

Formula.	Atomic Weight.	Specific Gravity.	Atomic Volume.
Vitriols.			
$Mg^2SO^4 . 7H^2O$	246	1·685	146
$Zn^2SO^4 . 7H^2O$	287	1·853	146·9
$Ni^2SO^4 . 7H^2O$	281·2	1·931	145·6
$Co^2SO^4 . 7H^2O$	281	1·924	146
$Fe^2SO^4 . 7H^2O$	278	1·884	147·5
$(MgCu)SO^4 . 7H^2O$	265·7	1·813	146·5
$MgZnSO^4 . 7H^2O$	266·5	1·817	146·6
$MgCdSO^4 . 7H^2O$	290·0	1·983	146·2
Double Magnesian Sulphates.			
$(NH^4)MgSO^4 . 3H^2O$	180	1·680	107·1
$KMgSO^4 . 3H^2O$	201·2	1·995	100·9
$(NH^4)ZnSO^4 . 3H^2O$	200·5	1·910	104·9
$KZnSO^4 . 3H^2O$	221·7	2·153	103
$(NH^4)NiSO^4 . 3H^2O$	197·6	1·915	103·2
$KNiSO^4 . 3H^2O$	218·8	2·123	103·1
$(NH^4)CoSO^4 . 3H^2O$	197·5	1·873	105·4
$KCoSO^4 . 3H^2O$	218·7	2·154	101·6
$(NH^4)FeSO^4 . 3H^2O$	196	1·813	108·1
$KFeSO^4 . 3H^2O$	217·2	2·189	99·2
$(NH^4)CdSO^4 . 3H^2O$	223·7	2·073	107·9
$KCdSO^4 . 3H^2O$	244·9	2·438	100·5
$(NH)^4CuSO^4 . 3H^2O$	199·7	1·931	103·4
$KCuSO^4 . 3H^2O$	220·9	2·137	103·3
Alums.			
$KAl^2S^2O^8 . 12H^2O$	474·6	1·722	275·6
$NaAl^2S^2O^8 . 12H^2O$	458·4	1·641	279·2
$(NH^4)Al^2S^2O^8 . 12H^2O$	453·4	1·621	279·6
$KCr^2S^2O^8 . 12H^2O$	500·8	1·845	271·4
$(NH^4)Cr^2S^2O^8 . 12H^2O$	479·6	1·736	276·2
$(NH^4)Fe^2S^2O^8 . 12H^2O$	482·0	1·712	281·4

The atomic volumes of the vitriols are very nearly equal; so likewise are those of the alums. Those of the double magnesian sulphates, $M(K;NH^4)SO^43H^2O$, differ somewhat more, the difference between the greatest and least amounting to 8·9. It is remarkable, however, that the atomic volume of the ammonium- and potassium-salts in each pair differs from the mean value (104) by nearly equal values, the former in excess, the latter in defect; thus, in the first pair we find, $107·1 - 104 = +3·1$; and $100·9 - 104 = -3·1$; and in the second pair: $104·9 - 104 = +0·9$; and $103 - 104 = -1·0$.

The following table contains the atomic volumes of certain chlorides, bromides, and iodides:—

Formula.	Atomic Weight.	Specific Gravity.	Atomic Volume.
Chlorides.			
Chloride of hydrogen	36·5	1·501	24·3
Chloride of lead	139·5	5·78	24·2
Chloride of iron (ferrosum)	63·5	2·528	25·1
Chloride of calcium	55·5	2·205	25·2
Chloride of nickel	65·0	2·56	25·3
Chloride of mercuricum	135·5	5·320	25·5
Chloride of silver	143·5	5·517	26·0
Chloride of cuprosum	98·9	3·70	26·7
Chloride of strontium	79·5	2·96	26·9
Chloride of sodium	58·5	2·148	27·2
Chloride of barium	104·1	3·82	27·2
Bromides.			
Bromide of hydrogen	82·0	2·00	41·0
Bromide of mercurosum	281·0	7·307	38·4
Bromide of sodium	104·0	2·952	35·2
Bromide of barium	149·6	4·23	35·3
Bromide of mercuricum	181·0	5·92	30·6
Bromide of silver	189·0	6·353	29·8
Bromide of lead	185·0	6·63	28·0
Iodides.			
Iodide of hydrogen	128·0	2·25	57·0
Iodide of potassium	166·2	2·85	58·3
Iodide of sodium	150·0	3·45	43·5
Iodide of mercurosum	327·0	7·644	42·8
Iodide of silver	235·0	5·35	43·9
Iodide of barium	195·6	4·917	39·8
Iodide of mercuricum	227·0	5·91	38·4
Iodide of lead	231·0	6·07	38·1

It will be observed that the atomic volumes of the bromides and iodides do not agree among themselves so nearly as those of the chlorides. The atomic volume of a bromide is not, for the most part, the mean between those of the corresponding chloride and iodide, but approaches more nearly to that of the chloride. (Schiff.)

That isomorphous compounds do in many instances occupy equal atomic volumes is sufficiently apparent from the preceding examples. Nevertheless, Schröder concludes, from calculations founded partly on his own determinations of specific gravity, partly on those of other observers, that equality of atomic volume is not necessarily connected with similarity of crystalline form, but is exhibited by heteromorphous elements and compounds quite as often as by those which are isomorphous, if not oftener. (Pogg. Ann. cvi. 226; cvii. 113.)

The connection between the atomic volumes of compounds and of their elements has not been so fully examined in solids as in liquids; nevertheless certain general relations have been shown to exist. The most important of these relations, first pointed out by Schröder, and further established by Kopp, is that *equivalent quantities of different elements, in uniting with the same quantity of a given element (or compound radicle) receive equal increments of volume.* Thus, when 207·4 grammes, or 18·44 cub. cent. of lead (Pb^2), 112 grm. = 13 c.c. cadmium (Cd^2), 63·7 grm. = 7·2 c.c. copper (Cu^2), or 65·2 grm. = 9·2 c.c. zinc (Zn^2), unite with 16 grms. of oxygen (O) to form the compounds Pb^2O, Cd^2O, &c., the increment of volume is found to be in each case nearly 2·6 cubic centimetres. Again, in the oxidation of 112 grm. iron (Fe^4) to ferric oxide, Fe^4O^3, the increment of volume is 8·1 = 3 × 2·7 c.c. The explanation of this law appears to be that certain elements enter into combination with the same atomic volume that they occupy in the separate state. Such, according to Kopp, is the case with the heavy metals: so that, by determining experimentally the atomic volumes of their oxides, chlorides, nitrates, &c., and deducting therefrom the volumes of the metals themselves as given in the table (p. 442), the atomic volumes of O, Cl, NO^3, &c.,

which cannot be observed directly, may be found; thus, a comparison of the oxides above-mentioned shows that the atomic volume of oxygen in these compounds is 2·6.

The metals of the alkalis and earths do not appear to enter into combination with the same volume that they occupy in the free state. Their atomic volumes in combination must, therefore, be calculated by deducting from the observed atomic volumes of their salts, the chlorides for example, the volume of the chlorine as determined from the chlorides of the heavy metals, this determination of course resting on the assumption that the atomic volume of the chlorine in combination is the same in all analogous compounds.

On these principles, Kopp has made the following estimations of the atomic volumes of the alkali-metals, earth-metals, and certain salt-radicles:—

NH^4 in its salts	17·4
K „ „	18·7
Na „ „	10·4
Ba „ „	11·4
Sr „ „	8·6
Ca „ „	4·8
CO^3 in the carbonates of Pb, Cd, Fe, Mn, Ag, Zn, Ba, Ca, K, Mg, Na, Sr	12·1
NO^3 in the nitrates of Pb, Ag, NH^4, Ba, K, Na, Sr	28·6
SO^4 in the sulphates of Cu, Ag, Zn, Ca, Mg, Na	18·9
SO^4 in the sulphates of Pb, Ba, K, Sr	14·9
Cl in the chlorides of Pb, Ag, Ba, Na	15·7
Cl in the chlorides of NH^4, Ca, K, Ccu, Hg, Hhg, Sr	19·6
O in the oxides Pb^2O, Cd^2O, Cu^2O, Hg^2O, Zn^2O, SnO, Sb^2O^3, Fe^4O^3, Co^4O^3, Bi^2O^3, Pb^3O^2	2·6
O in the oxides Ccu^2O, Ag^2O, Hhg^2O, Mo^2O^3	5·2

These values were determined in 1841, and many of them require correction according to the atomic weights and densities since established. According to Schröder (*loc. cit.*), the relations upon which they depend are true only with regard to isomorphous compounds, being regulated by the following general law: "If two elements or groups of elements, *A*, *B*, &c., unite with other elements or groups, *C*, *D*, *E*, &c., forming compounds *AC* and *BC*, *AD* and *BD*, *AE* and *BE*, &c., which belong to the same type, and are isomorphous by pairs, the differences of atomic volume of *AC* and *BC*, *AD* and *BD*, *AE* and *BE*, &c., are always equal; but, if these pairs of compound are not isomorphous, or belong to different types, then the differences of atomic volume are unequal."

Messrs. Playfair and Joule have observed some remarkable relations between the atomic volumes of crystallised salts and that of the water which they contain, viz. 1. In certain highly hydrated salts, viz. the *arsenates and phosphates with* 12 *at. water* and in *carbonate of sodium with* 10 *at. water*, the volume of the entire molecule is the same as that of the water of crystallisation frozen into ice, the particles of the acid and base appearing to be interposed between those of the water without increasing the total bulk. The following table contains the specific gravity of some of these salts, as calculated upon this hypothesis, and as determined by direct experiment:

Salt.	Specific Gravity.	
	Exp.	Calc.
$Na^2CO^3 . 10H^2O$	1·454	1·463
$Na^2HPO^4 . 12H^2O$	1·525	1·527
$Na^3PO^4 . 12H^2O$	1·622	1·622
$Na^2HAsO^4 . 12H^2O$	1·736	1·736
$Na^3AsO^4 . 12H^2O$	1·804	1·534

In *cane-sugar* and *milk-sugar*, the atomic volume is the same as that of the hydrogen and oxygen, supposed to be united as water and frozen. Specific gravity of cane-sugar on this hypothesis = 1·586; by experiment = 1·586; of milk-sugar, by calculation 1·534; by experiment 1·531.

2. In another class of salts, including the *hydrated magnesian sulphates* ($M^2O.SO^3 + 6H^2O$), *normal sulphate of aluminium*, *borax*, *pyrophosphate of sodium*, and the *alums*, the atomic volume is made up of the solid water and of the base (M^2O or M^4O^3); in other words, the volume of the hydrated salt is made up of that of the water of crytallisation frozen into ice, and that of the base as it exists in the free state, or in the anhydrous salt. (For details see the memoirs cited on page 449.)

ATOMIC WEIGHTS. The ultimate constitution of matter, and its finite or infinite divisibility, have been made the subjects of speculation and argument from almost the earliest times. The molecular idea of matter seems to have prevailed in the primitive philosophies of the Hindoos, Phœnicians, and Egyptians, from the last of whom it was probably transmitted to the Greeks. Among them, we find the notion of finite divisibility constituting the basis of the cosmogony of Democritus, who apparently acquired the doctrine directly from Leucippus. Subsequently Epicurus, and the Epicureans generally, extended the atomic hypothesis, which, however, was strongly opposed by Empedocles and the later Pythagoreans, who contended for the infinite divisibility of matter, and for its continuity in any given mass. Plato and Aristotle also, especially the latter, advocated the notion of infinite divisibility. In modern times, the doctrine of material atoms was maintained by Newton, and opposed by Descartes, Leibnitz, and Euler. After the time of Euler, the question of the ultimate constitution of matter fell into some neglect, although the non-atomic view seems to have been generally preferred, until Dalton, in 1804—8, revived the atomic hypothesis, in order to account for the phenomena of chemical combination in definite and multiple proportions, which he first brought prominently into notice. Prior to his discovery, the chemical composition of bodies, as determined by analysis, had been expressed in centesimal proportions only, whereby the relations in composition of different bodies were in great measure concealed from observation. Thus, the relative composition of olefiant gas and marsh gas, was expressed very imperfectly by saying that the former contained 85·7 per cent. of carbon and 14·3 per cent. of hydrogen, while the latter contained 75·0 per cent. of carbon and 25·0 per cent. of hydrogen. It was from the results of an examination of these two gases that Dalton was first led to the conception of his theory. He ascertained that both gases consist of carbon and hydrogen only, and set out the centesimal composition of each in the customary manner. But he observed further, that the ratio of hydrogen to carbon is exactly twice as great in the one case as in the other; that in olefiant-gas, for instance, the carbon is to the hydrogen as 6 to 1, whereas in marsh-gas it is as 6 to 2. Or, in other words, a given quantity of carbon unites with either one or two proportions of hydrogen to form the respective compounds, olefiant-gas and marsh-gas. Dalton, whose turn of mind was essentially mechanical, explained the constitution of these two compounds by supposing that the first consisted of 1 at. of carbon united with 1 at. of hydrogen ●⊙, while the second consisted of 1 at. of carbon united with 2 at. of hydrogen ⊙●⊙, the atom of carbon being considered to have 6 times the weight of the atom of hydrogen. He then calculated the composition of other bodies on the same plan, and found, for instance, that the quantity of hydrogen which unites with 6 pts. of carbon to form olefiant gas, unites with 8 pts. of oxygen to form water. Hence water was represented by the symbol ⊙○, the atom of oxygen being considered to have 8 times the weight of the atom of hydrogen. The crowning point of Dalton's theory was reached when he discovered that the numbers which expressed the respective combining proportions of carbon and oxygen with 1 pt. of hydrogen, also expressed the proportions in which they combine with one another. Thus the ratio of carbon to oxygen in carbonic oxide gas was found to be as 6 to 8; whereas in carbonic anhydride gas it was as 6 to *twice* 8. The former compound he considered to result from the union of 1 at. of carbon with 1 at. of oxygen ●○; and the latter to result from the union of 1 at. of carbon with 2 at. of oxygen ○●○. Dalton extended the same views to the compounds of nitrogen, and concluded that the quantity of that element which united with 1 pt. of hydrogen to form ammonia ⦶⊙, united with 8 pts. of oxygen to form nitrous gas ⦶○. We may apply this formula for nitrous gas to the compound known as nitrous anhydride, though, from an error in the rough process of analysis then adopted, it was intended to apply to what is now called nitric oxide, or deutoxide of nitrogen. Even at the present day, it is highly interesting to compare the information afforded by Dalton's expressions for the above-mentioned compounds, with the information afforded by a statement of their respective centesimal proportions, thus:—

	Dalton's Expressions.		Centesimal Proportions.
Olefiant-gas . . .	6 + 1	●⊙	85·72 + 14·28
Marsh-gas . . .	6 + *twice* 1	⊙●⊙	75·00 + 25·00
Water	8 + 1	○⊙	88·89 + 11·11
Carbonic oxide . .	6 + 8	●○	42·86 + 57·14
Carbonic anhydride .	6 + *twice* 8	○●○	27·27 + 72·73
Ammonia . . .	5 + 1	⦶●	82·35 + 17·65
Nitrous gas . . .	5 + 8	⦶○	36·80 + 63·20

Dalton thus established that general principle in chemistry known as the law of combination in definite and multiple proportions. He showed that a particular number might be selected for every element, in such a manner that the proportions by weight in which any two or more elements combine with one another, should be always in the ratios of their respective numbers, or of different multiples of those numbers. And he accounted for this law by supposing that the elements unite with one another atom to atom, and that the proportional number accorded to each particular element expresses the relative weight of its atom. Hydrogen being the lightest substance in nature, was at once chosen by Dalton as the unit in his scale of atomic weights, and the weights of the atoms of other elements were established by ascertaining, directly or indirectly, the respective quantities of those elements which unite either with 1 pt. of hydrogen, or with the quantity of some other element which unites with 1 pt. of hydrogen. But many chemists, who speedily acknowledged the truth of Dalton's laws of combination, refused to admit the atomic doctrine which he had deduced therefrom. Among these was Davy, who introduced the word proportion as a substitute for Dalton's word atom, conceiving the use of the latter word to be objectionable, as involving a theoretical assumption. At the present day, the word atom is most generally employed by chemists; but, while some use it in its strict Daltonian materialistic sense, others use it, in an abstract sense only, to express the smallest indivisible combining proportion of a body, and consider the proportional number of a body as an ultimate or unexplained property pertaining to it. Dalton's symbols were speedily replaced by those now in use, which represent the abbreviated names of the elements. Every such symbol is used to express one atomic proportion of its particular element. Thus, Cl stands for 35·5 pts. of chlorine, Na for 23 pts. of sodium, and As for 75 pts. of arsenic, as compared with 1 pt. by weight of hydrogen. Every compound body being composed of two or more elementary atoms, is expressed by an allocation of symbols. Thus, common salt or chloride of sodium is represented by the formula NaCl, which implies a compound of 23 pts., or 1 combining proportion of sodium, united with 35·5 pts., or 1 combining proportion of chlorine. Again, trichloride of arsenic is represented by the formula $AsCl^3$, which implies a compound of 75 pts., or 1 combining proportion of arsenic, united with 106·5 pts. or 3 combining proportions of chlorine.

The proportional number or atomic weight of a compound body is the sum of the atomic weights of its constituents. Thus, the atomic weight of chloride of sodium is 58·5 and that of trichloride of arsenic 181·5. The relative quantity of a compound body, represented by its formula, is frequently spoken of as its atom, and there is nothing unphilosophical in such an employment of the word. By the atom of sodium, for instance, is understood, the least indivisible proportion of the elementary body sodium, and by the atom of chloride of sodium, the least indivisible proportion of the compound body chloride of sodium, that can have any existence. Soon after the publication of Dalton's theory, it received a valuable corroboration, through its adaptability to groupings of elements or compound atoms. Wollaston, in the course of some analytical experiments, noticed, that if in the two carbonates of potassium, the weight of oxide of potassium be taken as constant, then the weights of carbonic anhydride in each salt are to one another as 1 to 2; and Thomson made a similar observation with regard to the two oxalates of potassium. Hence these salts were represented at that time, in accordance with Dalton's views, as consisting respectively of one compound atom of oxide of potassium, united with one or two compound atoms of carbonic anhydride, and with one or two compound atoms of oxalic anhydride. The compound atom of a body, or more correctly the atom of a compound body, is now often spoken of as its molecule, but in many cases there is a distinction between the application of the two words which will be presently adverted to.

The accuracy of Dalton's laws of combination in definite and multiple proportions, was confirmed by a reference to the previous neglected researches of Wenzel and Richter upon the double decomposition of salts; and by the subsequent brilliant researches of Gay-Lussac upon the laws of combination by volume; in which he showed that the combining proportions of simple and compound gases might be expressed volumetrically or by bulk, as well as numerically or by weight.

It is worth while to refer for a few moments to the above-mentioned experiments of Wenzel and Richter. If we add together solutions of chloride of sodium and nitrate of silver, which are both neutral salts, we get by double decomposition, chloride of silver and nitrate of sodium, and the mixture still remains neutral. There is no redundancy or deficiency of either sodium or silver, but the quantity of sodium separated from its chloride is exactly sufficient to replace the silver separated from its nitrate, and *vice versâ.* Wenzel of Freyberg in Saxony, as early as the year 1777, made very many analyses of salts with great accuracy, and was thereby enabled to account for this neutrality, resulting from the mutual decomposition of neutral salts, by showing that in all salts the quantities of salt-residue, so to speak, which are combined with equal weights of some one metal, will also combine with equal weights of any other metal. Thus, if y grains of chloride of sodium, and z grains of nitrate of sodium alike contain x grains of sodium, then $(y - x) + w$ grains of chloride of silver, and $(z - x) + w$ grains of nitrate of silver will alike contain w grains of silver; because the quantities x and w represent the relative combining proportions of the metals, silver and sodium, which can take the place of one another, and unite with the same amount of chlorine or other salt radicle, or residue. Richter of Breslau in Silesia, published, in the year 1792, what may be regarded as an extension of the views and experiments of Wenzel. He showed that the neutrality of a saline solution does not change during the direct precipitation or substitution of its metal by some other, and that the respective quantities of different metals which displace one another in salts, all unite with the same weight of oxygen. He also constructed a table of the quantities of different oxides or bases, which contain replaceable amounts of metal, and of the quantities of different acids which can be neutralised by those quantities of the respective bases. His experimental results were very inaccurate, but his notions of chemical decomposition, had they received due attention at the time, must have led directly to the doctrine of combining proportions, if not to the Daltonian theory of atoms. It was not until some time after the publication of Dalton's views, that Berzelius first called attention to the prior researches of Wenzel and Richter, as affording a valuable confirmation of the laws of chemical combination which Dalton had enunciated.

In the establishment of proportional numbers or atomic weights, two distinct points have to be considered, namely the exact determination of the ratios, according to which bodies combine, and the correct expression or interpretation of those ratios. The first is a question of experiment, while the second is one of judgment or inference. Thus whether the ratio of hydrogen to nitrogen in ammonia is as 1 to 5, or as 1 to 4·67 is a question of mere experiment: but whether the atom, or smallest indivisible combining proportion of nitrogen is 4·67 times, or 14 times as heavy as the atom or smallest indivisible combining proportion of hydrogen, and consequently, whether the molecule of ammonia consists of one light atom of nitrogen united with 1 of hydrogen, or of one heavy atom of nitrogen united with 3 of hydrogen, are questions for the judgment, which can only be decided by an intimate acquaintance with, and careful consideration of very many circumstances relating to the respective bodies and their congeners. The numbers originally chosen by Dalton to express the ratios in which the different elements unite with 1 part of hydrogen, are most of them very incorrect. Thus his number for nitrogen was 5 instead of 4·67, that for carbon 5 instead of 6, that for oxygen 7 instead of 8, that for phosphorus 9 instead of 10·33, that for sulphur 13 instead of 16, and similarly with the remainder. Davy raised the number for oxygen from 7 to 7·5, which Prout, soon after, on theoretical grounds increased to 8. But the first series of numbers, deduced from trustworthy experiments, was drawn up by Berzelius, whose results, the work of a lifetime, must ever excite our highest admiration for the marvellous industry and skill by which they were achieved. Of late years, when analytical and synthetical processes have been so greatly simplified and improved, many of his atomic weights have undergone slight corrections at the hands of Dumas, Marignac, Pelouze, Stas, Maumené, Erdmann, Marchand, and others, but the general exactitude of his numbers still remains unimpeached. Berzelius, following the example of Wollaston in this country, selected the atomic weight of oxygen as the unit of his scale, and the same plan was adopted until within this last twenty years by continental chemists in general. The atomic weight of oxygen was fixed at 100, and those of the other elements estimated in accordance therewith; but the simpler numbers by which most of the ratios are expressed on the hydrogen scale, have eventually secured for it the preference.

In the year 1815, Prout, in a paper "on the relations between the specific gravities of bodies in the gaseous state, and the weights of their atoms," propounded the idea that the atomic weights of all bodies are multiples of the atomic weight of hydrogen. His opinion was shared by Dalton on other grounds, and met with very general acceptance in this country. But it was never acknowledged by Berzelius, or until lately by any large number of continental chemists. Although Prout's views must be considered, in the present state of our knowledge, to rest rather upon a speculative than a substantial philosophical basis, it cannot be denied that the tendency of modern investigation has been to confirm his law or rather a certain modification of it, which Dumas first introduced in a definite form, but which Prout himself seems to have admitted. According to this modification, the atomic weights of all bodies are multiples by whole numbers of a submultiple of the atomic weight of hydrogen. A striking confirmation of this view occurred in the year 1840, when Dumas and Stas showed that the atomic weight of carbon is exactly 6. In 1843 Dumas also showed that oxygen and hydrogen unite to form water exactly in the ratio of 8 to 1, and his experiments were confirmed by those of Erdmann and Marchand. Then Pelouze and Marignac separately ascertained that the atomic weight of nitrogen is 14; and Maumené, Marignac, and Pelouze, separately ascertained that the atomic weights of chlorine, silver, and potassium coincide almost absolutely with the numbers of 35·5, 108, and 39 respectively. Pelouze showed also that the atomic weights of sodium, barium, and arsenic are 23, 68·5, and 75 respectively. At the present time, out of fifty-eight elementary atomic weights, calculated from the acknowledged best experiments, not more than half a dozen differ appreciably from multiples by whole numbers of half the atomic weight of hydrogen. Some of these exceptional numbers ought probably to be doubled, whereby they would accord with Prout's modified law, while others of them can hardly be looked upon as satisfactorily determined. It is worthy of observation also that the smallest atomic weights which, as a general rule, are those of the best known, and most easily estimated elements, accord the most precisely with Prout's law. Dumas is of opinion that some of the exceptional numbers are multiples of one-fourth the atomic weight of hydrogen. Stas, from an elaborate series of experiments, the exactness of which it seems impossible to exceed, has arrived at the conclusion that Prout's law is not true, or at any rate that it is only approximatively true. He has obtained the following numbers for potassium, sodium, silver, sulphur, nitrogen, chlorine, and lead. Each number has been derived from numerous closely concordant experiments performed by different processes, on a scale of magnitude and with a degree of delicacy, hitherto unequalled. His number for potassium, however, is the only one which differs considerably *i.e.* $\frac{1}{3}$ per cent. from the usually accepted number:

		Stas's numbers.	Differences.
Potassium	39	39·130	+ 0·130
Sodium	23	23·050	+ 0·050
Silver	108	107·943	− 0·057
Sulphur	32	32·074	+ 0·074
Nitrogen	14	14·041	+ 0·041
Chlorine	35·5	35·460	− 0·040
Lead	103·5	103·457	− 0·043

Hence it is apparent that the differences in the experimental determination of the ratios according to which bodies combine with one another, have been reduced within very narrow limits. But the case is far otherwise when we come to consider the interpretation of these ratios, or the establishment of the atomic weights of simple and compound bodies. Thus mercury unites with chlorine in two proportions to form calomel and corrosive sublimate respectively. In the former compound the ratio of chlorine to mercury is as 35·5 to 200; and in the latter as 35·5 to 100; or as *twice* 35·5 to 200. We have therefore to decide between the numbers 200 and 100, wherewith to express the atomic weight of mercury. If we select the number 200, the formula of calomel will be $HgCl$, and that of corrosive sublimate $HgCl^{2}$. If we select the number 100, the formula of calomel will be $Hg^{2}Cl$, and that of corrosive sublimate, $HgCl$. Much the same difficulty also exists in those cases in which two elements combine in only one proportion. Thus chlorine unites with silver in the proportion of 35·5 to 108, or to *twice* 54. Now supposing even that we all agree to represent calomel by $Hg^{2}Cl$, and corrosive sublimate by $HgCl$, we have still to consider whether chloride of silver is a body analogous to calomel or to corrosive sublimate, before we can decide upon representing it by the formula $Ag^{2}Cl$, in which $Ag = 54$, or by the formula $AgCl$, in which $Ag = 108$. Again, chlorine unites with aluminium in the single proportion of 35·5 parts of chlorine to 9 parts of aluminium. Chloride of aluminium may consequently be represented by the formula $AlCl$, in which $Al = 9$; or by $AlCl^{2}$, in which $Al = 18$; or by $AlCl^{3}$, in which $Al = 27$; or by $Al^{2}Cl$, in which $Al = 4·5$; or by $Al^{2}Cl^{3}$, in which $Al = 13·5$; or by one of many other possible formulæ. From a variety of considerations, more or less complicated, the last formula, $Al^{2}Cl^{3}$, is the one which has been generally but not unanimously adopted. Again, the composition of marsh-gas has been ascertained with the greatest certainty. The ratio of carbon to hydrogen is precisely as 3 to 1. Hence we may represent the gas by the formula CH in which the atomic weight of carbon = 3; or by the formula CH^{2}, in which $C = 6$; or by the formula CH^{3}, in which $C = 9$; or by the formula CH^{4}, in which $C = 12$; or we may represent the gas by the formula $C^{2}H^{4}$, in which $C = 6$; &c. &c. At the present time, all chemists are agreed that the molecule of marsh-gas contains four atoms of hydrogen, but they disagree as to whether it contains two atoms of carbon having each the value 6, or one atom of carbon only having the value 12.

It is obvious that the atomic weights of an element and of its combinations, should be selected so as to express the entire series of combinations by the simplest series of formulæ; so as best to accord with the chemical properties and metamorphoses of the bodies; so as best to illustrate their analogies with other bodies; and so as to be in relation with their physical properties, such as their specific volumes, specific heats, isomorphism, &c. Now it so happens that these different requirements, chemical and physical, are not always satisfied by one and the same number. Hence we have to subordinate requirements, much in the same manner that zoologists and botanists subordinate characters, and to select that atomic weight which fulfils the greatest number, or rather the most important of them. Many of the discrepancies which were formerly thought to exist between the numbers deduced respectively from chemical and physical considerations, have of late years been satisfactorily explained away; and we have every reason to believe that with increasing knowledge leading to higher generalisations, all such anomalies as at present exist will also disappear.

In a determination of the least indivisible combining proportion, or chemical atom of a body, it is clear that purely chemical considerations must be entitled to the greatest weight, and to some of these we will now direct our attention. If we examine marsh-gas, for instance, we soon perceive that its molecule contains four atoms of hydrogen; because we find ourselves able to displace one-fourth, or two-fourths, or three-fourths, or four-fourths of its hydrogen. In other words, we find that its hydrogen is divisible into four equal parts; and as the atom of hydrogen expresses the least indivisible part of hydrogen that can enter into a combination, it is evident that marsh gas must contain four of such parts, or four atoms, of hydrogen. Thus taking the formula $C^{r}H^{4}$ for marsh-gas, we have the following series of derivatives, the constitution of which could not be expressed, save by according four atoms of hydrogen to the molecule of the gas.

$C^{r}H^{4}$	Marsh-gas	$C^{r}H^{4}$.	
$C^{r}H^{3}Cl$	Chloride of methyl	$C^{r}H^{3}Na$	Sodium-methyl.
$C^{r}H^{2}Cl^{2}$	Dichloride of methylene	. .	
$C^{r}HCl^{3}$	Chloroform	$C^{r}HI^{3}$	Iodoform.
$C^{r}Cl^{4}$	Tetrachloride of carbon	. .	

Hence the metamorphoses of marsh-gas show that the most simple formula by which the ratio of its carbon and hydrogen can be expressed, namely, CH, is not the proper formula of the body. Again, the quantity of marsh-gas, which is the resultant of any reaction, cannot be expressed with less than four atoms of hydrogen. Thus, when acetic acid is decomposed by heat, we have the reaction, $C^{2rr}H^{4}O^{2} = C^{r}H^{4} + C^{r}O^{2}$. The quantity of carbon C^{r}, which unites with 4 pts. of hydrogen to form marsh-gas, unites with 32 pts. of oxygen to form carbonic anhydride; but whereas the quantity of hydrogen in marsh-gas is experimentally divisible into 4 pts., the quantity of oxygen in carbonic anhydride is experimentally divisible into 2 pts. only; so that while we represent marsh-gas by the formula $C^{r}H^{4}$, we represent carbonic anhydride by the formula $C^{r}O^{2}$, as will be again referred to.

The same class of chemical reasons which induce us to regard marsh-gas as tetrahydric, also induce us to regard ammonia as trihydric. In ammonia we can replace one-third, or two-thirds, or three-thirds of its hydrogen, but we cannot replace one-fourth, or two-fourths, or three-fourths. The hydrogen in marsh-gas being divisible into 4 equal parts, the hydrogen in ammonia is divisible into 3 equal parts only, and consequently the molecule of ammonia contains 3 indivisible proportions or atoms of hydrogen. We are acquainted with many ammonias in which one, two, and three-thirds of the hydrogen are displaced, for example:

$N^{r}H^{3}$	Ammonia.	$N^{r}HI^{2}$	Diniodamide
$N^{r}H^{2}K$	Potassamine	$N^{r}Hg^{3}$	Trimercuramine, &c. &c.

But the most striking illustration of displacement by thirds is afforded by Hofmann's researches on the volatile alkaloids, in which he successively displaced one, two, and three atoms of hydrogen in ammonia by a mere continuation of one and the same process:

Ammonia.	Ethylia.	Diethylia.	Triethylia.	Ethyl-methyl-aniline.
$N^{r}\left\{\begin{matrix}H\\H\\H\end{matrix}\right.$	$N^{r}\left\{\begin{matrix}H\\H\\Et\end{matrix}\right.$	$N^{r}\left\{\begin{matrix}H\\Et\\Et\end{matrix}\right.$	$N^{r}\left\{\begin{matrix}Et\\Et\\Et\end{matrix}\right.$	$N^{r}\left\{\begin{matrix}Et\\Me\\Ph\end{matrix}\right.$ &c. &c.

Again, in ninety-nine cases out of a hundred, the quantity of ammonia which is the agent or resultant of a reaction, must contain 3 or some multiple of 3 atoms of hydrogen. Thus when ammonia results from the hydrogenation of nitric acid, we obtain, for every molecule of nitric acid containing 1 atom of hydrogen, a quantity of ammonia containing 3 atoms; and when ammonia reacts with benzoic chloraldehyde to form benzamide and sal-ammoniac, we require, for every molecule of benzoic chloraldehyde decomposed, a quantity of ammonia containing *twice* 3 atoms of hydrogen, $2N^{r}H^{3}$; and so in other instances. In the great majority also of compounds which ammonia forms directly with other bodies, the quantity of combining ammonia must necessarily be represented with 3 or some multiple of 3 atoms of hydrogen. Thus the single molecule of aldehyde unites with $N^{r}H^{3}$, and the single molecule of nitrate of silver with $2N^{r}H^{3}$. &c. Express these combinations or reactions how we please, we cannot represent them save with a proportion of ammonia containing 3 or some multiple of 3 atoms of hydrogen, and ninety-nine cases out of a hundred will yield the same result. In those few exceptional cases in which the combining or reacting ammonia need not necessarily be represented with 3 atoms of hydrogen, it may be, and we contend ought to be, so represented. Thus when ammonia is decomposed by excess of chlorine, the reaction might be expressed, thus: $\overset{r}{N}^{3} + Cl = \overset{r}{N}^{5}Cl + HCl$: but it is quite certain that the molecule of chloride of nitrogen contains 3 at. of chlorine, and consequently the reaction by which it is produced ought to be expressed thus: $N^x H^3 + Cl^6 = N^x Cl^3 + 3HCl$; and so in other instances.

The same class of chemical reasons which induce us to regard marsh-gas as tetrahydric and ammonia as trihydric, also induce us to regard water as dihydric. In water we can replace one-half or two-halves of the hydrogen, but we cannot replace one-third or two-thirds as in ammonia, or one-fourth or three-fourths as in marsh-gas. If we act upon water $O^x H^2$ by metallic potassium, we displace one-half its hydrogen to form the very definite body *hydrate of potassium* $O^x KH$; and if we act upon hydrate of potassium by potassium, we displace the other half of the hydrogen and form *oxide of potassium* $O^x KK$. Or instead of introducing a second atom of potassium, we may turn out the first one. Thus if we treat hydrate of potassium $O^x KH$ with iodide of ethyl we obtain *alcohol* $O^x EtH$, or we put a molecular grouping called ethyl in the place of the potassium, which displaced one-half the hydrogen of the water. Now if we act upon the alcohol thus formed by potassium, it behaves exactly as did the hydrate of potassium, or in other words it yields the remaining half of the original hydrogen in exchange for potassium, and we obtain *ethylate of potassium* $O^x EtK$. If we now act upon this new body by the iodide of methyl or ethyl, we turn out the potassium representing one-half the original hydrogen and obtain *ethylate of methyl* $O^x EtMe$, or *ethylate of ethyl* $O^x EtEt$.

Again, in ninety-nine cases out of a hundred, the quantity of water, which is the agent or resultant of a reaction must contain 2 or some multiple of 2 atoms of hydrogen. Thus, whenever an alcohol, ketone, or any definite organic substance, yields a hydrocarbon or other compound by dehydration,—whenever an organic acid yields a pyroacid, or other pyrogenous product by dehydration,—whenever a salt of ammonia, phenylamine, or other volatile alkali loses water,—and whenever two compounds act upon one another to form a new body with simultaneous elimination of water, whether the action be that of an acid upon a hydrocarbon, of an acid upon an alcohol, of an acid upon an alkali, of an acid upon an acid, of an acid upon an aldehyde, of an alkali upon an aldehyde, or of an alkali upon an alcohol,—the quantity of water eliminated inevitably contains 2, or some multiple of 2 atoms of hydrogen. Moreover whenever a conjugated compound or diameride, a chloraldehyde, an organometallic body, &c. &c., is decomposed by water, the quantity of water which reacts must necessarily be represented with 2 or some multiple of 2 atoms of hydrogen. For example, when water reacts with hippuric acid to form benzoic acid and glycocine, for every molecule of hippuric acid decomposed, we require a quantity of water containing $O^x H^2$. When glycerin becomes acrolein by dehydration, for every molecule of glycerin decomposed we obtain a quantity of water containing $2O^x H^2$. When nitric acid reacts with naphthalene to form nitro-naphthalene, for every molecule of nitric acid which reacts, we have eliminated a quantity of water containing $O^x H^2$. When acetate of ammonia becomes cyanide of methyl by loss of water, for every molecule of the salt decomposed, we liberate a quantity of water containing $2O^x H^2$; and so in an infinite number of other instances. Again, in the majority of direct compounds which water forms with other bodies, the combining water must be represented with two atoms, or some multiple of two atoms of hydrogen. Thus the molecule of glucose differs from that of fructose, and that of lactine differs from that of dextrine by the addition of $O^x H^2$. The molecule of turpentine becomes hydrated turpentine by absorbing $3O^x H^2$, and so in many other instances. The water of crystallisation in the great majority of hydrated salts must be represented with 2 atoms, or some multiple of 2 atoms of hydrogen. Thus the molecules of chloride of barium, nitrate of mercurosum, and chloride of copper, crystallise with $O^x H^4$; the molecules of nitrate of cadmium, chloride of manganese, and nitrate of calcium with $2O^x H^4$; the molecules of chloride of calcium, nitrate of magnesium, and acetate of sodium with $3O^x H^2$; the molecules of microcosmic salt and hydrate of barium with $4O^x H^2$; the molecule of borax with $5O^x H^2$; the molecules of chloride of aluminium and potassio-sulphate of nickel, with $6O^x H^2$; the molecule of common arsenate of sodium with 7 or 12 $O^x H^2$; and the molecules of alum and rhombic phosphate of sodium with $12O^x H^2$, &c. &c. There are some comparatively few salts, the acetate of barium, for example, in which the water of crystallisation might be represented by $\frac{1}{2}O^x H^2$, or by $1\frac{1}{2}O^x H^2$, &c., but none in which it need be so represented, while there are scarcely any reactions in which the resulting or reacting water could possibly be expressed by $\frac{1}{2}O^x H^2$ or $1\frac{1}{2}O^x H^2$, and none in which it would be correctly so expressed.

We have mentioned above that the quantity of carbon which unites with four separable portions of hydrogen to form marsh-gas, also unites with two separable portions of oxygen to form carbonic anhydride. Now each of these separable portions of oxygen is identical with the quantity of oxygen O^x, which unites with 2 parts of hydrogen to form water.

Lastly, when we come to examine hydrochloric acid, we are unable to show that its hydrogen is divisible, and we consequently look upon its molecule as containing but one atom, or one indivisible proportion of hydrogen; whence we represent the compound by the formula $Cl^{x}H$; and we may anticipate here by remarking, that all physical evidence tends to show that the molecules of marsh-gas, ammonia, water, and chlorhydric acid contain respectively four, three, two, and one atom of hydrogen.

In addition to the class of binary hydrides, the atomic weights of the principal members of which we have just considered, there is another large class of hydrogenised bodies, namely, the class of ternary or oxacids, the correct determination of whose molecules is of the highest importance. The molecule of oxalic acid, for instance, may be represented by the formula $C^{x}HO^{2\times x}$, or $C^{2\times x}H^{2}O^{4\times x}$, according as the acid is found to be monhydric or dihydric, monobasic or dibasic. Now the polybasicity of an acid does not depend in any way upon the indivisibility of its formula, but solely upon its possession of certain specific characters; and the examination of the properties of oxalic acid soon shows us that its molecule must be represented, not by the more simple monobasic, but by the more complex dibasic formula. In fact the same class of chemical reasons which induce us to regard water as dihydric, must also induce us to regard oxalic acid as dihydric, and so in other instances. Inasmuch as the modes of distinguishing between monobasic, dibasic, tribasic, and tetrabasic acids have been minutely set forth in the article ACIDS, it is unnecessary here to repeat them. We will only observe that certain special acids, to the properties and metamorphoses of which we shall presently have occasion to advert, are proved by their specific characters to be dihydric and dibasic, namely:

Carbonic acid	$H^{2}C^{x}O^{3\times x}$
Oxalic acid	$H^{2}C^{x}O^{4\times x}$
Sulphurous acid	$H^{2}S^{x}O^{3\times x}$
Sulphuric acid	$H^{2}S^{x}O^{4\times x}$

We will now turn our attention to the atomic weights of the four elements with which the hydrogen of the four primary hydrides, whose atomic weights we have considered somewhat minutely, is combined; whereby it will appear that the quantities of carbon, nitrogen, oxygen, and chlorine which we have represented by the symbols C^{x}, N^{x}, O^{x}, and Cl^{x}, respectively, constitute the atoms of these elements, or the smallest indivisible proportions of them which can enter into chemical combination. To begin with carbon: we wish to prove that 12 parts of that element, or the quantity thereof which combines with 4 parts of hydrogen to form marsh-gas, is the smallest proportion of carbon that can exist in a compound. We find in the first place that the quantity of carbon contained in the great majority of carbon-compounds must necessarily be represented by 12, or some multiple of 12 parts. We may adduce in illustration of this position, the primary series of homologous fatty acids and their sodium-salts.

Formic	$C^{1\times 12}H^{2}O^{2\times x}$	$C^{1\times 12}H\ NaO^{x\times 2}$	Formate
Acetic	$C^{2\times 12}H^{4}O^{2\times x}$	$C^{2\times 12}H^{3}NaO^{x\times 2}$	Acetate
Propionic	$C^{3\times 12}H^{6}O^{2\times x}$	$C^{3\times 12}H^{5}NaO^{x\times 2}$	Propionate
Butyric	$C^{4\times 12}H^{8}O^{2\times x}$	$C^{4\times 12}H^{7}NaO^{x\times 2}$	Butyrate
Valeric	$C^{5\times 12}H^{10}O^{2\times x}$	$C^{5\times 12}H^{9}NaO^{x\times 2}$	Valerate
Caproic	$C^{6\times 12}H^{12}O^{2\times x}$	$C^{6\times 12}H^{11}NaO^{x\times 2}$	Caproate

The ratio of carbon to hydrogen in the sodium-salts, necessitates our expressing the constituent carbon as a multiple of 12. The mere ratio of carbon to hydrogen in the acids, would allow the carbon, in all of them, to be expressed satisfactorily by numbers which are not multiples of 12, but of 6. Valeric acid, for instance, might be represented by the formula $C^{5\times 6}H^{5}O^{x}$; but the circumstance that one-tenth part of its hydrogen can be displaced by sodium prevents the possibility of our halving the hydrogen in its molecule, and consequently of our reducing its carbon from a multiple of 12 to a mere multiple of 6.

From the circumstance that all carbon-compounds must be represented with 12 parts, or some multiple of 12 parts of carbon, it follows that whenever two compounds differ from one another by the different proportions of carbon which they respectively contain, that difference amounts to 12 parts of carbon, or to some multiple of 12 parts. Thus, *wood-spirit* consists of 16 pts. of oxygen, 4 pts. of hydrogen, and 12 pts. of carbon, whereas in *aldehyde* we have another 12 parts of carbon, and in *acrolein* two other 12 parts of carbon in addition, so that the three bodies may be represented by the respective formulæ:

$C^{1\times 12}H^{4}O^{x}$	Wood-spirit
$C^{2\times 12}H^{4}O^{x}$	Aldehyde
$C^{3\times 12}H^{4}O^{x}$	Acrolein

We are not acquainted with any bodies intermediate in composition between wood-spirit and aldehyde, or between aldehyde and acrolein, nor have we any reason to anticipate their formation at any future time. Again *toluene* contains 8 parts of hydrogen united with seven times 12 parts of carbon; whereas *cinnamene* contains another 12 parts of carbon, and *naphthalene* three other 12 parts of carbon in addition, thus:

$C^{7\times12}H^8$	Toluene
$C^{8\times12}H^8$	Cinnamene
$C^{9\times12}H^8$	Wanting
$C^{10\times12}H^8$	Naphthalene

Now the probability amounts almost to a certainty that a hydrocarbon intermediate between cinnamene and naphthalene will be discovered, and that a hydrocarbon intermediate between toluene and cinnamene, or between cinnamene and the expected compound, or between the expected compound and naphthalene will not be discovered. It follows also that when carbon, plus some other element or elements, is added to or taken from a body, the quantity of carbon added or subtracted is always 12 parts, or some multiple of 12 parts. Thus the molecule of *sodium-ethyl* absorbs 12 parts of carbon, plus some oxygen to form *propionate of sodium; aconitic acid*, by the loss of 12 parts of carbon, plus some oxygen, becomes *citraconic acid*; and *phthalic* acid, by the loss of twice 12 parts of carbon, plus some oxygen, becomes *benzene*. Moreover in those series of compounds known as homologous, the quantity of carbon in each successive member of the series increases by 12 parts, as shown in a preceding table of the fatty acids and their sodium-salts. All chemists recognise the fact, which is indeed indisputable, that the smallest increment or decrement of carbon that can be effected in a compound is 12 times as great as the smallest quantity of hydrogen that can be introduced into or displaced from a compound; so that if the entire series of carbon-compounds is to be represented by the simplest satisfactory formulæ, the atom or smallest combining proportion of carbon must be represented as having 12 times the weight of the atom or smallest combining proportion of hydrogen. But some chemists who from old association still accord to carbon the atomic weight 6, consider that all carbon-compounds contain an even number of atoms of carbon, and that in the decompositions and recompositions of these compounds, two inseparable carbon-atoms are always concerned. But if we understand the smallest inseparable or indivisible proportion of an element to constitute its atom, the conception of two inseparably associated atoms is clearly illogical. Two small atoms of carbon, having each the value 6, if they can never be separated from each other, must nececessarily constitute one large atom of carbon having the value 12.

There are two well-known compounds of carbon, namely, carbonic oxide, and carbonic anhydride, which may possibly be regarded as constituting exceptions to some of our previously made assertions. Thus the molecules of these two bodies may be represented by one or other of the following pairs of formulæ:

$C^{1\times6}O^{1\times8}$	Carbonic oxide	$C^{1\times12}O^{1\times16}$
$C^{1\times6}O^{2\times8}$	Carbonic anhydride	$C^{1\times12}O^{2\times16}$

Now provided we recognise the dibasicity of the carbonic, oxalic, and other similar acids, as their chemical properties require us to do, it is quite certain that a proportion of either carbonic oxide or carbonic anhydride, containing only 6 parts of carbon, is incapable of effecting or of resulting from a definite chemical reaction. Carbonic anhydride in particular, is a very frequent product of chemical action, but in no definite decomposition do we ever obtain a smaller proportion of the gas than that represented by 12 parts of carbon plus 32 of oxygen. A few illustrations are appended of the formation of carbonic oxide and carbonic anhydride, from the decomposition by heat of three monobasic acids, namely, the formic, acetic, and benzoic; of two dibasic acids, namely, the oxalic and tartaric; and of one tribasic acid, namely, the aconitic, the decomposition of which last has been before referred to.

Formic acid	$C^{1\times12}H^2O^{2\times x} = C^{1\times12}O^{1\times x} + H^2O$
Acetic acid	$C^{2\times12}H^4O^{2\times x} = C^{1\times12}O^{2\times x} + C^{1\times12}H^4$
Oxalic acid	$C^{2\times12}H^2O^{4\times x} = C^{1\times12}O^{1\times x} + C^{1\times12}O^{2\times x} + H^2O^x$
Benzoic acid	$C^{7\times12}H^6O^{2\times x} = C^{1\times12}O^{2\times x} + C^{6\times12}H^6$
Tartaric acid	$C^{4\times12}H^6O^{6\times x} = C^{1\times12}O^{2\times x} + C^{3\times12}H^4O^{3\times x} + H^2O^x$
Aconitic acid	$C^{6\times12}H^4O^{6\times x} = C^{1\times12}O^{2\times x} + C^{5\times12}H^4O^{4\times x}$.

With regard to nitrogen, all chemists are agreed that 14 parts of that element, or the quantity thereof which combines with 3 parts of nitrogen to form ammonia, is the smallest proportion of nitrogen that can exist in a combination. We find that the quantity of nitrogen contained in the great majority of nitrogenous compounds, including all salts of ammonia and of organic alkaloïds, must necessarily be represented by 14 parts, or some multiple of 14 parts. Among miscellaneous bodies we may adduce cyanogen, indigo, and nitric acid, each of which contains 14 parts of nitrogen; urea, asparagin, and chrysammic acid, each of which contains twice 14 parts of nitrogen; creatine and carbazotic acid, each of which contains three times 14 parts of nitrogen; uric acid and caffeine, each of which contains four times 14 parts of nitrogen, &c. &c. From the circumstance that all nitrogenous compounds must be represented with 14 parts of nitrogen, it follows that whenever nitrogen is liberated by a chemical reaction, and whenever nitrogen plus some other element is introduced into a chemical compound, the quantity of nitrogen concerned must be represented by 14 parts or some multiple of 14 parts. Thus by the action of nitric acid upon the hydrocarbons, and upon a great variety of other compounds, we can introduce into the compounds 14 parts, or twice 14 parts, or three times 14 parts, &c. &c. of nitrogen, whereas we cannot introduce any intermediate proportion. Again, when sal-ammoniac is decomposed by chlorine, for every molecule of the salt decomposed, 14 parts of nitrogen are liberated; and when nitrate of ammonia is decomposed by metallic zinc, for every molecule of the salt decomposed twice 14 parts of nitrogen are liberated; and so on. There are a few bodies formed on the type of one or more atoms of ammonia, in which the ratios of the constituent elements might be satisfactorily expressed by formulæ in which the quantity of nitrogen represented was not a multiple of 14. Thus trimercuramine might be represented by the formula $N^{1\times4\cdot7}Hg$, and triethylamine, by the formula $N^{1\times4\cdot7}C^2H^5$. Similarly, all derivatives of ammonia in which the whole of the hydrogen is displaced by one and the same metal, hydrocarbon, or halogen, might be represented by formulæ in which $N = 4\cdot7$; which formulæ moreover, would be more simple than those in which $N = 14$. But the same class of reasons which induce us to represent the molecule of ammonia with 3 atoms of hydrogen, induce us to represent the molecules of these bodies with 3 atoms of metal, radicle, or halogen. Thus triethylamine is the third of a series of compounds, namely, $N^{1\times14}H^2(C^2H^5)$, $N^{1\times14}H^1(C^2H^5)^2$, and $N^{1\times14}(C^2H^5)^3$, obtained successively by a continuance of the same reaction. Moreover, a quantity of triethylamine containing less than 14 parts of nitrogen, is not sufficient to effect any decomposition, or to combine with the molecule of any acid or salt. It is observable that the entire series of compounds is represented most simply by formulæ, in which $N = 14$, although one particular member of the series may be represented most simply by a formula in which $N = 4\cdot7$.

Let us now direct our attention to oxygen. We wish to show that 16 parts of that element, or the quantity thereof which unites with 2 atoms of hydrogen to form water, is the smallest proportion of oxygen that can enter into a combination. We find in the first place that the quantity of oxygen contained in the great majority of definite oxidised compounds, must necessarily be represented by 16 or some multiple of 16 parts. Thus the molecules of all hydrates, double oxides, acids, oxisalts, aldehydes, ketones, alcohols, oxacid-ethers, and a great number and variety of other compounds, doubtless forming together 99 per cent. of all known compounds of oxygen, cannot be represented save with 16 parts, or some multiple of 16 parts of oxygen. For example, the molecules of *hydrate of potassium*, *benzoic aldehyde*, *acetone*, *chloral*, *hypochlorite of sodium*, &c. &c. each contain 16 parts of oxygen. The molecules of *spinelle*, *brown-hæmatite*, *camphor*, *benzile*, *acetate of sodium*, *benzoic acid*, &c. &c. each contain twice 16 parts of oxygen. The molecules of *nitric acid*, *glycerin*, *chlorate of potassium*, *salicylic acid*, *augite*, &c. &c. each contain three times 16 parts of oxygen. The molecules of *phosphate of sodium*, *perchloric ether*, *garnet*, *olivine*, *sulphovinic acid*, &c. &c. each contain four times 16 parts of oxygen. The molecules of *starch*, *acid malate of lead*, *nitrosalicylic acid*, &c. &c. each contain five times 16 parts of oxygen. The molecules of *mannite*, *cream of tartar*, &c. &c. each contain six times 16 parts of oxygen, while the molecules of *citric acid*, *pyrophosphate of copper and sodium*, &c. &c. contain each seven times 16 parts of oxygen, and so on. From the circumstance that nearly all oxidised compounds must necessarily be represented with 16 or some multiple of sixteen parts of oxygen, it follows that when two bodies differ from one another in composition by the different proportions of oxygen which they respectively contain, that difference amounts to 16 parts or some multiple of 16 parts of oxygen, as is well seen in the two following series of bodies.

KCl	Chloride of potassium	C^2H^4	Ethylene
$KClO^{1\times16}$	Hypochlorite of potassium	$C^2H^4O^{1\times16}$	Aldehyd
$KClO^{2\times16}$	Chlorite of potassium	$C^2H^4O^{2\times16}$	Acetic acid
$KClO^{3\times16}$	Chlorate of potassium	$C^2H^4O^{3\times16}$	Glycolic acid
$KClO^{4\times16}$	Perchlorate of potassium	$C^2H^4O^{4\times16}$	Glyoxylic acid.

It follows also that the quantity of oxygen which can be liberated by any reaction, and which, either alone or together with some other element, can be added to, substracted from, or displaced in a compound, must be 16 or some multiple of 16 parts. Now why this should be unless the 16 parts constitute an indivisible proportion or chemical atom, is quite inconceivable. We may adduce the following illustrations. Each molecule of nitrate of sodium decomposed by heat into oxygen and nitrite of sodium, yields 16 parts of oxygen. Each molecule of permanganate of potassium, decomposed by sulphuric acid into oxygen and manganese-alum, yields twice 16 parts of oxygen. Each molecule of chlorate of potassium decomposed by heat into oxygen and chloride of potassium, yields three times 16 parts of oxygen. Each molecule of pentachloride of phosphorus, converted by treatment with water into phosphoric chloraldehyde and hydrochloric acid, acquires 16 parts of oxygen in exchange for an equivalent quantity of chlorine. Each atom of alcohol converted into aldehyde by oxidation, reacts with 16 parts of oxygen, and each atom of alcohol converted into acetic acid by oxidation, reacts with twice 16 parts of oxygen. Each molecule of bromacetic acid, converted by the action of water into glycolic acid, acquires 16 parts of oxygen and 1 part of hydrogen, in exchange for one atom of bromine. Each atom of benzene, converted by treatment with nitric acid into nitrobenzene, acquires twice 16 parts of oxygen, and 14 parts of nitrogen, in exchange for one atom of hydrogen, and so on. But precisely as there are some nitrogenised bodies which with the atomic weight of nitrogen = 4·7, may be divided into thirds, and can thus receive simpler formulæ than with the atomic weight of nitrogen = 14; so are there some comparatively few oxidised bodies which, with the atomic weight of oxygen = 8, may be divided into halves, and can thus receive simpler formulæ than with the atomic weight of oxygen = 16. We have seen, however, that if the comparable molecules of nitrogenised bodies were correctly formulated they would all be represented more simply by formulæ in which N = 14, than by formulæ in which N = 4·7; so it will appear that if the comparable molecules of oxidised bodies were correctly formulated, they would all be represented more simply by formulæ in which O = 16, than by formulæ in which O = 8. Those oxidised bodies in which the ratio of the oxygen to the other constituents can be satisfactorily expressed by assigning to the oxygen a number which is not 16 or a multiple of 16, but only 8 or a multiple of 8, comprise most compounds in which the oxygen is united with one kind of matter only, including all the simple metallic oxides. Thus in water and lime, the ratio of the constituent oxygen to the hydrogen and calcium respectively, is as satisfactorily expressed by the formulæ $O^{1\times 8}H$, and $O^{1\times 8}Ca$, as by the formulæ $O^{1\times 16}H^2$, and $O^{1\times 16}Ca^2$. The only question is, which of these pairs of formulæ represents the molecules of the two bodies. Now it is no more necessary to argue the point whether $O^{1\times 8}Ca$, is the correct expression for the metallic oxide, lime, than it was to argue the point whether $N^{1\times 4\cdot 7}Hg$, was the correct expression for the metallic nitride, mercuramine. The accordance of a trihydric formula to ammonia, necessitates the accordance of a trimetallic formula to mercuramine, and in a precisely similar manner, the accordance of a dihydric formula to water necessitates the accordance of a dimetallic formula to lime. It may be observed, moreover, that many strictly comparable reactions can be effected by means of water, hydrate of calcium, and lime respectively, and that in these cases the quantities of the reagents can only be expressed by the formulæ $O^{1\times 16}HH$, $O^{1\times 16}HCa$, and $O^{1\times 16}CaCa$. Again, in bodies analogous to ordinary ether and the homogeneous anhydrides, the ratio of the oxygen to the other constituents may be satisfactorily represented by formulæ in which the proportion of oxygen is expressed by 8 parts only. Thus ether may be represented by the formula $O^{1\times 8}Et$, and benzoic anhydride by the formula $O^{1\times 8}Bz$; but all arguments founded on mode of formation, on reactions, on vapour-densities, on seriated position and properties, &c. tend to show that the above formulæ are not correct expressions of the molecules of the bodies represented, which, like that of water, contain 16 parts of oxygen. Thus, ether is one of the following series of bodies: $O^{1\times 16}HEt$, ethylate of hydrogen, or alcohol; $O^{1\times 16}MeEt$, ethylate of methyl; $O^{1\times 16}EtEt$, ethylate of ethyl or ether; $O^{1\times 16}PrEt$, ethylate of propyl; and benzoic anhydride is one of the following series. $O^{1\times 16}HBz$, benzoate of hydrogen, or benzoic acid; $O^{1\times 16}BzBz$, benzoate of benzoyl, or benzoic anhydride; $O^{\times 16}AcBz$, benzoate of acetyl, or aceto-benzoic anhydride; &c. &c. Lastly, in certain dibasic acids and their salts of one metal, the ratio of the oxygen to the other constituents may be satisfactorily expressed by monobasic formulæ, in which the oxygen is expressed not as a multiple of 16, but as a multiple of 8. Thus sulphurous acid and sulphite of sodium may be formulated as follows: $HS^{\overset{\prime\prime}{\frac{1}{2}}}O^{3\times 8}$, and $NaS^{\overset{\prime\prime}{\frac{1}{2}}}O^{3\times 8}$, respectively. But as we have before observed, the distinctions between monobasic and dibasic acids and their salts are very decided; and inasmuch as these acids and salts are indisputably dibasic (see ACIDS), their molecules cannot be correctly represented by monobasic formulæ. The simplest dibasic formulæ for carbonates, sulphites, and sulphates respectively, are the following, in which the proportion of oxygen is necessarily expressed as a multiple of 16 parts:

$H^2CO^{3\times16}$	$H^2S^{=}O^{3\times16}$	$H^2S^{=}O^{4\times16}$
$CaHCO^{3\times16}$	$NaHS^{=}O^{3\times16}$	$KHS^{=}O^{4\times16}$
$Ca^2CO^{3\times16}$	$Na^2S^{=}O^{3\times16}$	$K^2S^{=}O^{4\times16}$
$MgCaCO^{3\times16}$	$NH^4NaS^{=}O^{3\times16}$	$NiKS^{=}O^{4\times16}$

Many chemists, who acknowledge that the molecule of water consists of 2 parts of hydrogen united with 16 pts. of oxygen, and that, in ninety-nine cases out of a hundred, the smallest quantity of oxygen that can enter into the composition of a well-defined molecule must be represented by 16 parts, prefer, from old association, to accord to oxygen the atomic weight 8, and to admit that all oxygenated molecules contain two inseparably associated atoms of oxygen, or some multiple of two inseparably associated atoms. Thus, they represent water by the formula $H^2O^{2\times8}$ instead of H^2O, and nitric acid by $HNO^{6\times8}$ instead of HNO^3, &c. This practice is evidently most inconsequent: for the conception of two inseparable proportions of 8 each, amounts after all to that of one indivisible proportion of 16, that is to an atomic proportion of 16. To be consistent, we must represent the molecules of hydrochloric acid, water, ammonia, and marsh-gas either by Gerhardt's atomic, or by Dalton's equivalent formulæ, thus:

$HCl^{1\times35\cdot5}$	Hydrochloric acid	$HCl^{1\times35\cdot5}$
$H^2O^{1\times16}$	Water	$HO^{1\times8}$
$H^3N^{1\times14}$	Ammonia	$HN^{1\times4\cdot7}$
$H^4C^{1\times12}$	Marsh-gas	$HC^{1\times3}$

except that Dalton took, not marsh-gas, but olefiant-gas, for his standard hydrocarbon, and accorded to it the formula $HC^{1\times6}$, whereby marsh-gas became $H^2C^{1\times6}$. Now-a-days we know that the molecules of marsh-gas and olefiant-gas both contain the same number of hydrogen-atoms, and that their formulæ are $C^{1\times16}H^4$ and $C^{2\times16}H^4$ respectively.

With regard to chlorine, all chemists are agreed that 35·5 parts of that element, or the quantity thereof which unites with 1 part of hydrogen to form hydrochloric acid, is the smallest quantity of chlorine that can enter into a combination. We find that 35·5 parts of chlorine are capable of directly displacing 1 part of hydrogen in a great variety of compounds; that in all well defined molecules, the quantity of constituent chlorine must be represented by 35·5, or some multiple of 35·5 parts; that whenever two bodies differ from one another in composition by the quantity of chlorine they respectively contain, the difference amounts to 35·5, or some multiple of 35·5 parts; and that it is impossible to add to, subtract from, or displace in any compound a proportion of chlorine which is not represented by 35·5, or some multiple of 35·5 parts.

In the course of the preceding observations, reference has occasionally been made to the principle of analogy as a guide in determining the molecule of a compound body, and the atomic weights of its constituent elements. Thus we have referred to the analogy of triethylamine with ammonia, and to that of lime or oxide of calcium with water or oxide of hydrogen. But, in addition to the arguments already used, we may show more especially that the principle of analogy is in favour of the atomic weights and molecules which we have adopted. Thus the indisputable analogies of nitrous acid, nitric acid, and peroxide of nitrogen, with chlorous acid, chloric acid, and peroxide of chlorine respectively, are shown very clearly by formulæ in which $N = 14$, whereas they would be concealed by formulæ in which $N = 4\cdot7$, as seen below:

Chlorous acid,	$HClO^2$	HNO^2	Nitrous acid	HN^3O^2
Chloric acid,	$HClO^3$	HNO^3	Nitric acid	HN^3O^3
Perchloric oxide,	Cl^2O^4	N^2O^4	Pernitric oxide	N^6O^4

Again, with the molecule of water = 9, the relation of water to the alcohols as the undoubted vanishing term of the series, would not be manifested as it is with the molecule = 18. Thus, if we write alcohol $C^2H^6O^{2\times8}$, wood-spirit $CH^4O^{2\times8}$, and water $HO^{1\times8}$, the relation of water to the alcohols does not appear, but in the following series of formulæ with $O = 16$, it is perfectly apparent:

$C^5H^{12}O$, Amylic alcohol	C^2H^6O, Ethylic alcohol
$C^4H^{10}O$, Butylic „	CH^4O, Methylic „
C^3H^8O, Propylic „	H^2O, Hydric „

The relation of water to the alcohols, as shown in the above formulæ, is not a mere paper relation, but has its foundation in experiment. When water and alcohol respectively are acted upon by potassium, by chloride of benzoyl, by pentachloride of phosphorus, and by a host of other reagents, the reactions are acknowledged by all to be precisely similar. All chemists, no matter what the formulæ they employ, recognise the fact that the quantity of water which in a reaction corresponds to one proportion of alcohol, must contain two units of hydrogen. Similarly, with regard to hydrated bases and acids. The reactions of the bodies clearly show that the quantity of water which corresponds to one proportion of hydrate of potassium, or of hypochlorous acid, for instance, must contain two units of hydrogen. If we write hydrate of potassium $KHO^{2\times 8}$, hypochlorous acid $HClO^{2\times 8}$, and water $HO^{1\times 8}$, the formulæ do not represent comparable quantities. But, in the following series of formulæ with O = 16, the relations of the bodies are rendered perfectly evident:

KKO, Oxide of potassium	HClO, Hypochlorous acid
KHO, Hydrate of potassium	ClClO, Hypochlorous anhydride
HHO, Water	KClO, Hypochlorite of potassium

Moreover the principle of analogy is frequently allowed to overrule all other considerations. Thus the smallest quantity of aluminium that can enter into a combination is 27·5 times as great as the smallest quantity of hydrogen. This quantity of aluminium, like 14 parts of nitrogen, is capable of uniting with 3 atoms of chlorine, and of its representatives. But, from the strong analogy existing between aluminic and ferric compounds, the atomic weight of aluminium is fixed at 13·75, in order that its compounds may be represented by formulæ which, though more complex than those with Al = 27·5, are in accordance with the formulæ of corresponding ferric compounds, thus:

Fe^2Cl^3,	Sesquichloride of iron
$KFe^2(SO^4)^2 . 12H^2O$,	Iron alum
HFe^2O^2,	Brown hæmatite
Al^2Cl^3,	Sesquichloride of aluminium
$KAl^2(SO^4)^2 . 12H^2O$,	Common alum
HAl^2O^2,	Diaspore

The principle of analogy frequently enables us to determine satisfactorily the molecules and atomic weights of bodies with which we are comparatively but little acquainted. Thus the analogy of selenium and tellurium compounds, in so far as they are known, to the well-known compounds of sulphur, requires us to give similar formulæ to the similar compounds of all three elements. With regard to sulphur itself, precisely the same reasons that induce us to represent water by the formula H^2O, and to accord to oxygen the atomic weight 16, must induce us to represent sulphydric acid by the formula H^2S, and to accord to sulphur the atomic weight 32. But even if our acquaintance with sulphur were much less intimate than it is, still the analogy of its best known compounds with those of oxygen would suffice to allow of a satisfactory determination of its atomic weight. The principle of analogy induces us to accord to the primary hydrides and chlorides of the more or less electronegative elements, the following formulæ, and to classify them in four principal groups, thus:

Monatomic.	Diatomic.	Triatomic.	Tetratomic.
HF	H^2O	H^3N	H^4C
HCl	H^2S	H^3P	H^4Si
HBr	H^2Se	H^3As	Cl^4C
HI	H^2Te	H^3Sb	Cl^4Si
ClI	Cl^2O	Cl^3N	Cl^4Sn
	Cl^2S	Cl^3P	
		Cl^3As	
		Cl^3Sb	
		Cl^3Bi	

The following table represents the atomic weights of the elementary bodies on the hydrogen scale (H = 1) as determined by the preceding considerations. Those on the oxygen-scale (O = 100), which are now but little used, may be found by multiplying the hydrogen-numbers by $\frac{100}{16}$ or 6·25. The actual determinations of the atomic weights are given, with the methods of quantitative estimation, under each element.

Table of Atomic Weights.

Name.	Symbol.	Atomic Weight.	Formula of Compound analysed.	According to Experiments by
Aluminium . . .	Al	13·75	Chloride of aluminium, Al^2Cl^3	Dumas.
Antimony . . .	Sb	120·3	Trisulphide, Sb^2S^3	Schneider.
		122	Trichloride, $SbCl^3$	Dumas.
Arsenic	As	75	„ $AsCl^3$	Pelouze, Berzelius.
Barium	Ba	68·6	Chloride, BaCl	Marignac, Pelouze.
Bismuth	Bi	210	„ $BiCl^3$	Dumas.
Boron	B	11	Boric anhydride, B^2O^3	Berzelius.
			„ chloride, BCl^3	Dumas.

TABLE *continued.*

Name.	Symbol.	Atomic Weight.	Formula of Compound analysed.	According to Experiments by:
Bromine	Br	80	Bromide of potassium, KBr	Marignac.
Cadmium	Cd	56	Oxide, Cd^2O	Von Hauer.
Calcium	Ca	20	Lime, Ca^2O	Erdmann and Marchand.
Carbon	C	12	Carbonic anhydride, CO^2	Dumas and Stas. Erdmann and Marchand.
Cerium	Ce	46	Cerous oxide, Ce^2O	Marignac, Hermann.
Chlorine	Cl	35·5	Chloride of potassium „ „ silver	Marignac, Penny; Maumené, Berzelius. Dumas.
Chromium	Cr	26·2	Chromic anhydride, Cr^2O^3	Péligot, Berlin.
Cobalt	Co	29·5	Chloride, CoCl	Dumas.
Columbium or Niobium	Cb	97·6	Tetrachloride, $CbCl^4$	H. Rose.
Copper	Cu	31·7	Cupric oxide, Cu^2O	Erdmann and Marchand.
Didymium	Di	48	Oxide, Di^2O	Marignac.
Erbium	E			
Fluorine	F	19	Fluoride of calcium, CaF „ „ sodium, NaF	Louyet. Dumas.
Glucinum	Gl	4·7 7·0	Glucina, Gl^2O „ Gl^4O^3	Awdejew.
Gold	Au	196	Auric chloride, $AuCl^3$	Levol, Berzelius.
Hydrogen	H	1	Water, H^2O	Dumas; Erdmann and Marchand.
Iodine	I	127	Iodide of potassium, KI „ „ silver, AgI	Marignac. Dumas.
Iridium	Ir	98·6	Dichloride, $IrCl^2$	Berzelius.
Iron	Fe	28	Ferric oxide, Fe^4O^3 Ferric chloride, Fe^2Cl^3	Svanberg and Norlin. Maumené, Erdmann and Marchand. Berzelius. Dumas.
Lanthanum	La	46	Oxide, La^2O	Marignac.
Lead	Pb	103·6	„ Pb^2O	Berzelius.
Lithium	Li	6·5 7·0	„ Li^2O Carbonate, Li^2CO^3 Sulphate, Li^2SO^4	„ Troost. Mallet.
Magnesium	Mg	12	Magnesia, Mg^2O Chloride, MgCl	Berzelius. Dumas.
Manganese	Mn	27·6	„ MnCl	Berzelius.
Mercury	Hg	100	Mercuric oxide, Hg^2O	Erdmann and Marchand.
Molybdenum	Mo	46 48	Molybdic anhydride, Mo^2O^3	Svanberg and Struve; Berlin. Dumas.
Nickel	Ni	29 29·5	Oxide, Ni^2O Chloride, NiCl	Schneider. Dumas.
Nitrogen	N	14	Sal-ammoniac, NH^4Cl	Pelouze, Marignac, Penny.
Osmium	Os	100	Dichloride, $OsCl^2$	Berzelius, Frémy.
Oxygen	O	16		
Palladium	Pd	53	Chloride, PdCl	Berzelius.
Phosphorus	P	31	Phosphoric anhydride, P^2O^5 Pentachloride, PCl^5	Schrötter. Dumas.
Platinum	Pt	99	Dichloride, $PtCl^2$	Berzelius, Andrews.
Potassium	K	39 39·2	Chloride, KCl	Marignac, Frémy, Maumené. Stas.
Rhodium	Rh	52	Sesquichloride, Rh^2Cl^3	Berzelius.
Ruthenium	Ru	52	„ „ Ru^2Cl^3	Claus.
Selenium	Se	79	Selenide of mercury, Hg^2Se	Berzelius, Sacc, Erdmann and Marchand.
Silicon	Si	28	Chloride, $SiCl^4$	Dumas.
Silver	Ag	108	„ AgCl	Marignac, Maumené, Penny, Berzelius
Sodium	Na	23	„ NaCl	Penny, Pelouze, Dumas.
Strontium	Sr	43·8	„ SrCl	Dumas.
Sulphur	S	32	Cinnabar, Hg^2S Sulphide of silver, Ag^2S	Erdmann and Marchand, Struve. Dumas.
Tantalum	Ta	137·6	Tetrachloride, $TaCl^4$	H. Rose.
Tellurium	Te	128	Bromide of potassium and tellurium, K^2TeBr^6	v. Hauer.
Terbium	Tr			
Thorinum	Th	59·5	Thorina, Th^2O	Berzelius.
Tin	Sn	116 118	Stannic oxide, SnO^2 „ chloride, $SnCl^4$	Mulder, Vlaanderen. Dumas.
Titanium	Ti	50	Tetrachloride, $TiCl^4$	Pierre.
Tungsten	W	92	Tungstic anhydride, W^2O^3	Schneider, Birch, Dumas.
Uranium	U	60	Uranic oxide, U^4O^3	Péligot.
Vanadium	V	68·5	Vanadic anhydride, V^2O^3	Berzelius.
Yttrium	Y			
Zinc	Zn	32·5	Oxide, Zn^2O	A. Erdmann.
Zirconium	Zr	33·5 89·5	Zirconia, Zr^4O^3 „ ZrO^2	Berzelius, Erdmann.

We will now turn our attention to the determination of atomic weights from physical considerations, and observe how far the weights deduced from physical and chemical considerations coincide with one another. In the first place then, we will discuss the combining volumes of gases and vapours; from the observation of which we derive the most important of all means for controlling our conclusions as to the atomic weights of volatile bodies. If we take the specific gravity of hydrogen gas as unity, we find experimentally that the specific gravities of most other elementary gases and vapours are represented by the numbers we have selected to express their atomic weights. Hence, these atomic numbers represent the weights of equal volumes of the respective gases and vapours; and the formula of a compound body shows the number of elementary volumes of which it is composed. Thus while the formula for nitric acid HNO^3 represents a compound of one part of hydrogen, fourteen parts of nitrogen, and three times sixteen parts of oxygen, it also represents a compound of one volume of hydrogen, one of nitrogen, and three of oxygen. The relative specific gravities of the following elements, when in the gaseous state, and exposed to the same pressure and temperature, have been ascertained to be respectively:

$H = 1$ $Cl = 35{\cdot}5$ $O = 16$ $N = 14$
$Hg = 100$ $Br = 80$ $S = 32$ $P = \frac{31}{2}$
$Cd = 56$ $I = 127$ $Se = 79{\cdot}5$ $As = \frac{75}{2}$

Hydrochloric acid gas is composed of one volume of hydrogen, and one volume of chlorine united without any condensation. Consequently the molecule of hydrochloric acid is represented by two volumes of gas □□, whilst the atoms of hydrogen and chlorine respectively are represented by one volume only □. Hence while the specific gravity, or weight of a unit of volume of chlorine coincides with its atomic weight, the specific gravity or weight of a unit of volume of hydrochloric acid coincides with the half of its atomic weight, $\frac{1 + 35{\cdot}5}{2} = 18{\cdot}25$. Now ninety-nine per cent. of all known volatile compounds agree with hydrochloric acid in this particular, namely, that their specific gravities in the gaseous state are the halves of their atomic weights. Thus the atomic weight of water $H^2O^{1\times16}$, being 18, one volume of steam is found to be 9 times as heavy as one volume of hydrogen. The atomic weight of ammonia, $H^3N^{1\times14}$, being 17, one volume of ammoniacal gas is found to be 8·5 times as heavy as one volume of hydrogen. The atomic weight of marsh-gas, $H^4C^{1\times12}$, being 16, one volume of the gas is found to be 8 times as heavy as one volume of hydrogen, and so forth. Inasmuch, therefore, as half the atomic weight coincides with the specific gravity, or weight of one unit of volume, the entire atomic weight must represent *twice* the specific gravity or the weight of two units of volume; a conclusion which may be confirmed by actual experiment. Thus one volume of oxygen, and two volumes of hydrogen at the temperature 100° C. can be converted into two volumes of steam at the temperature 100°. Again two volumes of ammonia, when decomposed by the transmission of a series of electric sparks, yield one volume of nitrogen, and three volumes of hydrogen. No matter what the number of atoms or volumes which enter into the constitution of any volatile compound, they all become condensed into two volumes, as shown by the fact that the specific gravity or vapour-density of the compound is the half of its atomic weight.

Seeing that the molecule of a compound body corresponds with two volumes of gas or vapour, and the atom of an element with but one volume, it is evident that the quantity of an element which is strictly comparable to the molecule of a compound body must be represented by two atoms. Hence the symbols $\boxed{H \mid H}$, $\boxed{H \mid Cl}$, and $\boxed{Cl \mid Cl}$, represent comparable quantities of the three bodies, hydrogen, hydrochloric acid, and chlorine respectively which, thus formulated, present an obvious relation of sequence to one another. By the molecule of an element, therefore, we invariably understand two atoms or two volumes; and there is great reason to believe that our acquaintance with the uncombined elements pertains exclusively to their molecules. So that while Cl, for instance, represents the atom, or smallest proportion of chlorine that can enter into a combination, Cl^2 represents the molecule or smallest proportion of free chlorine that can result from or effect a reaction. There are certain compound molecular groupings also, which like the elementary molecules, occupy two volumes when in the free state, and become halved in combination. Thus ethyl in the free state is represented by C^4H^{10} = □□, in the combined state by C^2H^5 = □, and so in other instances.

It is evident from the preceding observations that, in the great majority of instances, the molecules we have deduced from chemical considerations, are identical with the molecules deduced from the physical law of gaseous volumes enunciated by Ampère, namely, that all gases contain the same number of molecules within the same volume. But if we had represented water by the formula $HO^{1\times8}$, sulphydric acid by the formula $HS^{1\times16}$, and carbonic oxide by the formula $C^{1\times6}O^{1\times8}$, we should have represented their molecules as having only half the volume of the molecule of hydrochloric acid, and should consequently have violated Ampère's physical law. The general conclusions at which we have arrived, however, namely that the chemical atoms of elementary bodies correspond with one gaseous volume, and the chemical molecules of simple or compound bodies, with two gaseous volumes, is quite in accordance with physical requirements. Nevertheless there are some exceptions, real or apparent, to which we must now direct our attention. We may premise by saying that some chemists attach so great an importance to the law of volumes, that they would be guided exclusively by it, and would accord to all bodies whatsoever, such atomic weights as would be in accordance with it. In the present state of knowledge, however, it seems to us preferable to deduce the chemical atom or molecule of a body chiefly from chemical considerations, and to wait for further investigation to clear up the few anomalies which at present exist between the results of chemical and physical inquiry.

Certain apparent exceptions to the law of volumes have of late years been satisfactorily explained away, by having regard to the following habitudes of volatile bodies. In the first place, some vapours, at temperatures but little raised above their condensing points, have anomalous densities which are much too high, or, in other words, the volumes of their atomic proportions are much too small; whereas at higher temperatures their densities and volumes are perfectly normal. Thus at a temperature a little above its condensing point, an atomic proportion of sulphur vapour occupies only $\frac{2}{3}$ the bulk of an atomic proportion of hydrogen gas at the same temperature; but at the temperature 1000° C. the two atomic proportions occupy the same volume. Again the molecule of acetic acid vapour at the temperature 230° C. has the same volume as the molecule of hydrochloric acid gas at that temperature; but at lower temperatures, its volume decreases almost to one-half that of hydrochloric acid gas at the same temperatures. In reference to this property it must be borne in mind that vapours near their condensing points manifest variations from several of the physical laws affecting gases. It would seem, indeed, that a vapour must be heated to a temperature considerably above its condensing point before it acquires the properties of a perfect gas. The recognition of this circumstance enables us to account in several instances for those departures from Ampère's law, in which the density of the gas is too high. In the second place, several compounds at the high temperatures required to bring them into a perfectly elastic state, seem to undergo a change, which has been investigated by Kopp, Marignac, Deville, Hofmann, Kékulé and others, and has been termed *disassociation*. According to these investigators, the molecule of a volatile compound, when strongly heated, sometimes breaks up into two simpler molecules which, on a reduction of temperature, reunite to form the original body, so that at the temperature at which the density is taken, we are really operating, not upon one more complex, but upon two less complex molecules; whence the densities are found to correspond with four volumes of vapour instead of with only two. The anomalous volumes or densities of the following compounds have been explained in this way.

	4 Vols		2 Vols.		2 Vols.
Sal-ammoniac	NH^4Cl	=	NH^3	+	HCl.
Sulphuric acid	H^2SO^4	=	SO^3	+	H^2O.
Pentachloride of phosphorus . .	PCl^5	=	PCl^3	+	Cl^2.
Hydrate of ethylendiamine . . .	$C^2H^{10}N^2O$	=	$C^2H^8N^2$	+	H^2O.

The phenomenon of disassociation then frequently enables us to explain various departures from Ampère's law, in which the densities are too low; or in which, in other words, the volumes are too great. But there still remain certain exceptions, which, in the present state of knowledge, cannot be satisfactorily explained by either of the above described considerations. Thus the atomic volumes of the vapours of phosphorus and arsenic respectively, are only one-half that of hydrogen. In order to make their atomic weights correspond with their atomic volumes, the ordinarily received atomic weights would have to be doubled, whereby they would become 62 and 150 respectively. But this doubling of the atomic weights of phosphorus and arsenic would be in violation of all chemical considerations, and likewise of all physical considerations except that relating to the atomic volumes of the elements themselves. Thus the formula for phosphamine would become $P^{1 \times 62}H^6$, and that for arsenamine $As^{1 \times 150}H^6$, despite the analogy of the two compounds to ammonia NH^3, and despite the fact that the hydrogen of the two compounds is divisible into thirds only and not into sixths. Moreover the vapour-densities of the compounds $P^{1 \times 62}H^6$ and $As^{1 \times 150}H^6$ would correspond to 4 volumes instead of 2, and would consequently be in opposition to Ampère's law. Again, the atomic heats of phosphorus and arsenic corresponding to the atomic weights 62 and 150 respectively, would be twice as high as the highest atomic heat of any other element. Lastly, by doubling the atomic weights of arsenic and phosphorus, the isomorphism of certain compounds of ammonia with the corresponding compounds of phosphamine and arsenamine would become unintelligible. At present then we are forced to admit that the vapour-densities of the elements, phosphorus and arsenic, are anomalous, and that we are incapable of explaining the cause of the anomaly. It may be that the vapours of these elements, like that of sulphur, though anomalous at one temperature, become normal at a higher temperature, though it must be admitted that the recent experiments of Deville do not countenance such an expectation. Or it may be that the anomalies depend upon allotropy. Phosphorus and arsenic are known to exist in different allotropic conditions, and it is not improbable that each allotropic form may have a different atomic weight. Hence the anomaly might be explained by supposing that phosphamine, for instance, contains the element phosphorosum, having the atomic weight 31; whilst phosphorus-vapour is composed of the element phosphoricum, having the atomic weight 62. This supposition of vapour-allotropy might also serve to explain the anomolous vapour-density of acetic acid at a low temperature. Normal acetate of potassium has the formula $C^2H^3KO^2$, but there is also an acid-acetate having the formula $C^4H^7KO^4$. The small vapour-density might possibly represent an acetic acid corresponding to the former salt, and the high vapour-density an acetic acid corresponding to the latter.

Certain other real or apparent exceptions to the law of volumes, are afforded by the chlorides and ethylides of zinc, mercury, and some other metals, as indicated below:

Hydrochloric acid	HCl	= 2 vols.		
Hydride of ethyl	HEt	,, ,,		
Chloride of ethyl	ClEt	,, ,,		
Chloride of mercury	HgCl	= 1 vol.	or Hg^2Cl^2	= 2 vols.
Ethylide of mercury	HgEt	,, ,,	,, Hg^2Et^2	,, ,,
Ethylide of zinc	ZnEt	,, ,,	,, Zn^2Et^2	,, ,,
Methylide of zinc	ZnMe	,, ,,	,, Zn^2Me^2	,, ,,

In consequence of the anomalous vapour-densities of the molecules of these compounds, as above expressed, some chemists have proposed to double the ordinarily received atomic weight of the metals mercury and zinc, so as to represent the molecules of the above volatile compounds by the following 2-volume formulæ; and it must be acknowledged that very strong reasons may be urged in favour of the duplication:

	Chloride of mercury	$Cl^2Hg^{1 \times 200}$
	Ethylide of mercury	$Et^2Hg^{1 \times 200}$
	Ethylide of zinc	$Et^2Zn^{1 \times 65}$
	Methylide of zinc	$Me^2Zn^{1 \times 65}$
corresponding to	Hypochlorous oxide	$Cl^2O^{1 \times 16}$
	Water	$H^2O^{1 \times 16}$

It is admitted both by those who advocate and those who deprecate the proposal, that the duplication of the atomic weights of the metals mercury and zinc, would necessitate the duplication of the atomic weights of several other metals, including magnesium, cadmium, lead, copper, iron, chromium, and aluminium. Now the principal objections to the adoption of this proposal are the following. Firstly, because, although the duplication of the atomic weights of the metals would bring the volumes of their chlorides and ethylides into accordance with Ampère's law, it would bring the volumes of the elements themselves into discordance therewith. Thus, the atomic volumes of mercury and cadmium corresponding to the atomic weights 200 and 112 respectively, would each be twice as great as the atomic volume of any other element. Secondly, because the chlorides, oxides, &c., of these metals, which are ordinarily represented as proto-compounds, would have to be represented as deuto-compounds, thus $HgCl^2$, $ZnCl^2$, $CdCl^2$, &c., a result not warranted by chemical considerations, seeing that in their chemical properties, these compounds are quite undistinguishable from undisputed proto-compounds. Moreover, the adoption of these doubled atomic weights would lead to most complex expressions for very many compounds. Of course, if it could be proved that the true atomic weights of these metals were really the doubles of those ordinarily employed, the circumstance of the duplication leading to inconvenient formulæ would have to be disregarded; but in the absence of such proof, the complexity to which the conclusion would lead is *pro tanto* evidence against the probability of its being true. Thus, phosphate of lead would become $Pb''^3P^2O^8$ instead of Pb^3PO^4; potassio-sulphate of copper would beecome $K^2Cu''(SO^4)^2.6H^2O$ instead of $KCuSO^4.3H^2O$; sulphovinate of zinc would become $Et^2Zn''(SO^4)^2.2H^2O$ instead of $EtZnSO^4.H^2O$; mercaptide of mercury would become $Et^2Hg''S^2$ instead of EtHgS, &c. &c.

Other exceptions to Ampère's law are furnished by the sesquichlorides of aluminium, iron, and chromium, the vapour densities of each of which, as determined by Deville, correspond to one volume of vapour only, instead of to two volumes. Hence it has been proposed to double the weights of the molecules of these compounds, and to represent them by the formulæ Al^4Cl^6, Fe^4Cl^6, and Cr^4Cl^6 respectively. But it is observable that if the molecule of sesquichloride of aluminium really contains 6 atoms of chlorine, it must also contain 55 parts of aluminium, and as a consequence, 55 parts of aluminium will constitute the smallest combining proportion of the metal, or the smallest, quantity which ever exists in a combination; in which case the smallest combining proportion of aluminium will have twice the specific heat of the smallest combining proportion of any other element, a result that must throw considerable doubt upon the propriety of the change on which it would be consequent. Again the vapour-density and chemical relations of chlorochromic aldehyde alike show that its molecule must be expressed by the formula $Cr^2O^2Cl^2$; while the correlations of sesquichloride of chromium and chlorochromic aldehyde require the molecules of the two compounds to be represented by formulæ expressing the same amount of chromium, which would not be the case if the sesquichloride were represented by the formula Cr^4Cl^6. There is, moreover, another compound, namely, arsenious anhydride, As^2O^3, the vapour-density of which corresponds to only one volume of vapour instead of two volumes, although no reason for the anomaly has yet been brought forward. There are also three well-known compounds, the vapour-densities of each of which correspond to four volumes, instead of to only two, namely, nitric oxide, N^2O^2, pernitric oxide, N^2O^4, and perchloric oxide, Cl^2O^4. In its chemical relations, the molecule of nitric oxide, N^2O^2, corresponds to the molecule of chlorine, Cl^2, and the atom of nitric oxide, NO, corresponds to the atom of chlorine, Cl: but whilst the atom of chlorine corresponds to one volume, and the molecule of chlorine to two volumes, the atom of nitric oxide corresponds to two volumes, and its molecule to four volumes of gas, and similarly with pernitric oxide and perchloric oxide. At present no satisfactory explanation has been given of these anomalies, though it is not improbable that they may be explicable on the principle of disassociation. Thus, it is possible that the atom of sulphurous anhydride, $(SO^2)''$, which, like that of oxygen, O'', is capable of displacing two atoms of hydrogen, would also, like the atom of oxygen, be represented by one gaseous volume, were it not for the circumstance that the molecule of oxygen, O^2, cannot split into two other molecules, whereas the molecule of sulphurous anhydride, S^2O^4, corresponding thereto in equivalency, can split into two separate molecules, each of which is capable of occupying two volumes; and this relation of oxygen to the diequivalent atoms of sulphurous anhydride, sulphuric anhydride, carbonic oxide, carbonic anhydride, &c., may be a parallel of the relation which subsists between chlorine and the protequivalent atoms of nitric oxide, pernitric oxide, and perchloric oxide respectively.

Out of many hundred volatile bodies whose vapour-densities have been ascertained, the following table comprises all the well-known exceptions to Ampère's law, though doubtless the strict chemical analogues of some of these bodies would also prove exceptional:

Symbol.	Vapour.	Atomic weight.	Theoretical volume.	Actual volume.
P	Phosphorus	P = 31	1	$\frac{1}{2}$
As	Arsenic	As = 75	1	$\frac{1}{2}$
HgCl	Corrosive sublimate	Hg = 100	2	1
HgEt	Mercuric ethyl		2	1
HgMe	Mercuric methyl		2	1
ZnEt	Zinc-ethyl	Zn = 32·5	2	1
ZnMe	Zinc-methyl		2	1
As^2O^3	Arsenious anhydride	As = 75	2	1
Al^2Cl^3	Aluminic chloride	Al = 13·75	2	1
Fe^2Cl^3	Ferric chloride	Fe = 28	2	1
$Cr Cl^3$	Chromic chloride	Cr = 26·2	2	1
N^2O^2	Nitric oxide	N = 14	2	4
N^2O^4	Pernitric oxide		2	4
Cl^2O^4	Perchloric oxide	Cl = 35·5	2	4
H^2SO^4	Sulphuric acid	S = 16	2	4
NH^4Cl	Sal-ammoniac	N = 14	2	4
NH^4CN	Cyanide of ammonium	C = 12	2	4
$NH^4.HS$	Sulphydrate of ammonium	S = 32	2	4
PCl^5	Pentachloride of phosphorus	P = 31	2	4
$C^2H^{10}N^2O$	Hydrate of ethylene-diammonium	C = 12	2	4
$C^6H^{18}N^2O$	Hydrate of diethyl-ethylene-diammonium		2	4

The anomalous volumes of the last seven compounds are clearly explicable on the principle of disassociation. With regard to the duplication of the atomic weights of those metals whose chlorides and ethylides have anomalous densities, it must be remembered that the proposal is at present young, and that further investigation may suffice to remove some of the objections which at present surround it; precisely as further investigation removed the objections which in the first instance seemed to oppose with overwhelming force, Gerhardt's proposal to double the then received atomic weights of carbon, oxygen, and sulphur. This same remark applies to the proposal of Cannizzaro, which we shall next have to consider.

It was contended by Dulong and Petit, who were the earliest investigators on the subject, that all elementary atoms have the same capacity for heat, or, in other words, that the specific heats of all elementary atoms are the same. If this law be admitted, it is obvious that the determination of the specific heat of an element must furnish a ready means of fixing its atomic weight. The atomic heats of simple and compound bodies have been of late years ascertained with great care, though from the nature of the subject it can scarcely be said with great accuracy, by Regnault, whose results, corresponding to the atoms which we have adopted, are as follows:—

12	Carbon	2·89	80	Bromine	6·74
32·5	Zinc	3·10	127	Iodine	6·87
56	Cadmium	3·16	32	Sulphur	6·48
13·75	Aluminium	2·93	79	Selenium	6·62
28	Iron	3·18	128	Tellurium	6·06
29·5	Nickel	3·20	31	Phosphorus	5·85
29·5	Cobalt	3·15	75	Arsenic	6·10
31·7	Copper	3·01	120·3	Antimony	6·09
100	Mercury	3·19	210	Bismuth	6·57
103·6	Lead	3·25	118	Tin	6·57
53	Palladium	3·15	23	Sodium	6·75
99	Platinum	3·19	39	Potassium	6·71
27·5	Manganese	3·1	108	Silver	6·16
26·2	Chromium		196	Gold	6·38
12	Magnesium				
20	Calcium				
43·8	Strontium				
68·6	Barium				

The numbers representing Regnault's atomic heats were obtained by multiplying the observed specific heats of the bodies, referred to that of water as unity, by their atomic weights on the oxygen scale. But it would be found more convenient in practice to assume the atomic heat of lead, which corresponds nearly with the mean atomic heat, as unity; whereby the atomic heats of the first class of metals would approximate more or less closely to the number 1, and those of the second class to the number 2. On this scale, the specific heats of the first class elements would correspond to the reciprocals of their atomic weights on either scale, and those of the second class to twice their reciprocals.

At the time of Regnault's researches, the atomic weights of all the elements in the second column, with the exception of sodium, potassium, and silver, were frequently expressed by the halves of the numbers we have adopted. Regnault proposed to halve the atomic weights of these three metals also, whereby the atomic heats of all the elements would be in accordance with Dulong and Petit's law, and would be expressed by numbers approximating more or less closely to 3·0 on the water-unity scale, or to 1·0 on the lead-unity scale. It is observable that in no case does the experimental atomic heat thus obtained differ from the mean atomic heat in the proportion of 1·1, or 0·9, to 1·0; whereas the extreme atomic weights differ from one another in the ratio of 1 to 9. Concerning this close correspondence in the atomic heats of the elements, Graham writes: "The law (of Dulong and Petit) would probably represent the results of observation in a perfectly rigorous manner, if the specific heat of each body could be taken at a determinate point of its thermometrical scale, and if the specific heat could be further disencumbered of all the foreign influences which modify the observation," such as the original state of hardness or softness of the body, its crystalline or amorphous condition, the heat absorbed to produce softening, and the heat absorbed to produce dilatation, &c. Recent chemical research, however, has rendered it impossible for chemists to halve the atomic weights of the elements in the second column, so as to make their atomic heats coincide with that of lead; and hence Cannizzaro has been led to advocate a transposition of Regnault's proposal, so as to maintain the integrity of Dulong and Petit's law, by doubling the atomic weights of the metals in the first column, whereby the atomic heats of all the elements, with the possible exception of carbon, would be expressed by numbers approaching more or less closely to 6.

Cannizzaro has also pointed out that if his atomic weights were adopted, the atomic heats of many compound bodies, when divided by the number of their constituent atoms, would give a number approximating more or less closely to 6, or in other words, the atomic heats of these bodies approximate to the sum of the atomic heats of their constituent elements. It is observable, however, that the latter mode of expressing the fact applies equally well, whether or not we double the atomic weights in the first column. Thus the atomic heat of chloride of silver approximates to 6 + 6 or 12, and that of chloride of lead to 6 + 3, or 9.

It is evident that the atomic weights proposed by Cannizzaro, from considerations of specific heat, frequently correspond with those which he and others have been led to from considerations of atomic volume; and their adoption is consequently liable to the objections which we have already taken.

Cannizzaro's proposal, moreover, would involve the dissassociation of silver from lead, and that of the metals of the alkalis from those of the alkaline earths. The chlorides of silver and potassium, for instance, would be represented as protochlorides by the formulæ $AgCl$ and KCl respectively, whilst those of lead and barium would be represented as dichlorides by the formulæ $PbCl^2$ and $BaCl^2$ respectively. Now the highly basic characters of the alkaline earth-metals, the strongly alkaline reactions of their dissolved hydrates, the perfect neutrality and great permanency of their salts, seem to demonstrate their analogy to undisputed protequivalent metals, such as potassium, rather than to undisputed di-equivalent metals, such as tin. Again, the large number of similar compounds to which silver and lead give origin, the close resemblance in chemical properties of their corresponding compounds, their very general paramorphism, and not unfrequent isomorphism, seems to forbid their representation by discordant formulæ. The two metals are soft, malleable, fusible, volatile, and isomorphous. The two chlorides are anhydrous and insoluble, or sparingly soluble; the two sulphates are anhydrous, insoluble and similiform; the two hydrates are sparingly soluble, forming alkaline solutions; the two sodium-double-chlorides, potassium-double-iodides, protosulphides, cuprosulphides, monobasic and tribasic sulphantimonites, are similar in their chemical, and isomorphous in their physical relations.

It seems to us that the objections to Cannizzaro's general proposition, are, in the present state of knowledge, too great to admit of its adoption; but still it is a question whether some of the metals comprised in the first column might not advantageously, receive the doubles of their ordinarily admitted atomic weights. With regard to the metals palladium and platinum, for instance, it is not by any means improbable that their real atomic weights may prove to be 106 and 198 respectively. With regard to aluminium, again, it is certain that, so far as our actual knowledge goes, the smallest indivisible proportion of aluminium that can exist in a combination is twice the proportion expressed by its ordinarily received atomic weight, or, in other words, it amounts to 27·5, instead of to only 13·75 parts. All chemists invariably represent the compounds of aluminium to contain 27·5 parts of aluminium, which is indeed its smallest combining proportion or chemical atom. Consequently, by employing the number 13·75 to express the atomic weight of aluminium, all aluminous compounds have to be represented as containing two inseparable atoms, or some multiple of two inseparable atoms of the metal, a result which is evidently unphilosophical. The chemical habitudes of the metal aluminium resemble the chemical habitudes of the metal bismuth, 27·5 parts of the former corresponding to 210 parts of the latter: and there is no greater chemical reason for halving the 27·5 parts of aluminium in order to represent its trichloride as a sesquichloride, than there is for halving the 210 parts of bismuth in order to represent its trichloride as a sesquichloride. Somewhat similar observations apply to the metals, iron, manganese, and chrome, when entering into the constitution of ferric, manganic, and chromic salts, respectively. Throughout all the decompositions and recompositions of ferric compounds, for instance, so long as they continue to be ferric compounds, we find 56 parts of iron constituting one indivisible combining proportion or chemical atom. We have two allotropic forms of the metal iron, one of which we call *ferrosum*, having the atomic weight 28, the atomic heat 3, and combining with 1 atom of chlorine, to form a protochloride; — the other, which we call *ferricum*, having the atomic weight 56, the atomic heat 6, and combining with 3 proportions of chlorine to form a trichloride; and similarly with *chromosum* and *chromicum*, *manganosum* and *manganicum*. The ferrous and ferric atoms have distinct chemical properties and form distinct series of compounds, which differ more from one another than do the salts of ferrosum from those of nickel and copper, or than do the salts of ferricum from those of aluminium and bismuth. So great, indeed, is the difference, that, had we been unacquainted with the methods of converting ferrous and ferric compounds into one another, we should never have suspected them to contain the same metal, or even similar metals. Now, that two different allotropic forms of the same element may have different atomic weights and different equivalent functions, seems to be no longer questionable. Brodie's reseaches on *graphon* have shown conclusively that compounds may be prepared which contain the graphitic modification of carbon, and are altogether dissimilar from compounds containing the ordinary form of carbon. In fact, ordinary carbon-compounds present a greater analogy to corresponding compounds of sulphur than they do to any of the known compounds of graphon, precisely as the salts of ferrosum resemble salts of nickel more closely than they do the salts of ferricum. The only circumstance wanting to complete the parallel is that not only carbon and graphon compounds, but isolated carbon and graphon are known to chemists; whereas, though ferrous and ferric compounds are well known, chemists have not yet recognised any form of iron distinct from ferrosum, unless indeed we make the by no means improbable assumption that iron in the passive state constitutes ferricum. The specific heats of carbon, graphon, and diamond correspond clearly with different atomic weights. Thus, if we accord to carbon the atomic weight 12, to graphon the atomic weight 18, and to diamond the atomic weight 24, the atomic heats of the three bodies, calculating from Regnault's results, will be 2·8980, 3·6324, and 3·5232 respectively, giving a mean of 3·3512. But it seems probable from chemical considerations that the atomic weight of graphon is not 18, but 36 (33 Brodie), in which case its atomic heat will be 7·2048, or exactly as much above the mean as that of phosphorus is below it.

Precisely as the double atoms of iron and aluminium in ferric and aluminic salts constitute indivisible proportions, so do the double atoms of copper and mercury in cuprous and mercurous compounds constitute indivisible proportions throughout all the decompositions and recompositions of their respective salts. So long as the metals remain in the state of *cuprosum* and *mercurosum*, so long do 63·5 parts of the former and 200 parts of the latter constitute their respective atomic weights or smallest indivisible combining proportions. Each metal would have for its atomic heat the number 6, and would combine with one atom of chlorine to form a protochloride, so that while the atoms of ferrosum and ferricum combine with the halogens, &c., in different proportions, or, in other words, have different degrees of equivalency, the atoms of mercurosum, and mercuricum though having different atomic weights and different atomic heats, combine each with the same proportion of halogen, or, in other words, have the same degree of equivalency; and similarly with cuprosum and cupricum (see EQUIVALENTS). A convenient mode of representing the atoms of ferricum, mercurosum, &c., consists in doubling one of the letters of the respective symbols used to express the atoms of ferrosum and mercuricum, &c., so as to indicate that the atoms of the former elements are twice as heavy as those of the latter. In a similar manner the atom of graphon might be represented by the symbol Ccc, to imply that it had three times the atomic weight of carbon. In this way we might arrange the following series of atoms:

Atomic heats = 3.			Atomic heats = 6.		
Carbon .	. C''''	12	Graphon .	. Gr or Ccc	36
			Aluminium	. All'''	27·5
Ferrosum	. Fe'	28	Ferricum	. Ffe'''	56
Manganosum	. Mn'	27·5	Manganicum	. Mm'''	55
Chromosum	. Cr'	26·25	Chromicum	. Ccr'''	52·5
Mercuricum	. Hg'	100	Mercurosum	. Hhg'	200
Cupricum	. Cu'	31·75	Cuprosum	. Ccu'	63·5

By thus recognising the quantities represented in the second column as distinct atoms, we obtain nearly all the advantages, with scarcely any of the disadvantages, which would accrue from Cannizzaro's proposal, and are enabled to account satisfactorily for the frequent isomorphism or parallelism of the double proportions of these elements, with the single proportions of other elements, as illustrated below:

$KClO^4$	with	$KMmO^4$	instead of	KMn^2O^4
K^2SO^4	,,	K^2MmO^4	,,	$K^2Mn^2O^4$
K^2SO^4	,,	K^2CcrO^4	,,	$K^2Cr^2O^4$
SO^3	,,	$CcrO^3$	,,	Cr^2O^3
SO^2Cl^2	,,	$CcrO^2Cl^2$	,,	$Cr^2O^2Cl^2$
Ag^2S	,,	Ccu^2S	,,	Cu^4S
Ag^3SbS^3	,,	$Pb^2CcuSbS^3$	,,	$Pb^2Cu^2SbS^3$
Pb^2S	,,	$PbCcuS$	,,	$PbCu^2S$

In addition to vapour-density and specific heat, isomorphism also furnishes a valuable aid in the determination of atomic weights. As a rule, the isomorphism of a comparatively unknown substance, with a substance of which the formula and atomic weight are well determined, warrants us in according to the less known body a formula and atomic weight corresponding to those of the better known body. Thus, the isomorphism of the stannic and titanic anhydrides, of the chromate and molybdate of lead, of the sulphate and selenate of sodium, assists us materially in our determination of the atomic weights of titanium, molybdenum, and selenium respectively, and of the formulæ of their respective compounds. But atomic weights deduced chiefly from isomorphous considerations, require to be received with very great caution, for the following reasons. We sometimes find obvious chemical analogies to exist in cases, where from dimorphism, or some other cause, the isomorphism is very imperfectly developed; and on the contrary, we sometimes have a marked isomorphism existing between bodies whose chemical correlations are very unsatisfactory. Thus, the isomorphism of potassium and sodium salts is not by any means striking. Nitrate of potassium, for instance, usually crystallises in right rhombic prisms, and nitrate of sodium in rhomboïds. It seems, however, that each salt can crystallise in both systems, and that while the ordinary form of nitrate of sodium corresponds with the rare form of nitrate of potassium, the ordinary form of nitrate of potassium corresponds with the rare form of nitrate of sodium. Again, the chemical analogies of similar lead and mercury compounds are extremely well marked, but isomorphism is manifested in a very few instances only. Indeed the isomorphous relations of lead and calcium are more decided than are the isomorphous relations of lead and mercury. Again, tellurium is heteromorphous with its chemical analogues, selenium and sulphur, and isomorphous with its chemical heterologues, arsenic and antimony. One might here refer for a moment to the well-known isomorphism of certain sulphides and arsenides. Thus, sulphide of nickel, Ni^2S, is isomorphous with the arsenide Ni^2As, and the antimonide Ni^2Sb. Marcasite, Fe^2S^2, is isomorphous with mispickel, Fe^2SAs; and common pyrites, Fe^2S^2, with cobalt-blende, Co^2SAs, and smaltine, Co^2As^2. From this isomorphism a general analogy in composition between arsenic and sulphur compounds, might possibly be inferred, were it not that such an inference would speedily be found incompatible with the results of chemical analysis. But if arsenic had been a rare and imperfectly known element, the isomorphism of marcasite and mispickel might not improbably have led to the association of its compounds with those of sulphur instead of with those of phosphorus.

Moreover, 2 atoms of one element are not unfrequently isomorphous with 1 atom of another. We have already given several examples of this phenomenon when referring to the isomorphism of sulphates with chromates, M^2SO^4 and $M^2Cr^2O^4$, of perchlorates with permanganates, $MClO^4$ and MMn^2O^4, and of salts of silver with salts of cuprosum, Ag^2S and Cu^4S; and we have shown how the anomaly could be readily explained away. Nevertheless it may be useful to point out definitely the kind of difficulty to which this sort of isomorphism might possibly give rise. At the present time, the ordinary salts of zinc, iron, lead, and silver, are alike thought to be protosalts. Now we find that copper forms two chlorides, two oxides, two sulphides, &c., in one set of which, the proportion of copper is twice as great as in the other. Which of these sets then comprises the protosalts? Judging from the isomorphous relations of cupric compounds with salts of iron and zinc, we should say that the cupric compounds were protocompounds, and that the atomic weight of copper was 31·7. Judging, on the other hand, from the isomorphous relations of cuprous compounds with salts of lead and silver, we should say that the cuprous compounds were the protocompounds, and that the atomic weight of copper was 63·4.

Lastly, we find that isomorphism sometimes subsists between compounds of a somewhat similar, but not of a strictly analogous chemical constitution. Thus, hæmatite, $(Fe^2)^{''''''}O^3$, is isomorphous with ilmenite, $Fe''Ti''''O^3$; and zircon, $Z''''SiO^4$, with wernerite, $(Al^2)^{''''''}Ca''SiO^4$. Again, nitrate of sodium, $NaNO^3$, calc-spar, Ca^2CO^3, and red-silver, Ag^3SbS^3, are isomorphous with one another; as are also nitrate of potassium, KNO^3, arragonite, Ca^2CO^3, and bournonite, $Pb^2CcuSbS^3$. Perchlorate of potassium, $KClO^4$, is isomorphous with sulphate of barium, Ba^2SO^4; and sulphate of iron, $Fe^2SO^4.7H^2O$, is paramorphous, if not isomorphous, with arsenate of sodium, $Na^2HAsO^4.7H^2O$. These illustrations are sufficient to show that the inferences deducible from isomorphism, unless supported by chemical or by some other physical evidence, must not be inconsiderately adopted as certain means for the determination of atomic weights and chemical formulæ. W. O.

ATRAMENTUM STONE. *Atramentenstein.* — A product of the partial oxidation of iron pyrites, consisting of a mixture of ferrous and ferric sulphates with free ferric oxide and a variable quantity of cupric sulphate and undecomposed pyrites. It is used in the manufacture of ink (*atramentum*).

ATRIPLEX. Many plants belonging to this genus are used for the extraction of soda. (Rochleder.)

ATRIPLEX VERRUCIFERA, a chenopodiaceous plant growing in the Kergis steppes, leaves 12·5 per cent. of ash containing 43·3 per cent. of soluble salts, viz. 7·2 per cent. sulphate of potassium, 4·8 sulphate of sodium, and 8 carbonate of sodium, 24·6 chloride of sodium, and 1·9 caustic soda. (Göbel.)

ATROPIC ACID. An organic acid stated by Richter (J. pr. Chem. xi. 33) to exist in belladonna, and to be obtained by treating the aqueous extract with alcoholic ammonia, evaporating the solution with potash, and decomposing the resulting potassium-salt with sulphuric acid. It is said to resemble benzoic acid in form and volatility; but its properties, and indeed its separate existence, have not been well made out.

ATROPINE, or **DATURINE.** $C^{17}H^{23}NO^3$, or $C^{34}H^{23}NO^6$.—This alkali, discovered in 1833, almost at the same time by Geiger and Hess (Ann. Ch. Pharm. vii. 269), and by Mein (*ibid.* vi. 67), exists in all parts of the deadly nightshade (*Atropa Belladonna*); it is also contained in the seeds of the thorn-apple (*Datura stramonium*). The alkaloïd has been analysed by Liebig (Ann. Ch. Pharm. vi. 66), and by Planta (*ibid.* lxxxiv. 245); the latter has also analysed many of its salts.

To extract it, the roots of the belladonna are treated with strong alcohol, and the extract left some hours in contact with caustic lime, then filtered, and supersaturated with sulphuric acid, the alcohol having been previously driven off by a gentle heat. A concentrated solution of carbonate of potassium is then added, and the liquid filtered as soon as it begins to show turbidity. The crystals of atropine, which separate after a while, are purified by repeated crystallisation from alcohol. Care must be taken not to apply too strong a heat, as the atropine is easily decomposed.—Rabourdin extracts the atropine by chloroform. Fresh belladonna taken at the period of flowering, is heated to 80° or 90° C. to coagulate the albumin. The clarified juice, when cold, is mixed with caustic potash and chloroform, in the proportion of 4 grms. potash and 30 grms. chloroform to a litre; and the whole is agitated for a minute and then left to settle. After half an hour, the chloroform charged with atropine separates in the form of a greenish oil, which after being washed, is distilled till all the chloroform passes over. The residue in the retort is extracted with a little water acidulated with sulphuric acid, which dissolves the atropine, leaving a green resinous matter behind. The acid solution is then treated with carbonate of potassium, and the precipitated atropine crystallised from alcohol.

Atropine crystallises in colourless silky needles united in tufts; by slow evaporation of its alcoholic solution, it is often obtained in the form of a translucent vitreous mass. It is but slightly soluble in water, but dissolves readily in alcohol, less in ether. It is strongly alkaline, and has a very bitter taste. It melts at 90°, and volatilises at 140° C., undergoing partial decomposition. It is highly poisonous, causing vertigo, headache, and even death; it also produces persistent dilatation of the pupil.

Chlorine acts but slowly on atropine, producing a yellowish liquid, which contains a considerable quantity of hydrochlorate of atropine. Tincture of *iodine* colours it brown. Hot *nitric acid* attacks it, with evolution of red fumes. *Chloric acid* dissolves it, but deposits it again unaltered, by spontaneous evaporation.

Atropine dissolves readily in *acids*, but the salts are difficult to crystallise. They are bitter, acrid, and poisonous; inodorous in the pure state. They are permanent in the air at ordinary temperatures, but become coloured even at the temperature of boiling water; most of them are soluble in water and alcohol, and insoluble in pure ether. *Potash*, *ammonia*, and their *carbonates*, precipitate atropine only from highly concentrated solutions of its salts; the precipitate dissolves readily in excess of the alkali. *Tannin* precipitates it only after addition of hydrochloric acid.

Acetate of atropine forms nacreous prisms grouped in stars: it is permanent and very soluble; after being several times dissolved, it loses a little of its acid. (Geiger.)

The *chloro-aurate*, $C^{17}H^{23}NO^3.HCl.AuCl^3$, is precipitated as a yellow powder, gradually becoming crystalline, when a strong solution of hydrochlorate of atropine is poured into a dilute solution of trichloride of gold; the liquid should be well shaken during the mixing, to prevent the agglutination of the precipitate. The *chloromercurate* is precipitated only from very concentrated solutions. The chloroplatinate is a pulverulent precipitate, which rapidly agglutinates: it is very soluble in hydrochloric acid. The *hydrochlorate* crystallises in tufts (Geiger); according to Planta, it is uncrystallisable. The *nitrate* forms a syrupy deliquescent mass. The *picrate* is a yellow pulverulent precipitate. The *sulphate* crystallises, according to Geiger, in delicate, colourless, nacreous needles, grouped in stars or tufts: it is very soluble. Planta did not succeed in crystallising it. The *tartrate* is a syrupy mass, which becomes moist in contact with the air.

The *valerate*, prepared by dissolving atropine in an equivalent quantity of valerianic acid diluted with 2 pts. of ether, and cooled to 0° C., then adding a further quantity of rectified ether (of 60° Cartier), equal to five times the weight of the atropine used, and leaving the solution to itself in a glass cylinder at 10° C., forms colourless transparent rhombic crystals, which refract light strongly. According to Callmann (J. pr. Chim. lxxvi. 69), they contain $C^{17}H^{23}NO^{3} + \frac{1}{2}H^2O.C^5H^{10}O^2$. They melt at 42° C., give off the greater part of their water at 100°, and at 120° begin to evolve vapours of valerianic acid. The salt prepared as above is perfectly soluble in water.

AUGITE. *Pyroxene.* (Gm. iii. 402; Handw. d. Chem. ii. 556.) — The name of a class of minerals distinguished: —1. By a certain form, belonging to the monoclinic or oblique prismatic system, being a prism of 87° with the base inclined at an angle of 74°; —and 2. By the general formula $SiM^2O^3 = M^2O.SiO^2$, or $3\mathit{MO}.2\mathfrak{S}\mathrm{i}\mathit{O}^3$,* where M consists for the most part of Mg and Ca, giving the formula $\begin{matrix}\mathrm{Ca}\\ \mathrm{Mg}\end{matrix}\mathrm{O.SiO^2}$, less frequently of Fe or Mn. Occasionally also 1Mg is replaced by 3H (polymeric isomorphism); and in the varieties called aluminous augites, 1 at. SiO^2 by 1 at. Al^4O^3 (or $2\mathfrak{S}\mathrm{i}\mathit{O}^3$ by $3\mathit{Al}^2\mathit{O}^3$).

Specific gravity 3·23 to 3·5. Hardness = 3 to 6. Lustre vitreous, inclining to resinous: in some varieties, pearly. Colour green, of various shades, verging on one side to white or greyish-white, and on the other to brown or black. Streak white to grey. Transparent to opaque. Fracture conchoïdal to uneven. Brittle.

The nature of the metals, whether calcium, magnesium, or iron, which enter into the composition of the mineral, produces considerable variations, not only of colour, lustre, transparency, and density, but also of crystallographical development, sometimes giving rise to differences in the magnitude of the angles in the primitive forms. These differences of character constitute the distinctions between the several species of augite, the principal of which are the following.

Common Augite, (M = Ca, Mg, Fe), the silica being sometimes also replaced by alumina. Black, greenish, or brownish-black crystalline masses, with cleavage parallel to the faces of a monoclinic prism of 87° and 93°. Specific gravity 3·33 to 3·36. The best developed crystals are found in basalt and other volcanic rocks. It occurs in the lavas of Etna and Vesuvius, in the volcanic Eifel, in the Bohemian Mittelgebirge, in the Fassathal, Iceland, and in numerous other localities. In some of these augites, the Mg is almost wholly replaced by iron and calcium. *Hudsonite* from North America, contains chiefly iron and scarcely any magnesium, a considerable portion of the silica in this mineral is also replaced by alumina (SiO^2 by Al^4O^3).

Pyroxene.—This name is sometimes used as synonymous with augite, to denote the entire family; but it is especially applied by some mineralogists to certain varieties of augite, having a green or dark green colour, viz. *Fassaite*, *Coccolite* (consisting of an aggregation of roundish crystalline grains), *Funkite*, *Baikalite*, &c. They are distinguished from common augite chiefly by containing a smaller amount of iron.

Diopside (white augite, Mussite).—Essentially a silicate of calcium and magnesium, $(CaMg)SiO^3$, some varieties, however, containing small quantities of iron, manganese, and even hydrogen (H^2 instead of Mg). Colour, white, greyish, or greenish-white, and light green. Occurs in very fine crystals, especially on the Mussa Alp in Piedmont.

Malacolite.—An augite rich in magnesium, also containing hydrogen, calcium and iron being only subordinate. The water which it contains renders it softer than the anhydrous augites. *Salite* and *Pyrgom* are related in chemical composition to malacolite on the one hand, and to pyroxene and diopside on the other.

Diallage and *Broncite* are, like malacolite, hydrated augites rich in magnesia, but having also the silica more or less replaced by alumina. In *hypersthene*, the iron predominates very strongly as protoxide. All these minerals, to which also the *augitic talcs* are related (see TALC), possess a laminated structure, arising from the peculiar facility with which they cleave in a particular plane.

Asbestoïdal augites, are hydrated calcio-magnesian augites of fibrous structure: some of them occur as paramorphoses. This is the case with *Traversellite*, a hydrated ferroso-magnesian augite from Traversella in Piedmont. To this sub-species appears also to belong a nearly pure ferrous augite, analysed by Grann. (Compt. rend. xxiv. 794.)

The following minerals also belong to the augite family: *Ægyrin*, probably a calcio-sodium augite; *Acmite* or *Achmite* (p. 36), in which silica is replaced by alumina; *Spodumene* in which $3M^2O$ are replaced by Al^4O^3; *Jeffersonite*, an augite containing zinc; *Rhodonite*, a nearly pure manganese augite.

---

* $\mathfrak{S}\mathrm{i}\mathit{O}^3 = 21 + 3 \times 8$. $SiO^2 = 28 + 2 \times 16$.

The following are analyses of certain varieties of augite:

	Wackenroder.	Bonsdorff.	H. Rose.			Berzelius.
	a	*b*	*c*	*d*	*e*	*f*
Lime	24·74	24·76	23·57	24·34	23·47	20·00

Alumina	0·20	0·28	0·21			
	100·00	99·73	99·99	100·66	99·67	96·35

a is diopside from Fassa; *b* from Fammare; *c*, salite from Sala; *d*, malacolite from Orrijerfor; *e* from Dalecarlia; *f* from Dagerö.

Crystals having the form, structure, and composition of augite may be obtained by exposing a mixture of 1 at. lime, 1 at. magnesia, and 2 at. silica (SiO^3) to the heat of a porcelain furnace, and leaving it to cool very slowly (Berthier, Ann. Ch. Phys. [2] xxiv. 376); similar crystals are likewise found among the slags of blast-furnaces (Nöggerath, J. pr. Chem. xx. 501.)

The augites are not completely decomposed by any acid except hydrofluoric acid Their behaviour before the blowpipe varies according to their constitution. Diopside yields a colourless nearly transparent glass; ferruginous augite, a dark-coloured glass. Augite dissolves readily in borax, but with difficulty in microscosmic salt, forming a skeleton of silica.

AUGUSTITE. Syn. with APATITE.

AURADE. The name given by Plisson to a body which separates from oil of neroli, on addition of alcohol, in white nacreous laminæ; it is probably the camphor or stearoptene of the oil, and appears to agree in composition with the camphor of rose-oil. It melts at 50° C., and on cooling solidifies to a waxy non-crystalline mass; in a close vessel it sublimes without decomposition. It is insoluble in water, dissolves in 10 pts. of boiling alcohol of 44° Bm.; soluble also in ether and in oil of turpentine. It is not attacked by acids. Fresh oil of neroli, which appears to be richer in this substance than the old oil, yields about 1 per cent. of it. (Handw. d. Chem. ii. 558.)

AURANTIN. Syn. of HESPERIDIN.

AURICHALCITE. (Aurum, *gold*, and χαλκος, *ore*.) A mineral occurring in transparent, verdigris-green, needle-shaped crystals at Loktewsk on the Altai Mountains. It appears to contain $2CO^3Cu^2.3ZnHO$. When reduced, it yields a gold-coloured alloy of copper and zinc.

AUROTELLURITE. See TELLURIUM, GRAPHIC.

AUTOMALITE. See SPINEL.

AUTUNITE. Lime-uranite. (See URANITE.)

AURUM MOSAICUM or **MUSIVUM.** The old name of disulphide of tin prepared in the dry way. (See TIN.)

AVENIN. A nitrogenous substance contained in oats, similar to, and most probably identical with, legumin.

AVENTURIN or **AVANTURIN.** A variety of quartz rock, which, when polished, exhibits a strong reflected light from innumerable points of its surface, proceeding partly from minute crystals of mica embedded in the mineral, partly from minute cracks and fissures. The most beautiful comes from Spain, but very fine specimens have also been found at Glen Fernat in Scotland. The most usual colour is brown or reddish-brown, enclosing golden-coloured spangles. The mineral is used as a gem, but is often replaced by the artificial aventurin-glass, which even excels it in beauty.

AVENTURIN GLASS, also called *gold-flux*. — A brownish-coloured glass interspersed with small spangles, which give it a peculiar shining appearance. This glass was formerly used in the arts and for ornaments, and its preparation was long kept secret by the manufacturers at Murano near Venice: it is now, however, prepared in other localities. The following are analyses of this glass: *a*, by Schnedermann and Wöhler; *b*, by Péligot; *c*, by Kersten.

	SiO^2	P^2O^5	Al^4O^3	Fe^4O^3	Fe^2O	Ca^2O	Mg^2O	K^2O	Na^2O	Cu	Sn	Pb
a	65·2	1·5	—	6·5	—	8·0	4·5	2·1	3·2	3·0	trace	—
b	67·7	—	trace	—	3·5	8·9	—	5·5	7·1	3·9	2·3	1·1
c	67·3	—	—	2·4	—	9·0	—	5·3	7·0	4·0	2·3	1·0

Gahn first observed that the spangled appearance of the glass is due to minute shining, opaque, crystals, having the form of octahedral segments. Hence, and from the composition of the glass, it was concluded that the crystals consist of metallic copper. Clemandot and Fremy (Compt. rend. xii. 339), by melting together for 12 hours a mixture of 300 pts. of pounded glass, 40 pts. of copper filings, and 80 pts. of iron filings, and cooling slowly, obtained a rather dull-looking glass containing copper diffused through it in octahedral crystals.—Pettenkofer, on the other hand, maintains that the spangles consist of crystals of a cuprous silicate, identical in composition, but larger in size than the crystals of the compound which impart the deep-red colour to hæmatinone-glass or *porporino* (*q. v.*), and are diffused through a mass of glass coloured green by protoxide of iron, the red crystals seen through the green glass producing a mixed or resultant tint of brown. Aventurin-glass may in fact be prepared with certainty by adding to 100 pts. of a not too refractory glass, 8 to 10 pts. of a mixture of equal parts of ferrous and cuprous oxides, and leaving the mixture to cool very slowly so as to facilitate the formation of crystals. A red crystalline cuprous compound then separates, and the ferrous oxide remains in the glass, imparting a green colour. Pettenkofer has also converted hæmatinone into aventurin-glass by addition of iron. (Handw. d. Chem. 2ᵗᵉ Aufl. ii. 504.)

AVENTURIN GLAZE. A glazing for porcelain invented by Wöhler (Ann. Ch. Pharm. lxx. 57). To prepare it, 31 pts. of kaolin from Halle, 43 quartz-sand, 14 gypsum, and 12 porcelain fragments, the whole finely ground and levigated, are stirred up with 300 pts. of water, and to the paste thus formed are successively added the solutions of 19 pts. of acid chromate of potassium, 47 acetate of lead, 100 protosulphate of iron, and sufficient ammonia to precipitate the whole of the iron. After the potassium and ammonium-salts have been washed out by repeated decantation, the glazing is ready for use, and is laid on the burnt wares in the ordinary manner, and burnt by the heat of the porcelain furnace. When cold, it forms a brownish ground, containing crystalline laminæ which have a golden lustre, but appear green and transparent under the microscope and by transmitted light; these crystals are regarded by Wächter as chromic oxide or a compound of that oxide with ferric oxide.

AVIGNON, GRAINS OF. (*French Berries.*) See YELLOW-BERRIES.

AXE-STONE. A sub-species of jade, from which it differs in not being of so light a green, and in having a somewhat slaty texture. The natives of New Zealand work it into hatchets. It is found in Corsica, Switzerland, Saxony, and on the banks of the River Amazon, whence it has been called Amazonian stone. Its constituents are, silica 50·5, magnesia 31, alumina 10, oxide of iron 5·5, water 2·75, oxide of chromium 0·05. U.

AXINITE. A silicate containing boric acid, so named from the axe-like bevelling of its lateral edges. It is also called *Thumite*, from one of its localities, Thum in Saxony. Its formula is $6M^2O.2M^4O^3.8SiO^2.B^2O^3$, where M^2O stands for magnesia and protoxide of iron, and M^4O^3 for alumina, sesquioxide of iron, and sesquioxide of manganese (Gm. iii. 453). Crystalline system, the triclinic or doubly oblique prismatic. Specific gravity 3·294. Harder than felspar. Colour varying from a fine violet-brown to leek-green, sometimes plum-colour; some crystals are white and transparent, with a glassy lustre. Before the blowpipe it exhibits the reaction of boron with acid sulphate of potassium. In the unignited state, it is not attacked by hydrochloric acid, but yields to it after fusion. It is found in various localities in France, Norway, Saxony, the Harz, and the Alps; at Botallack, near the Land's End, Cornwall; and at Trewelland in that neighbourhood.

AZADIRINE. A bitter principle, perhaps an alkaloid extracted from *Melia Azadirachta*, an East Indian tree, by Piddington (Geiger's Mag. xix. 50), who states that it may be used as a substitute for quinine. According to O'Shaughnessy (Pharm. Centr. 1844, p. 365), all the parts of *Azadirachta Indica* are very bitter. The leaf is bitter and nauseating; the bark is peculiarly bitter, and somewhat astringent, and is used effectively in Bombay as a substitute for cinchona bark; the husk of the ripe fruit yields a very bitter fat oil, which possesses anthelmintic properties, and is used as an embrocation.

AZELAIC ACID. An acid stated by Laurent (Ann. Ch. Phys. [2] lxvi. 154) to be produced, together with suberic and other acids, in the oxidation of oleic acid by nitric acid. It closely resembles suberic acid, being distinguished merely by a lower melting point and greater solubility in ether. Laurent assigned to it the formula $C^{10}H^{18}O^4$; but it is probably nothing but impure suberic acid. (Compare Ann. Ch. Pharm. xxxv 103.)

AZOBENZENE. *Azobenzide*, *Azobenzol.* $C^{12}H^{10}N^2$. (Mitscherlich, Ann. Ch. Phys. xxxii. 224); Zinin, J. pr. Chem. xxxvi. 96; lvii. 173; Laurent and Gerhardt, Compt. chim. 1849, 417.)—A product of the reduction of nitrobenzene, or of the oxidation of benzidine. It is obtained, together with phenylamine, by the dry distillation of azoxybenzene; or simply by distilling a mixture of nitrobenzene and alcoholic potash; or by distilling a mixture of 1 pt. nitrobenzene, 3 pts. iron, and 1 pt. acetic acid (Noble). Azobenzene passes over towards the end of the operation, as a red oil, which solidifies on cooling; it is freed from aniline by hydrochloric acid, and recrystallised from alcohol or ether. It forms large reddish-yellow scales, scarcely soluble in water, readily in alcohol or ether. It melts at 65° C., boils* at 293°, and distils undecomposed (P. W. Hofmann). Vapour-density, by experiment, = 94, referred to hydrogen; 6·50 referred to air; by calculation (2 vol.), 91 referred to hydrogen, 6·32 referred to air (P. W. Hofmann, Ann. Ch. Pharm. cxv. 364). It is soluble in nitric or sulphuric acid, and is reprecipitated by water. Sulphide of ammonium and sulphurous acid convert it into benzidine. It is not decomposed when heated to 250° C. over soda-lime.

When acted on by fuming nitric acid, it yields two nitro-substitution compounds.—*Nitrazobenzene*, $C^{12}H^9(NO^2)N^2$, is formed when the reaction is not prolonged: it separates out in reddish-yellow crystals, which, after the acid has been decanted, are washed with water, and dissolved in boiling alcohol (which generally leaves a residue of the dinitro compound). The solution deposits orange-yellow crystals of nitrazobenzene, which are washed with alcohol and ether. When heated, it melts, and cools into a crystalline mass. It is less soluble in alcohol than azobenzene.—*Dinitrazobenzene*, $C^{12}H^8(NO^2)^2N^2$, is formed when the action of the nitric acid is prolonged for a few minutes: red crystals are deposited, which are washed with nitric acid, water, and ether, and recrystallised from boiling alcohol. It forms small reddish needles, which may be obtained larger by crystallisation from fuming nitric acid. When heated, it melts to a blood-red liquid, which crystallises on cooling. It is less soluble than nitrazobenzene in alcohol or ether. Sulphide of ammonium converts it into diphenine (*q. v.*) F. T. C.

AZOBENZIL. $C^{21}H^{15}NO$.(?) (Zinin, Ann. Ch. Pharm. xxxiv. 190; Laurent, Rev. scient. xix. 445).—Formed as a white granular precipitate, when a not too concentrated alcoholic solution of benzil is mixed with aqueous ammonia: after standing in the liquid for ten hours, it is washed and recrystallised from alcohol. It forms long, lustrous, iridescent needles, which are soluble in alcohol, alcoholic potash or ammonia, and hydrochloric acid (whence it crystallises unaltered); insoluble in water, potash, or ammonia. F. T. C.

AZOBENZOIDE. $C^{42}H^{32}N^3$ (?) (Laurent, Ann. Ch. Phys. [2] lxvi. 190).—A white amorphous powder, formed by the prolonged action of ammonia on crude bitter-almond oil. It is insoluble in alcohol and ether. When heated, it melts, and solidifies in crystalline granules; more strongly heated, it is decomposed.

F. T. C.

AZOBENZOIDINE. $C^{42}H^{27}N^3$. (?) (Laurent, Ann. Ch. Phys. [3] i. 302.)—A product of the action of ammonia on crude bitter-almond oil. It forms small, shining, oblique prisms: is inodorous, nearly insoluble in alcohol, slightly soluble in ether. It is dissolved and decomposed by nitric, hydrochloric, or sulphuric acid. It solidifies after fusion into a non-crystalline transparent mass. F. T. C.

AZOBENZOILIDE. $C^{14}H^{11}N$. (Laurent, Ann. Ch. Phys. [3] i. 304; xviii. 272.)—A product of the action of ammonia on pure bitter-almond oil. The oil was shaken up with potash and chloride of iron, distilled, and the first $\frac{1}{8}$ which passed over was covered with an equal volume of ammonia. Crystals were gradually deposited, and in three weeks the oil was half solidified. The mass, when extracted with ether, left a residue of azobenzoilide.

$$2(C^7H^6O) + NH^3 = C^{14}H^{11}N + 2H^2O.$$

It forms a microscopic crystalline powder, inodorous, insoluble in alcohol, very slightly soluble in ether. It is decomposed by prolonged fusion. Hot nitric acid dissolves it, apparently without decomposition; hot sulphuric acid dissolves it, forming a yellow solution, in which ammonia produces a white precipitate. F. T. C.

AZOBENZOYL. $C^{21}H^{16}N^2$. (Laurent, Ann. Ch. Phys. [2] lxvi. 185.)—A product of the action of ammonia on crude bitter-almond oil. When the yellow resinous mass obtained by leaving the oil for four weeks in contact with an equal volume of ammonia, is treated with boiling ether, a mixture of azobenzoyl and benzoylazotide is left undissolved: the former is dissolved out by boiling alcohol, and purified by recrystallisation. It forms a white, shining, crystalline, indorous powder, composed of irregular six-sided tables; insoluble in water, not very soluble in boiling alcohol. After fusion, it cools to a transparent mass; it is decomposed by a strong heat, leaving a residue of carbon.

---

* The boiling point of azobenzene is commonly stated, on Mitscherlich's authority, to be 193° C. doubtless from a misprint in the original memoir.

According to Laurent (Ann. Ch. Phys. [3] i. 300), a mixture of equal volumes crude bitter-almond oil, ammonia, and sulphide of ammonium, solidifies after a long time; and on treating the product with boiling ether, a white crystalline powder remains behind, consisting of microscopic rhombic tables, which are nearly insoluble in alcohol, and slightly soluble in boiling ether. Laurent calls this body *hydrosulphate of azobenzoyl*, and assigns to it the formula $C^{21}H^{18}N^{2}S^{14}$, upon which no reliance can be placed. F. T. C.

AZOBENZOYL, HYDRIDE OF. Syn. with Hydrobenzamide (*q.v.*)

AZOCINNAMYL, HYDRIDE OF. See Cinnamyl.

AZOCODEINE. An organic base which Anderson obtained by the action of sulphide of ammonium on nitrocodeine. (See Codeine.)

AZODIFUNE. Gmelin's name for Azobenzide.

AZOERYTHRIN. See Orcein.

AZOLEIC ACID. Syn. with Œnanthylic Acid.

AZOLITHOFELLIC ACID. See Lithofellic Acid.

AZOLITMIN. See Litmus.

AZOMARIC ACID. See Pimaric Acid.

AZOPHENYLAMINE of Zinin. A product of the decomposition of nitrophenylamine by sulphide of ammonium. (See Phenylamine.)

AZOPHENYLAMINE of Gottlieb, more correctly *Nitrazophenylamine.* A product of the decomposition of dinitrophenylamine by sulphide of ammonium. (See Phenylamine.)

AZORITE. A mineral occurring in the trachytic rock of the Azore Islands, in small greenish or yellowish white pyramids. According to Hayes, it consists for the most part of tantalate of calcium.

AZOSULPHIDE OF BENZENE. Syn. with Hydride of Sulphazo-benzoyl or Thiobenzaldin. (See Benzoyl-hydride, decompositions by sulphide of ammonium.)

AZOTE. (α privative and ζωή life.)—Lavoisier's name for nitrogen.

AZOTAN. A name, not much used, for chloride of nitrogen.

AZOTIDES Syn. of Nitrides.

AZOXYBENZENE. *Azoxybenzide, Azoxybenzol.* $C^{12}H^{10}N^{2}O$. (Zinin, J. pr. Chem. xxxvi. 96; lvii. 173; further, Ann. Ch. Pharm. cxiv. 217; Laurent and Gerhardt, Compt. chim. 1849, 417.)—When to a solution of 1 pt. nitrobenzene in 10 vols. absolute alcohol, 1 pt. powdered potash is added, the whole becomes brown, and is heated to boiling. The mixture is shaken up and kept boiling for some minutes: on cooling it sometimes deposits brown crystals. The mother-liquor is decanted, and distilled till it forms two layers. The upper is a brown oily liquid, which, after decantation and washing with water, solidifies into a mass of brown needles; the lower contains aqueous potash, carbonate of potassium, and a brown potassic salt, almost insoluble in alcohol. The crystals are dried with filter-paper, and recrystallised from alcohol or ether: they are easily decolorised by passing chlorine through their alcoholic solution. 2 pts. nitrobenzene yield 1½ pt. azoxybenzene.

Thus obtained, azoxybenzene forms yellow, shining, four-sided needles, often an inch long, as hard as sugar, without smell or taste, insoluble in water, hydrochloric, or dilute sulphuric acid, potash, or ammonia, readily soluble in alcohol, still more so in ether. It melts at 36° C., and solidifies on cooling to a crystalline mass: it is decomposed by dry distillation, yielding aniline and azobenzene, and leaving a residue of carbon. It is not attacked by chlorine: bromine attacks it, forming a yellow componnd, very slightly soluble in alcohol. Strong sulphuric acid dissolves it, forming apparently a copulated acid. Sulphide of ammonium and sulphurous acid convert it into azobenzene.

Nitrazoxybenzene, $C^{12}H^{9}(NO^{2})N^{2}O$.—Azoxybenzene is not attacked by dilute nitric acid, but when gently heated with nitric acid of specific gravity 1·45, it dissolves, with great evolution of heat, and the liquid, if carefully cooled, solidifies after a while, to a thick pulp, consisting of two isomeric nitro-compounds, nitrazoxybenzene, and isonitrazoxybenzene, which may be separated by their different solubility in alcohol. If the pulp just mentioned be thrown on a filter, washed with water, treated three or four times with a quantity of boiling alcohol not sufficient to dissolve the whole (not more than 4 pts. alcohol to 1 pt. azoxybenzene), and the decanted liquors left to cool, crystals of nitrazoxybenzene are first deposited; and after a while, shining needles make their appearance in the midst of them. If the liquid be then filtered, and part of the alcohol distilled off, isonitrazozybenzene separates on cooling, in the form of an oil, which quickly solidifies in a crystalline mass; it may be purified by two or three crystallisations from small quantities of very strong alcohol.

Nitrazoxybenzene is a yellowish crystalline body, slightly soluble in boiling alcohol or ether. It is promptly attacked by boiling alcoholic potash, and coloured brown; on adding water, a yellowish-red powder is precipitated, which may be crystallised from boiling oil of turpentine. This compound appears to contain $C^{12}H^{9}N^{3}O$ (Laurent and Gerhardt). If the action of alcoholic potash be prolonged, the mixture becomes blue; the colour is destroyed by water. An alcoholic solution of sulphydrate of ammonium converts nitrazoxybenzene, with separation of 3 at. sulphur into a crystallisable base, which dissolves readily in alcohol and in benzene, and forms salts with acids.

Isonitrazoxybenzene forms crystals very much like those of nitrazoxybenzene, but easily soluble in alcohol. It dissolves also in a large quantity of ether, and in benzene, and often crystallises from these liquids in fine rhomboïdal prisms. It melts at 49° C. but does not volatilise without decomposition. When 1 pt. of this substance is treated with a solution of 1 pt. of potash in 8 pts. of alcohol, it melts and dissolves with ebullition, giving off the odour which is evolved on treating nitrobenzene with alcoholic potash. On boiling the liquid, a resinous mass separates, which yields by distillation an orange-coloured product, which crystallises from alcohol, and resembles nitrophenylamine. At the same time, an oily body is formed not possessing basic properties, and charcoal remains behind.

Isonitrazoxybenzene treated with alcoholic sulphydrate of ammonium, yields a body having the composition $C^{12}H^{9}N^{3}O$:

$$C^{12}H^{9}(NO^{2})N^{2}O + 2H^{2}S = C^{12}H^{9}N^{3}O + 2H^{2}O + S^{2}.$$

This body is insoluble in water, very soluble in alcohol, ether, benzene, and rock-oil soluble also in acids; but does not form definite salts. It melts at 85° C. to a yellow liquid, which solidifies on cooling, provided the temperatnre has not been raised too high. If a strong heat be applied, a brown liquid distils over, soluble in alcohol, though less so than the original substance. F. T. C.

AZOXYDIFUNE. Gmelin's name for Azoxybenzene.

AZULMIC ACID. A brown substance produced by the spontaneous decomposition of cyanogen and hydrocyanic acid.—An aqueous or a dilute alcoholic solution of cyanogen or aqueous hydrocyanic acid, when left to itself for some time, especially after addition of ammonia or potash, acquires a brown colour and gradually deposits brown flakes, consisting of azulmic acid. The solution contains azulmate of potassium or ammonium, from which the acid may be precipitated by the stronger acids. The same product is obtained by passing cyanogen gas into aqueous ammonia or alcoholic potash.—Respecting the composition of this substance, statements vary greatly; according to Pelouze and Richardson (Ann. Ch. Pharm. xxvi. 63), it is $C^{4}H^{4}N^{4}O^{2}$, that is to say, 4 at. cyanogen + $2H^{2}O$: but it is doubtful whether any of the analyses have been made upon a pure definite compound. The acid yields by dry distillation hydrocyanic acid, ammonia, and water, and leaves a residue of charcoal containing nitrogen. (For a full account of all the modes of preparation, properties, and reactions of azulmic acid, see Gmelin's Handbook, xi. 375.)

AZURE-BLUE. See Smalt.

AZURE-STONE } See Lazulite.
AZURITE }

B

BABINGTONITE. A mineral consisting principally of silicate of iron and calcium, found near Arendal in Norway, in the Shetland Isles, at Gouverneur in St. Lawrence County, New York, and at Athol in Massachusetts. It forms short, nearly right angled rhomboïdal prisms, of the triclinic system, with truncated edges and obtusely bevelled summits. Fracture imperfectly conchoïdal. Colour dark greenish-black, with vitreous lustre. Opaque in the mass, translucent in thin splinters. Hardness 5·5 to 6·0. Specific gravity 3·4 to 3·5. Brittle, producing a greenish-grey streak. Melts easily with intumescence before the blowpipe, forming a brownish-black shining globule, attracted by the magnet. It is slowly decomposed by boiling hydrochloric acid. The mineral has been analysed by Arppe (Berz. Jahresb. xxii. 20), and by R. D. Thomson (Phil. Mag. [3] xxvii. 123), but its formula has not yet been determined:

SiO^{2}	$Mg^{2}O$	$Ca^{2}O$	$Fe^{2}O$	$Mn^{2}O$	$Al^{4}O^{3}$	Loss by ignition.		
54·4	2·2	19·6	21·3	1·8	0·3	0·9	=	100·5 (Arppe)
47·5	2·2	14·7	16·8	10·2	6·5	1·2	=	99·1 (Thomson)

BABLAH or **NEB-NEB.** The commercial names for the fruits of several species of acacia. The principal varieties are East Indian bablah, from the *Acacia Bambolah* (*Roxburgh*), and Senegal and Egyptian bablah, from *Acacia nilotica* (*Delile*). The pericarp of these fruits contains a dark brown astringent juice. The aqueous extract contains, according to Chevreul (*Leçons de Chimie appliquée à la Teinture*, ii. 211), gallic and tannic acids, a red colouring matter, and a nitrogenous substance, besides other substances not yet examined. East Indian bablah yields to boiling water 49 per cent. of soluble matter; Senegal bablah 57 per cent.; nevertheless, according to Guibourt, the East Indian variety is richer in tannic and gallic acid, and therefore more valuable. Bablah is used in calico-printing in combination with alumina and iron mordants, to produce various shades of fawn-colour. The tint produced by the seeds is different from that obtained with the husks; the seeds are said to contain a red colouring matter, and to be used in Egypt and India for dyeing morocco. (Handw. d. Chem. 2te Aufl. ii. 603.)

BABUL-GUM or **GOND-BABUL**, an inferior sort of gum arabic, from the babul tree, *Acacia Arabica* (*Willd.*) growing in Bengal.

BABYLONIAN QUARTZ. This name is given to peculiar groups of quartz-crystals, composed of thin crystalline plates, disposed one above the other like terraces. It is found at Beerlston in Devonshire.

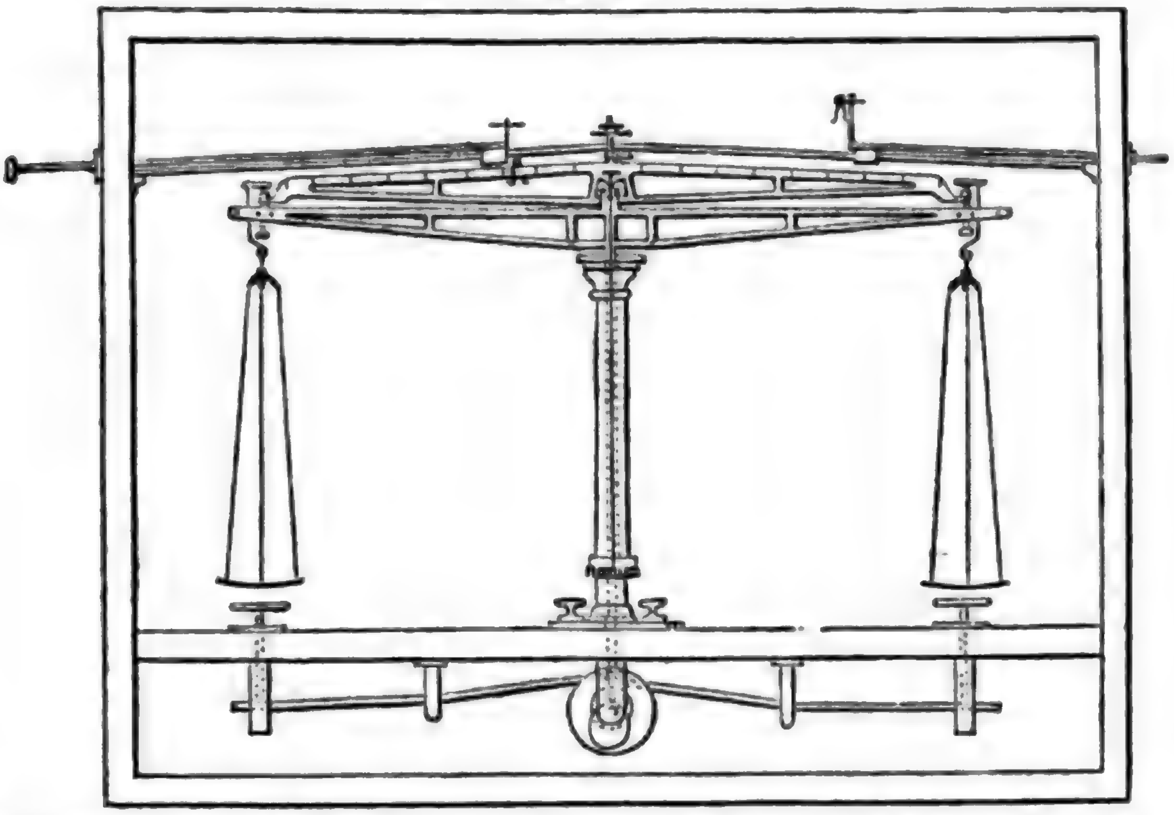
BAGRATIONITE. See Orthite.

BAIERIN or **BAIERITE.** A variety of niobite found at Bodenmais in Bavaria and at Limoges in France.

BAIKALITE. A green modification of diopside.

BALANCE. Chemistry being concerned with the relative masses or quantities of the elements which compose all known substances, and the weight or force of gravitation of a body being the only practicable measure of its mass or quantity of matter, the balance, which shows the equality of two weights, and may hence determine the ratio of all commensurable weights, is the chemist's most important instrument.

Fig. 78.

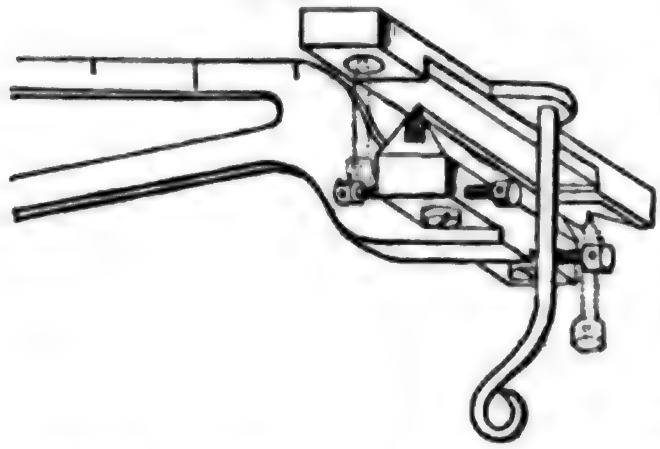


Theoretically speaking, the balance consists of a lever or inflexible straight line turning with perfect freedom on its central point. A weight is applied to each extreme point, and the force of gravity acting perpendicularly downwards, if either of these weights be in the least degree greater than the other, it will prevail and cause the lever to revolve in its own direction. The equilibrium of the lever or balance affords the desired criterion of perfect equality of weight; and an arbitrary weight being assumed as a standard, we can arrive, theoretically speaking, at any of its multiples or submultiples by successive duplication and bisection combined with addition and subtraction, and a perfect measure of all weights from the greatest to the least may thus be attained. The results of course are not absolute weights, as we say in common speech, but *ratios* of weights to each other, or to the standard unit-weight.

Practically, however, the balance consists of a metal beam with two almost equal and similar arms, suspended near its centre of gravity on a pivot, the weights to be compared being also suspended from two pivots at nearly equal distances from the centre pivot. In the balance thus constructed, we have by no means the simple and perfect comparison of two weights supposed in theory; the weight of the beam, the friction of the pivots, their unequal distances from the middle one, the resistance of the air, and possibly other causes, introduce small extraneous forces, which render the comparison required more or less uncertain and erroneous.

The Chemical Balance, is adapted for the ordinary operations of quantitative analysis, and is usually capable of weighing any quantity less than 100 grammes or 1500 grains. In its most perfect form (see *fig.* 78) it consists of a perforated brass beam, cast in a single piece, combining great strength and perfect inflexibility with comparatively small weight. It is suspended at the centre on a knife-edge of agate about an inch long, and turns on a single polished plane of agate fixed on a projecting brass support, which enters a perforation of the beam, and does not impede its motion. The agate knife-edge is firmly embedded in a wedge-shaped piece of brass, and being once adjusted exactly at right-angles to the plane of the beam, is then permanently fixed. At each end of the beam is a smaller agate prism (see *fig.* 79), with the edge uppermost, fixed in a brass setting, which is capable of a little lateral movement, but slides upon a brass plane, in such a manner that the two extreme edges and the centre edge are all appreciably in one plane, as may be seen by looking along them. The extreme edges may be moved to or from the centre edge by little adjusting screws, and fixed in the desired position with the assistance of two clamping screws.

Fig. 79.



Upon these extreme edges (*i. e.* knife-edges) are balanced two agate planes, from which, by the bent wire and a series of hooks and light wires, the pans are suspended.

Except, however, when a weighing is actually being made, the agate planes and edges are never in contact, but the beam and pan suspensions are borne by a frame or movement, having in the centre two Y's (*fig.* 78) which catch projecting pins close to the centre edge, and lift the beam about $\frac{1}{100}$ of an inch off the plane, while steel points (shown in dotted outline in *fig.* 79.) entering hollows in the lower surface of the pan-suspensions, likewise raise these planes off the edges, and retain them in the exact positions proper for a new experiment. The movement of the brass frame is governed by a rod descending through the pillar of the balance and resting on a simple eccentric, by the turning of which it is gradually raised or lowered. In the best balances too, a second eccentric, by means of two bent levers, raises supports beneath the pans of the balance, and either holds these safely while weights are being placed in them, or checks their oscillations preparatory to the release of the beam. The two eccentrics are so adjusted that on turning the handle, the pan supports are first rapidly dropped; the beam is then very gently lowered on to the centre plane; and lastly the pan-suspensions are in the most delicate manner left free upon the extreme edges, the beam being perfectly horizontal and undisturbed, so as not to show the slightest preponderance one way or another. Much of the excellence of a balance, as it is employed in chemistry, depends upon these several movements being smoothly performed, and the parts being released without the least stickiness; otherwise the beam is thrown into oscillation, and the true approach to equilibrium cannot be readily observed.

Most of the weight of the beam and frame is usually borne by a spiral spring in the interior of the column. An index moving over an ivory scale one inch long, divided into twenty parts, indicates the movement of the beam. The index should, of course, point exactly to the centre division, both before the beam is raised and when it is free and unloaded. The balance is enclosed in a glass case, with convenient windows, not shown in the figure; but when a very bulky object has to be weighed, the finger-screws at the base of the column (*fig.* 78) are to be loosened: the column and beam may then be turned through about 60°, so that the scales extend without the case. Two spirit-levels, or a circular level, and levelling screws, are attached by which the whole instrument must be adjusted to horizontality. Above the centre of the beam is a small weight, which we may call the *gravity-bob*, and which, being screwed up or down, regulates the stability of the balance, while a small *vane* being turned to the right or the left adjusts the beam to equilibrium. In the figure too will be seen an arrangement of rods, by which a small rider weight may be placed upon any part of the beam, the balance case remaining closed.

The balance above described is by Oertling, of Bishopsgate Street, London, who likewise constructs the chemical balance in seven different varieties more or less elaborate.

Fig. 80.

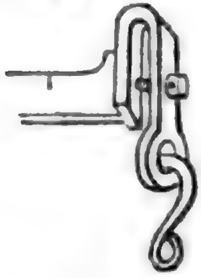


Fig. 81.

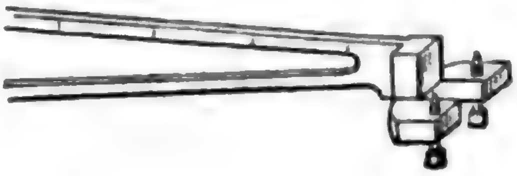

Fig. 82.

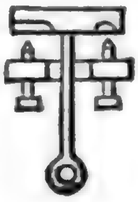

The largest of these, with a 16-inch beam, able to bear two pounds in each pan, and yet turn with $\frac{1}{100}$ grain is a remarkably fine instrument. The German balances made by Oertling of Berlin, Staudinger of Giessen, Steinheil of Munich, and others, are extremely delicate and well made instruments. Deleuil of Paris enjoys also a just celebrity for his chemical balances. M. Stas, in his late researches upon the atomic weights, employed a balance by Gambey, which turned to half a milligramme when laden with a kilogramme; also one by Sacré of Brussels, carrying two or three kilogrammes and turning with 0·3 milligramme. *Fig.* 83 shows the terminal suspension of a delicate balance by Fortin of Paris, capable of indicating one part in a million, while *fig.* 84 is from a German balance.

Fig. 83.

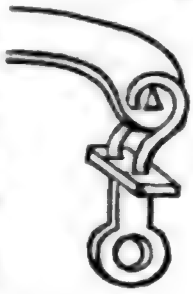

Fig. 84.

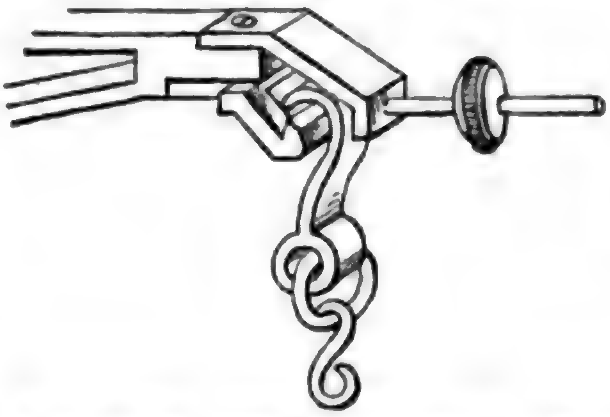


The Assay Balance is specially adapted for weighing small objects with great accuracy and rapidly. The French assay balances consist of a very light steel beam mounted in the manner of a pair of scales with hook pan suspensions, yet their performance is good.

Oertling constructs the assay balance in five forms, of which the most commonly employed has an 8-inch plain brass beam with a centre steel knife-edge and hook pan suspensions, adjustable by a small screw, as shown in *fig.* 80. It is not adapted to bear more than two grammes in each pan, and will perhaps indicate the $\frac{1}{20}$ part of a milligramme.

Another kind has an 8-inch perforated beam, with three agate edges and planes, and in fact all the elaborate movements and adjustments of the chemical balance above described, on a small scale. It will bear 10 or 15 grammes in each pan, and yet indicate surely and *rapidly* about $\frac{1}{20}$ of a milligramme.

Lastly, we may mention the 10-inch assay balance, with a very light perforated beam. A figure and a short description of this balance will be found under the article Gold Assay, but the terminal suspensions are shown here in *figs.* 81 and 82, and are formed of two small screws, bearing sharp points of ruby, one working into a little hollow, the other into a little channel in a steel cross-piece, from which the pan is suspended.

In contrast to the last balance it may be mentioned that Oertling constructs balances on the principles of the chemical balance with a beam 4 feet long, able to bear 2000 ounces in each pan, and yet turn with half a grain, or the one-millionth part of the load. They are chiefly employed in the several English and American mints for weighing bullion, but might be useful in some scientific investigations. See Jury Reports on the Great Exhibition of 1851 (p. 258).

It is of little use to describe forms of the balance which are now antiquated. Those by Robinson, by Ramsden, and his successor, Berge, and by Barrow, had beams composed of two hollow brass cones joined at the base with many elaborate adjustments. A balance made by Ramsden for the Royal Society is said to have indicated one part in seven millions. In the Göttingen Transactions, is described a balance constructed by Gauss and Weber, the beam and scales of which were poised on watch springs, a method contrived by Gauss. Beams suspended by ribbons, threads, or turning on little spheres of steel have been tried by Steinheil; but in no instrument have attempts to invent new forms been more futile.

The Adjustment of the Beam to the due degree of sensibility and accuracy has to be entirely performed by repeated trial-weighings, and requires the greatest skill.

Firstly, if the three edges of suspension are not already in one plane, but admit of adjustment, as is sometimes the case, proceed as follows:—Without weights in the pans poise the beam, and then raise or lower the *bob* until the vibrations are rendered very slow; now put weights into the pans equal to about half the greatest load the balance is to carry, so that the beam may be poised again; if it now vibrates slowly as before, it proves the adjustment to be perfect; but in case it either oversets or vibrates too quickly, restore it to slow motion by the adjusting weight or *gravity-bob*, as we may call it, noting the number of turns of the screw and parts of a turn which were required to produce slow motion; now turn the screw the contrary way, through double the noted quantity, and then produce the required slow motion by the proper adjustment at the end of the beam. Repeat the operation till the adjustment is perfect.

Secondly, to adjust the edges of suspension to equal distances; poise the beam with weights as in the last case, and then change the pans and suspensions from one side to the other. If equilibrium still holds, the adjustment is perfect; if not, take as much hair or wire as when put into the apparently lighter scale, will restore the balance; take away half of it, and poise the beam by the proper adjustment at the left end, which completes the process. Instead of placing any weights in the pans, all the poising may be conveniently done by a rider-weight on the beam, and in the last operation it is to be removed half way towards the centre of the beam. The adjustment of the edges to perfect parallelism is of course indispensable; we only presume that it is done by placing narrow planes or hooks on different parts of the edges and moving these until the apparent weight is the same on whatever part the weight bears.

A good balance in perfect adjustment should bear most of the following tests: Without weights, of course, it should remain with the index at zero, or make equal slow excursions on either side. The pans being removed, the beam alone should be in equilibrium, and oscillate probably much more quickly. If there be nothing in the construction of the balance to hinder it, the beam should be turned round from left to right and should act as before; this test is a severe one, generally disclosing as it does some defect in the work of the middle knife-edge and the planes on which it rests. If the pans and suspensions have been separately adjusted to equality, which is advantageous, although not quite necessary, equilibrium should hold when the pans and suspensions are variously changed in both positions of the beam. Lastly, the pans being fully and equally loaded, the weights should be changed from pan to pan, and equilibrium yet hold, proving the lengths of the arms to be fully equal.

A good balance, too, may be known by its giving the weight of an object, the same or nearly so, when weighed several times successively. There are few balances that will do this with certainty to the last minute fractions which they are capable of indicating.

Weights.—The results required by the chemist in analyses being merely comparative or proportional, the choice of a unit weight is a matter of indifference, provided that it be not varied during the progress of an experiment. But it is most convenient to adopt weights connected with some national standard, so that absolute weighings may if necessary be recorded. Grain weights are still sometimes used by English chemists, but most men of science of all nations appear by a kind of tacit agreement to have adopted the French standard weight, the gramme, with its uniform series of decimal multiples and submultiples; and we therefore strongly recommend its exclusive employment by every scientific chemist.

A complete set of weights extends from the smallest that the balance will indicate, up to the greatest that it will bear, and the series usually supplied with a balance is as follows:—

·001 gramme	·01 gramme	·1 gramme	1·0 gramme	10·0 grammes
·001 ,,	·01 ,,	·1 ,,	1·0 ,,	10·0 ,,
·001 ,,	·02 ,,	·2 ,,	1·0 ,,	20·0 ,,
·002 ,,	·05 ,,	·5 ,,	2·0 ,,	50·0 ,,
·005 ,,			5·0 ,,	

the whole making up just 101 grammes. These are arranged most conveniently in two little wooden stands, which may either be introduced into the balance case or enclosed together with the forceps in a separate box. A glass cover also lies over the small weights. The weights from 1 gramme upwards are best made of brass *gilt;* below 1 gramme, of platinum in the form of flat squares, with a corner bent up for holding in the forceps, the weight being stamped on each piece. The milligramme weights are sometimes made of palladium or aluminium; but the latter metal is rather too soft for the purpose, and is apt to wear away.

An admirable improvement in the modern balance consists in its partial employment on the principle of the steel-yard, as far as regards the estimation of the last minute fractions. A small *rider*, or hanging weight of thin gold (or brass) wire, is placed upon the upper edge of the beam either by the forceps, or more conveniently without opening the case, by a brass sliding rod and a little arm (see *fig.* 78), on either side of the beam. Now the weight which this rider exerts towards turning the beam is such a fraction of its whole weight in the pan, as its distance from the centre of the beam is of the distance of the pan-suspension from the centre. The rider commonly weighs ·01 gramme, and each arm of the beam is graduated into twenty parts; but the fifth part of these divisions may easily be guessed, so that the fractional weight may really be read off to the $\frac{1}{100}$ part of the rider weight, or ·0001 gramme. This simple contrivance, compared with the use of minute weights in the pans, presents the following advantages.

1. Saving of much time and trouble. 2. Greater accuracy, small weights being liable to collect dirt, or to be rubbed or injured. 3. Minute estimation of weights to any required degree. 4. Diminished chance of error in reading off the weight. With numerous small weights errors are *certain* frequently to occur.

The series of grain weights 1, 2, 3, 4, 10, 20, 30, 40, &c. is not uncommonly employed, and is quite as convenient as the series 1, 1, 2, 5, 10, &c. As a curious fact, it may be mentioned, that the series of powers of 3, viz. 1, 3, 9, 27, 81, affords the greatest number of combinations to a given number of weights. Thus twelve such weights give by *addition or subtraction*, any integral number from 1 to 265,720, while 21 weights of the series, 1, 1, 2, 5, do not reach 200,000.

Weights when used in a laboratory must almost always become too light by wear, or more commonly too heavy by corrosion of the brass. Were the error always proportional to the size of the weight, all error would be eliminated in any comparative result. But this is not usually the case, since the mass increases as the cube, while the surface increases as the square of the diameter. Hence the small weights will be more erroneous in proportion than the large. Weights should never be rubbed, and if dusty, should be wiped with a silk handkerchief or a camel's-hair brush. Small *platinum* weights may be cleaned if necessary, by momentary exposure to the flame of a spirit-lamp. One set of weights should, if possible, be carefully preserved beyond the influence of fumes, and should not be touched but by ivory-pointed forceps. The weights commonly used should occasionally be tested against these, to see whether their errors be disproportionate; or weights may less satisfactorily be tested against each other. An experienced weigher will never trust even the best balance maker as to the accuracy of his weights, but will always test them against each other in various ways, on first receiving them. Many conclusions, observes Faraday, tending to subvert most important chemical truths, might be quoted as having arisen solely from errors in weights and balances.

In assaying (see Gold Assay), a special unit and set of weights is adopted to suit the weighings required; the same might be advantageously done in any large set of analyses or experiments.

Much time will on the whole be saved in weighing, if the weights be taken methodically in their proper order, 10, 5, 2, 1, 1, except, of course, the slow motion of the balance indicate that only a small weight more should be added. For if an unknown weight exceed 10 but fall short of 20, it is an even chance that it be above or below 15, so that if the weights 2, 1, 1, be used after the 10, it is *as likely as not* that the weigher will lose his trouble, and have to resort to the weight 5. In this respect the series of weights (avoirdupois) 16, 8, 4, 2, 1, $\frac{1}{2}$, $\frac{1}{4}$, &c. is obviously the most advantageous.

When equilibrium is nearly attained, the expert weigher will notice the rapidity with which the index of the beam traverses the arc, or the extent of the oscillation if it be less than the whole arc, and comparing this with the load in the pans, and with his previous experience of the same balance, will closely estimate the alteration of weight required, and thus save half the time and trouble which the adjustment would otherwise have occupied. It will afterwards be shown that the oscillations of a good balance may give sure determinations of the most minute fractional weights.

We cannot too strongly impress upon the reader the danger of mistakes in reading off the weights in the pan of a balance. The danger is greater with small than with large weights, and this alone would be sufficient reason for the use of a rider weight. In any case, the weights in the pan should be read, then taken out and arranged in order, and again read; lastly restored to the pan, and fresh trial made. Or the reading of the weights may be compared with the vacancies in the box of weights. When the vibrations of the balance have to be read, the divisions of the scale should be numbered from left to right continuously. For if the zero be in the centre, the signs + and − must be used, and mistakes are sure to occur. Under the article Gold Assay will be found an instance in which vibrations are used with great convenience in estimating the last fractions of weights.

The casual sources of mistake are too many to mention. Not unfrequently a rider may remain unnoticed on some part of the beam, and vitiate several weighings. When a bulky or flexible object is being weighed, some part is very likely to come in contact with the balance case. We have even known a scrupulously exact gold-assayer led into serious mistakes by a small fly, which settled on his balance, unobserved at the time.

An object heated many degrees above the temperature of the air, cannot be accurately weighed; for it is surrounded by ascending currents of air, which cause its apparent weight to vary every moment, and it is very likely to heat and expand unequally the arms of the beam above. Special modes of weighing hygroscopic substances, liquids, powders, gases, &c., must be adopted according to the nature of the case; the chemist must generally depend for these on his own ingenuity, but will find many valuable directions in Faraday's Chemical Manipulation, section II., also in Greville Williams's Chemical Manipulation.

If we have to compare the weights of any two objects, A and B, which are held or accompanied by other objects, X and Y, the weights of the latter may be perfectly eliminated if each of A and B be weighed as often in X as in Y, and the mean result taken.

We will make the following suggestions for the care of a balance.

1. It should never be moved, if possible, from its appointed place; for this would not only disturb its adjustment to horizontality, but the swinging and shaking of the pans and beam would be likely to injure or slightly alter the condition of the balance. The operator too will never weigh so well as in a place, and with a light to which he is accustomed.

2. The balance should not be cleaned or altered often or hastily. A good cleaning, once every three months, for instance, is enough, if the balance case be kept well closed. An hour or sometimes two or three, may well be spent in the operation of cleaning. All the loose parts should be carefully taken out and dusted; the movements cleaned and fresh oiled; the suspensions polished with a piece of soft leather. Then all the parts are to be put together again, and brought to elaborate adjustment, which with careful usage will be maintained for some months.

3. The chemist should be perfectly acquainted with the capacity, the general character, and also the particular condition, at any moment, of each of his balances.

4. Before every weighing, or set of weighings, he should try whether the unloaded balance is in perfect equilibrium; if not, he may brush the pans or beam with a camel's hair brush, to remove dust, or if he dust the preponderating side only, it will often restore equilibrium. He should not touch the little regulating vane, or alter any part of the balance, without being satisfied that some special cause for it has arisen. The one great essential of accuracy is perfect uniformity in everything but the thing to be measured, and no one can have faith in a measuring instrument which is always changing.

5. It is almost needless to say that a balance, especially one with steel knife-edges, must be kept beyond reach of all acid fumes or damp. A small vessel of quick lime or chloride of calcium should be in the balance case, and this should be kept constantly closed.

All weighing out of reagents, where a grain more or less is not material, should be made with common apothecaries' scales on the laboratory table.

A balance should be placed in a good light, falling if possible over the right shoulder of the operator. But it may also with advantage be placed before a window, provided that a purple silk shade be used. The purple light thus thrown behind the balance is subdued, agreeable, and complementary to the yellow of the brass. As a general rule, the object to be weighed should always be placed in the left hand pan, which we may hence call the *object-pan*. The other, or *weight-pan*, will thus be conveniently opposite the right hand. In assaying, this arrangement is reversed.

The number of balances required in a chemical laboratory may vary from one to twenty, or more, according to the size and purposes of the laboratory. For the common operations of quantitative analysis, the chemical balance first described is alone necessary. A larger balance will, however, be almost indispensable in water-analyses, and in many physico-chemical investigations, and will always be advantageous by allowing the use of large evaporating dishes and vessels, or the weighing of a series of drying tubes, or other apparatus as a whole. But a laboratory is not complete without an assay balance, which will perform all light weighings with an accuracy and expedition impossible in a large balance.

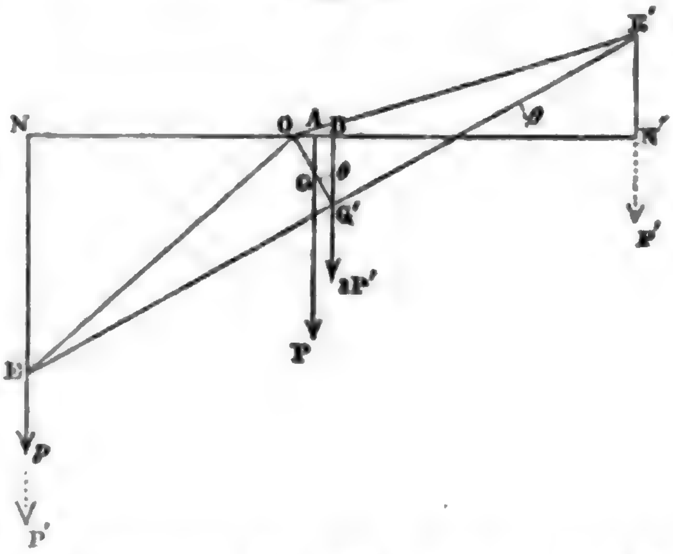
When the employment for balances is very extensive, it will be best accommodated, not so much by increasing the number of balances as by classifying them, assigning to each its proper work, and strictly adhering to rules once laid down. Where there are two balances of the same kind, it is obviously best to retain one for the more refined purposes, and make the other perform all common work, and two balances thus used may serve better than half a dozen indiscriminately worked and spoiled.

Mechanical Theory of the Balance.

Properly to understand the action of a balance, it must be considered both statically and dynamically, that is to say, both when the beam is at rest and while it is in motion; for the oscillations of a good balance are almost as valuable an indication as its position at rest.

First, however, to show the conditions of equilibrium, let O (*fig.* 85) be the central axis of suspension of a balance, and EE', the extreme axes of suspension not necessarily in the same straight line with O. Suppose equal weights, each = P', to act at E and E', including of course the whole weight of the burthen, pans, and other objects suspended at the extreme axes. Then the whole weight $2P'$ may be conceived as acting at G', the middle point of the line EE'. Assuming the axis O to be properly placed at equal distances from E and E', the line OG' will be perpendicular to EE', and the weight of the beam, say P, will act at its centre of gravity, which is, or should be, some point G, on this line or its prolongation.

***Fig.* 85.**



Lastly, let some small additional weight p act at E. The beam can not now remain horizontal, but may again rest in equilibrium in some position inclined at an angle, say θ, to the horizontal line NN'. Drawing E N, E' N', G A, G' B, perpendicular to NN', we must have, according to the principle of the lever, the sum of the moments of the forces on one side equal to that on the other, or

$$2P'.\mathrm{OB} + P.\mathrm{OA} = p.\mathrm{ON} = p(\mathrm{BN}-\mathrm{BO})$$

Or, substituting in terms of θ, we have

$$2P'.\mathrm{OG}'.\sin\theta + P.\mathrm{OG}\sin\theta \quad = p.\mathrm{G'E}.\cos\theta - p.\mathrm{OG}'.\sin\theta$$

$$\tan\theta = \frac{\sin\theta}{\cos\theta} = \frac{p.\mathrm{G'E}}{(2P'+p)\mathrm{OG}'+P.\mathrm{OG}}$$

Now for small values, $\tan\theta$ varies very nearly as the angle of deviation θ, which angle may be regarded as the true measure of the sensibility of the balance, and p being quite inconsiderable compared with $2P'$ and P, we may say that *the sensibility is increased by increasing the length of the beam, diminishing the weights of the beam and load, or diminishing the distances of G and G' from the axis O*, and also that *the sensibility varies very nearly in the direct or inverse ratio of these changes.*

Again, the force tending to restore the beam to the horizontal position when disturbed is $\sin\theta\,(2P'.\mathrm{OG}' + P.\mathrm{OG})$. This is the measure of the *stability* of a balance, a certain degree of which is required to render a balance useful. Now with given weights P and P', and for any given deviation θ, the force of stability will entirely depend upon the positions of G and G', and the following are the cases which arise.

1. The extreme points of suspension EE' may be so placed that G' falls above O. The stability is $\sin\theta\,(P.\mathrm{OG}-2P'.\mathrm{OG}')$, which for a certain value of P' will be *nothing*, so that the whole system will be suspended at the centre of gravity, and the beam being disturbed will have no tendency to return, but will rest in *neutral equilibrium*, indifferently in any position.

For a greater value of P', the force will be *negative*, and the equilibrium unstable, that is to say, the beam when loaded beyond a certain degree will *overset*, and permanently sink down on one side without a tendency to return, even when the weights on the two sides are not unequal. A balance of such construction then, could only be used for weights of a certain smallness, and its *sensibility* would increase and its stability decrease with its load.

2. If G fall above O and G' below, the stability is $\sin\theta\,(2P'.\mathrm{OG}-P'.\mathrm{OG})$, which will be *nothing* for a certain value of P', and negative for smaller values. The balance

then would be *stable* only when P', the load in the pans, is not less than a certain magnitude.

3. If G coincide with O (OG = 0) and G′ fall above O, the balance is always unstable and useless.

4. If G coincide with O and G′ fall below O, the stability is $2P' . OG' . \sin\theta$, which depends entirely upon the weight placed in the pans.

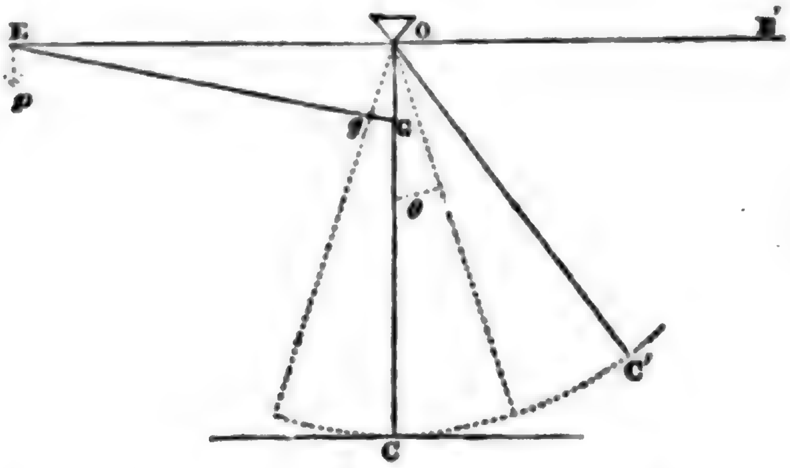
5. Now let G′ coincide with O, (OG′ = 0) the three points EOE′ being in a straight line, but let G fall below O. The stability is $\sin\theta . P . OG$, which for a given value of OG, is constant. Also $\tan\theta = \frac{p . OE}{P . OG}$ which depends only on p. In a balance of such construction, all weights may be weighed indifferently and with equal accuracy, and any required degree of sensibility may be obtained by duly regulating the length of OG.

6. Let G and G′ coincide; then $\sin\theta . OG(2P' + P)$ is the measure of stability, and is proportional to the weight to be moved. Also $\tan\theta = \frac{p . GE}{(2P' + P + p)OG}$ varies inversely as the total weight moved.

In any case of stable equilibrium, it will be easy to determine the position of the centre of gravity (say g) of the *whole system* from the formula $Og = \frac{p . OE}{\tan\theta(2P' + P + p)}$ by observing the deviation for several values of p, and for a given load P' in the pans. A different value will be found for Og for each different value of P′, unless the balance be constructed in the sixth mode described above. In a sensitive balance Og, will probably not exceed $\frac{1}{10000}$ part of an inch.

We may now consider the balance in the character of a compound pendulum, selecting for this purpose the fifth mode of construction above described. Thus if G, the centre of gravity of the beam (*fig.* 86), be vertically under O, and the weights in the pans be equal, the system will be at rest. But now suppose a small additional weight p added at E: the centre of gravity is no longer at G but say at g, nearer to E by a distance (Gg), such that

Fig. 86.



$$\frac{p}{P} = \frac{Gg}{gE} = \frac{Gg}{GE - Gg} \text{ or } Gg = \frac{p . GE}{P + p}$$

Since g is not vertically under O, the beam cannot remain at rest, but will vibrate about the perpendicular line OG, and the point C of the index fixed to the beam will describe the arc CC′, subtending the angle 2θ.

The velocity of the beam is greatest, of course, when g is vertically under O, and being proportional, as proved in the theory of dynamics, to the angle θ, is also nearly proportional to p. Hence when the deviation is small, *the greatest velocity which the beam attains may be observed as an indication of p.*

As in any other pendulum, the length of time occupied in a vibration is almost the same whether the vibration be great or small, as may easily be observed to be the case.

Fully to understand the motions of a beam, it would be necessary to determine its *moment of inertia round the axis*, which is the sum of the moments of each particle, the moment of inertia being the mass of a particle multiplied by the square of its distance from the axis. The velocity of the beam depends on the proportion of the force of stability or the force of disturbance, and the moment of inertia, which it has to overcome. Hence the force of stability alone gives a very imperfect idea of the motion of the beam, which will be slower the greater the weight in the pans, especially if the force of stability itself be not increased, as in the sixth case, by increasing the weight in the pans.

The mechanical problem of the balance is not so simple as may at first sight appear, and has not, so far as we are aware, been properly considered dynamically. The problem of the compound pendulum, will be found best treated by Poisson (Traité de Méchanique, t. ii. c. i. § 3). Euler, in the Petersburg Commentaries (x. 3), appears to have shown the statical conditions of a balance.

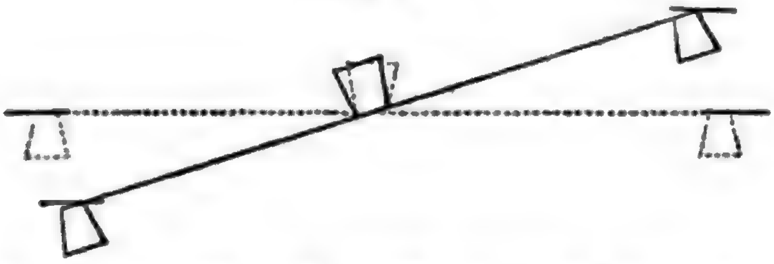
It will be apparent that, the length of the beam remaining constant, the properties of statical sensibility and stability are reciprocal to each other. By increasing the length of the beam, indeed, the balance is said to be rendered both more sensible and stable. But in reality the weight of the beam must be increased in a far greater proportion than its length, so that its motions will become much slower, to say nothing of the less convenience of a large instrument.

The construction in which the three axes are in one straight line, is undoubtedly the most perfect, and is especially suitable if the vibrations are to be used, as afterwards described, for the determination of fractional weights. But a balance in which the centre axis is slightly above the line of the extreme axes, will not become so much slower in its movements when heavily laden, and will yet indicate at least as small a fraction of its load when this is great, as when small. Hence such a balance will, we think, be suitable for most purposes. It is necessary however to bear in mind, that when the three points of suspension are not in one straight line, equilibrium may subsist when the beam is not horizontal, and the *weights in the pans are unequal*. For when the angle EON is greater than the angle E'ON', ON and ON' are unequal, and we may have equilibrium for $P' . \mathrm{ON} = P'' . \mathrm{ON}'$, where P' and P'' are unequal weights in the pans.

The truth is, that a balance must be so adjusted in its length, strength, weight, and relative position of the centres of suspension and gravity, as to combine the exact degrees of sensibility, stability, or quickness, and capacity for bearing weights, which its special employment requires. In this adjustment, the chief skill of the balance maker consists. Diminution of weight of the beam is an unqualified advantage, as long as the strength is sufficient. Thus the employment of aluminium in the construction of balances, will be of great advantage when accomplished; but an aluminium beam, which we have seen, was stated not to be trustworthy in point of strength and inflexibility.

The impediment to the free motion of a beam, is usually stated vaguely to be the *friction* at the knife edges. But although friction or adhesion may be of some importance, the variation in the length of the arms has really a much greater effect. Thus, suppose, as is generally the case, that the knife-edges, instead of being perfectly sharp or round, terminate in very narrow planes (*fig.* 87), of the width x. If the distances between the middle points of the knife edges be a, the real lengths of the two arms of the lever when the beam is not horizontal, will be $a-x$, and $a+x$, consequently weights which have the ratio of $a+x$, and $a-x$, may be apparently in equilibrium. In order then that a balance with a 20-inch beam may indicate the millionth part of its load, we must at the most have $\frac{1,000,000}{1,000,001} = \frac{a-x}{a+x}$ or $x = \frac{10}{2,000,001}$ inch; within the same length too, the two arms of the beam must be adjusted to equality if the balance is to be accurate within one millionth part of its load. Now this length, being inappreciable in a common microscope, will give some idea of the skill required in a balance-maker. We are thus prepared too for the statement of Prof. Miller (see reference below), that he not only detected a difference in the expansion of the arms of his balance by a change of temperature, owing to some difference in the quality of the metal, but that temperature also affected the sensibility of the instrument, which resembled an *over-compensated pendulum*, from the difference of expansion of the steel knife edge and the brass in which it was fixed.

Fig. 87.



The resistance of the air has but an inconsiderable effect upon a balance.

Elimination of Errors.—Since every balance however good, requires some *definite* weight to cause it to turn, a difference of this amount may exist between any two weights which are apparently in equilibrium. Thus if a balance when loaded refuse to turn with anything less than $\frac{1}{10}$ of a grain, it is an even *chance*, that two weights which do not cause the balance to move, differ by $\frac{1}{20}$ of a grain or more. In the common use of a balance, the turning-weight (*scrupulum* in Latin), will give the limit of accuracy of the weighings. Let this turning-weight be Δx; then the balance will turn when the weights $x + \Delta x$ and x are in the pans. It will also probably turn in the opposite direction when $x - \Delta x$ is substituted for $x + \Delta x$, because the balance, unless a very bad one, will turn as easily one way as the other. Thus the mean of $x + \Delta x$ and $x - \Delta x$, will be the true weight required, nearly freed from the error of insensibility. This operation may be resorted to when a balance has become insensible by age but is otherwise good, and may be very easily performed by the use of a rider weight. But the delicacy of balances is generally ahead of what is required of them. Any good balance should weigh with certainty to the $\frac{1}{100000}$ part of its load, but there are as yet few chemical operations which can pretend to an accuracy of $\frac{1}{10000}$ part.

The only other kind of error to which the determinations of a balance are essentially liable, is that caused by the inequality of the arms: for the extreme edges can never be adjusted at perfectly equal distances from the centre edge. This error is avoided entirely and without trouble, in the ordinary operations of the chemist, by taking care, during each analysis or series of experiments, to use, say the left pan invariably for the objects to be weighed, and the right pan for the weights. The apparent weights of all the objects are thus increased or diminished in precisely the same ratio, and the comparative results are therefore unaffected by the real falsity of the balance.

Thus if a be the length of the arm bearing the weight-pan, and b the length of that bearing the object-pan, then objects of the true weights, x, y, z, &c. will appear to weigh $\frac{b}{a}x$, $\frac{b}{a}y$, $\frac{b}{a}z$, but the ratios $\frac{b}{a}x : \frac{b}{a}y : \frac{b}{a}z$ are the same as $x : y : z$, the ratios of the true weights. That this elimination of error may be perfect, it is obviously necessary that no weights be placed in the object-pan, as is sometimes done, for the purpose of making up a given weight in the easiest manner by subtraction.

There are, however, two well known methods for obtaining the true absolute weight of an object, even by a false balance. The first, introduced by Gauss, proceeds by simply weighing the object alternately in one pan and the other. If the apparent weights are the same, they are each the true weight, or the balance is appreciably correct. If not, the geometric mean is the correct weight, and is found by multiplying the true apparent weights together, and taking their square root. For if the true weight be x, and a, b be the lengths of the balance arms as before, $\frac{a}{b}x$, and $\frac{b}{a}x$ will be the apparent weights in the respective pans, and $x = \sqrt{\frac{a}{b}x \cdot \frac{b}{a}x}$. If the apparent weights be very nearly equal, their common arithmetic mean $\frac{1}{2}\left(\frac{a}{b}x + \frac{b}{a}x\right)$ is quite close enough to the truth. Thus the arithmetic mean of 1·000 and 1·001 is 1·0005, and the geometric mean 1·0004998 . . . .

The second method for ascertaining absolute weights free from all error, is that known as the *method of substitution*, ascribed by French writers to Borda, but probably due to the Père Amiot. If there be one weight C in the weight-pan, and other weights X, Y, Z, &c. be in succession placed in the object-pan, and the balance is yet always in equilibrium, it is evident that $X = Y = Z = \frac{b}{a}C$. Thus we prove the perfect equality of X, Y, Z, although each of these may differ in an unknown degree from C, owing to the inequality of b and a, the lengths of the balance-arms.

To compare the weights of any two objects by this method, counterpoise the greater with the weight C, made up of shot, tin-foil, wire, or any convenient substance. Then substitute the second object for the first, and observe how many small weights must be added to the pan to restore equilibrium with C. The only errors which can affect such a result will be that of insensibility, and any error which may arise from a minute change of the edges of suspension during the substitution; but these errors may be eliminated by taking the mean result of many such operations, a new counterpoise being adjusted each time.

But when important weighings have to be made with the most rigorous accuracy, as in the comparison of standard weights, the method of vibrations must be resorted to. This being a process of pure observation, as distinguished from one of adjustment, admits of unlimited approach to absolute exactness, just as the difference of two standard yards may be ascertained to the $\frac{1}{1000000}$ part of an inch, although it would be impossible to make two yards agree within ten times that quantity.

The paper by Prof. W. H. Miller, on the Construction of the New Imperial Standard Pound (Phil. Trans. cxlvi. (1856) p. 753), should be studied by all engaged in exact determinations of weights, but a more explicit account of the method of vibrations will be found in Kupffer's work, "Travaux de la Commission pour fixer les Poids et Mesures de Russie," St. Petersburg, 1841. Prof. Miller's mode of observing the oscillations appears to be the most eligible. His balance had a very light ivory scale, about half an inch long, divided into spaces of about $\frac{1}{100}$ inch, *attached* to the right end of the beam. This scale, as it moved, was viewed through a fixed compound microscope, having a single horizontal wire in the focus of the eye-piece. A still more delicate mode of observation, is by a small mirror fixed to the beam, in which the reflection of a divided scale is viewed through a fixed telescope, as in the instruments of a magnetical observatory.

The weights to be compared being very nearly in equilibrium, the balance when released oscillates slowly through a very small arc, and the extreme points of each excursion are to be observed. Supposing the readings thus observed to be R^1, R^2, R^3, R^4. Then $\frac{R^1 + 2R^2 + 2R^3 + R^4}{6}$ is the position of equilibrium of the beam: for, by the nature of the pendulum already considered, the excursions will be as far on one side as on the other. In this expression, R^2 and R^3 are doubled, because they are the end of one half vibration and the beginning of another. Prof. Miller usually rejected the first reading because it is apt to exhibit slight irregularities, and his result was derived from $\frac{R^2 + 2R^3 + R^4}{4}$. This observation completed, a small known weight is added to the lighter of the weights compared, and the new position of equilibrium which the beam tends to take up, is observed by a new set of readings. Now the deviation from the horizontal position in a good balance being very nearly proportional to the weight causing it, we obviously learn from the angular difference of the two positions of the beam, the deviation corresponding to a given small weight. Hence we learn by the simplest calculation the difference of weight corresponding to the deviation in the first observation.

The method of weighing by reversal was found more convenient by Prof. Miller, than that by substitution, and was thus practised.

The nearly equal weights P and Q to be compared, were weighed directly against each other, but repeatedly reversed, and the balance was so adjusted by a small constant weight placed in one of the pans or on the beam, that on interchanging P and Q, the position of equilibrium was still near the middle of the scale. Then if (P, Q) be the reading of the scale in the position of equilibrium when P is in the left hand pan, and Q in the right hand pan, and (Q, P) the reading when Q is in the left hand pan, and P in the right hand pan; then $2Q = 2P + m((P, Q) - (Q, P))$, where m is the weight equivalent to one degree of deviation on the scale.

In the determination of the equivalents of the elements, and in many physico-chemical determinations, it is to be hoped that chemists will soon have to tax to the utmost these refined methods of weighing.

On the balance generally, the reader may further consult Biot, Traité de Physique, i. 9; Pouillet, El. de Phys. i. 66; Ann. de Chim. xxxvi. 3; Jury Reports on the Exhibition of 1851, pp. 257—262; Phil. Trans. cxvi. pt. 2, p. 36. For a description of Napier's "Automaton-balance" for weighing coin, see *Ure's Dictionary of Arts, Manufactures and Mines*, i. 245. W. S. J.

BALLUS, or BALAIS RUBY. A variety of spinelle, varying in colour from reddish-white to pale red.

BALLESTEROSITE. A variety of iron pyrites, found in Asturia and Gallicia, Specific gravity 4·75 to 4·90.

BALLOON. Receivers and flasks of spherical form are sometimes called balloons.

BALSAM. This term, originally confined to a single substance, viz. Balm of Gilead, Mecca Balsam, or Balsam of Judea, is now extended to a variety of products, more or less resembling that body, but exhibiting considerable diversity of composition and properties. They are viscid, aromatic liquids, which exude from growing plants, either spontaneously, or from incisions made for the purpose.

Balsams are mixtures of resins with volatile oils, the resins being produced from the oils by oxidation, so that a balsam may be regarded as an intermediate product between a volatile oil and a perfect resin. They may be divided into two groups, the one including those of purely oleo-resinous character, viz. *Copaiba balsam*, *Mecca bal-*

sam, and the *balsams* or *turpentines* of coniferous plants; the other group, including those which contain cinnamic acid, such as *Peru balsam*, *Tolu balsam*, *Liquidambar*, and *Storax*. Benzoin and Dragon's-blood are sometimes also classed among balsams; but they are more properly resins; the true balsams are liquids more or less viscid, and yield volatile oils by distillation with water. The balsams of the second group yield by dry distillation, cinnamate or benzoate of ethyl or methyl, and according to Scharling, these products, or perhaps others not previously existing in the balsams, may be formed from them by the action of aqueous alkaline leys.

Balsams of the First Group: Oleo-resins.

CANADA BALSAM or **CANADIAN TURPENTINE**, *Baume du Canada*, is the produce of *Abies balsamea* (Dec.), a coniferous tree growing in Canada, Virginia, and Carolina. It collects in vesicles under the bark, and is obtained by making incisions in the stem. It is either colourless or slightly yellowish, rather mobile, but tenacious and capable of being drawn into threads, turbid when fresh, but soon becomes perfectly transparent when left at rest. It turns the plane of polarisation of a luminous ray to the right, and has an index of refraction equal to 1·532. It dries up to a hard varnish when exposed in thin layers to the air for about forty-eight hours, and gradually thickens, even in closed vessels. Its power of hardening, its transparency, and its peculiar refractive power, which is nearly the same as that of crown glass, renders it very useful as a cement in the construction of optical instruments. In some countries it is used as a medicine; when taken internally, it imparts a nutmeg odour to the urine.

Canada balsam distilled with water, yields a volatile oil, of balsamic odour, agreeing in composition with oil of turpentine (Wirzen), and like that oil, turning the plane of polarisation to the left (Biot); it also leaves a resinous cake, brittle after cooling, and consisting of a mixture of several substances. The balsam is partially soluble in alcohol, a granular resin remaining undissolved.

Canada balsam contains, according to Bonastre (J. Pharm. viii. 572 [1822]), 18·6 per cent. volatile oil, 40·0 resins easily soluble in alcohol, 33·0 resin sparingly soluble in alcohol, together with 8·4 caoutchouc and bitter extractive matters soluble in water. The sparingly soluble resin is described as dry, friable, heavier than water, difficult to melt, and becoming electrical by friction. According to Caillot (J. Pharm. xvi. 436 [1830]), the balsam contains two neutral resins, one called *abietin* (see p. 1), being crystallisable and easily soluble in alcohol of 0·824, the other white, pulverulent, without crystalline form, very little soluble in alcohol of 0·824, or in rock oil, or potash-ley, and closely resembling the sparingly soluble resin obtained from other species of abies; also an acid resin, which forms a coherent paste when mixed with $\frac{1}{10}$ of its weight of magnesia, and imparts to Canada balsam the property of forming a white soap with potash. According to Wirzen (*De balsamis et præsertim de balsamo Canadense Dissertatio*, Helsingforsææ, 1849), Canada balsam contains 16 per cent. of volatile oil, 30 pts. of a resin α, soluble in boiling alcohol of 0·833, and containing $C^{40}H^{62}O^4$ (78·31 per cent. C and 10·08 H), 33 pts. of another resin β, insoluble in hot alcohol, but soluble in ether, and containing $C^{40}H^{60}O^5$; and, lastly, 20 pts. of a resin γ, insoluble in alcohol and ether. Wirzen's α resin is probably a mixture of abietin with an acid resin.

A balsam exactly resembling the preceding, excepting that it has a darker colour, is obtained from *Abies canadensis* (Link). Canada balsam is distinguished from all other varieties of turpentine by its peculiar odour, its perfect transparency and ductility, and the facility with which it hardens when exposed to the air. Strasburg turpentine, from *Abies pectinata*, which very much resembles it, is distinguished by its optical lævo-rotatory power; and Venice turpentine (from *Larix europæa*), by its easy and complete solubility in alcohol of ordinary strength, and its indifference towards calcined magnesia.

The other balsams, or turpentines, derived from coniferous plants, will be described in the article TURPENTINE.

COPAIBA or **COPAIVA BALSAM.** *Balsamum Copaivæ*, *Baume de Copahu.*—This balsam is produced by several species of *Copaifera* (order *Cæsalpineæ*), particularly by *Copaifera bijugal*, Willd., *C. multijuga*, Hayne, *C. Guianensis*, *C. Langsdorfii*, and *C. Jacquini*, Desf., which are indigenous in Brazil, Peru, Mexico, and the Antilles. It is obtained by making incisions or perforations in the trees during rainy weather, and flows so abundantly that a single incision often yields 12 pounds of the balsam.

Copaiba balsam consists of several resins dissolved in a volatile oil, the amount and nature of the resins varying considerably in balsam from different sources. There are three principal varieties, the Brazilian, the Antillian and the Columbian.

Brazilian copaiba is light yellow, generally transparent, of various degrees of consistence, from mobile to syrupy, and of specific gravity ranging from 0·920 to 0·985. It has a peculiar, aromatic, disagreeable odour, and a persistently bitter and irritating taste. By exposure to the air, it becomes darker in colour, of the consistence of turpentine, heavier than water, and ultimately solid and inodorous. When heated in contact with the air, it takes fire and burns with a bright, but very smoky flame. The balsam from the Antilles differs from the Brazilian by its more viscid consistence, darker colour, imperfect transparency, and turpentine-like odour. Columbian copaiba is distinguished by its turbidity, arising from suspended particles of resin, which are deposited as a crystalline crust when the balsam is left at rest.

The chemical examinations hitherto made of copaiba balsam relate chiefly to the Brazilian, of which two varieties are distinguished.

I. *Copaiba balsam chiefly containing acid resins.*—This variety, which was formerly the only one known, is distinguished by the following characters:—It is insoluble in *water*, but imparts to the water its taste and smell. It dissolves in all proportions in *absolute alcohol*, in *ether*, and in *oils*, both fixed and volatile; the alcoholic solution, however, is often rendered turbid by the separation of resinous flakes. Alcohol of 90 per cent. dissolves a large quantity of it; alcohol of 80 per cent. only $\frac{1}{10}$ to $\frac{1}{2}$ of its own weight. Mixed with an equal weight of fixed oil, it dissolves in 2 pts. of 90 per cent. alcohol, the fixed oil separating only on the addition of a considerable quantity of alcohol. It absorbs *chlorine gas*, becoming turbid at the same time, from formation of hydrochloric acid. With *strong sulphuric acid*, it assumes a red colour and viscid consistence, with evolution of sulphurous anhydride, and an odour of oil of amber. *Strong nitric* acid acts upon it with violence; dilute nitric acid more quietly, forming a hard yellow resin, which dissolves partially in the acid, and a yellow bitter substance insoluble in water and in alcohol. Distilled with 2 or 3 per cent. of its weight of strong *sulphuric acid* or with *hypochlorite of calcium*, it yields a volatile oil of fine blue colour (Löwe, Pharm. J. Trans. xiv. 65); the same oil is said to be produced by the action of acid chromate of potassium. Three pts. of the balsam mixed with 1 pt. of *potash-ley* containing $\frac{1}{8}$ pt. of hydrate of potassium, yield a clear liquid, which does not lose its transparency when mixed with alcohol or with a small quantity of water, but becomes milky on addition of a large quantity of water. A larger quantity of caustic potash-ley added to the clear liquid, throws to the surface a transparent copaiba-soap, which forms a turbid solution with a large quantity of water, or with absolute alcohol, but dissolves completely in ether or in hydrated alcohol. When an alcoholic solution of the balsam is mixed with dilute potash or soda-ley, a volatile oil rises to the surface, while the resulting compound of resin and alkali remains dissolved in the hydrated alcohol. This process may be used for the preparation of the volatile oil. Five pts. of the balsam form with 2 pts. of aqueous *ammonia* of specific gravity 0·921, a clear mixture, from which a larger quantity of ammonia separates a soapy compound. A mixture of 9 pts. of the balsam and 2 pts. aqueous ammonia well shaken up and left at rest at + 10° C., gradually yields a crystalline deposit, consisting of the resinous acid of the balsam. The balsam likewise combines readily with *magnesia*. It dissolves completely $\frac{1}{30}$ of its weight of calcined magnesia, and when mixed with $\frac{1}{16}$ of its weight of that substance, thickens to a stiff paste in the course of a few days; with $\frac{1}{8}$ in a few hours. Similarly with *quick lime*. Carbonate of magnesium likewise forms with 4 pts. of the pure balsam at mean temperatures (15° C. or 60° F.), a clear viscid solution.

The balsam distilled with *water* yields a volatile mobile oil, C^5H^8, possessing in a high degree the peculiar odour of the balsam, and forming a crystalline compound with hydrochloric acid (see COPAIBA OIL), while in the retort there remains a mass of brittle resin, which is resolved by treatment with rock-oil, into a crystallisable portion soluble in that liquid (the α resin of Berzelius), and an insoluble unctuous substance (β resin of Berzelius). The crystallisable resin has the formula $C^{20}H^{30}O^2$, and from its property of reddening litmus and uniting readily with acids, is called *copaivic acid*. The crystalline deposit which separates from the turbid balsam, is, according to Fehling's investigation, a resinous acid containing $C^{20}H^{28}O^3$. It is to these two resins that the peculiar reactions of the balsam with bases are due. The soft resin is, perhaps, formed by oxidation of the volatile oil in the air, and appears to have but a very slight affinity for bases, inasmuch as when isolated it dissolves but slowly, and only, with the aid of heat, in potash and ammonia, forming a turbid solution. (See COPAIBA RESINS.)

Besides these essential constituents, the balsam likewise contains occasionally a small quantity of water, and, according to Durand, small quantities of extractive matter, acetic acid (perhaps also succinic acid), and a fatty substance, which remains behind when the balsam is dissolved in alcohol of specific gravity 0·842; also traces of chloride of calcium. The following are analyses of this variety of copaiba balsam:

	Stoltze.*	Guibourt.†	Gerber.‡ Fresh balsam.	Gerber.‡ Old balsam
Volatile oil	38·00	45·0	41·0	31·97
Alpha-resin	52·75	53·9	51·38	52·68
Beta-resin	1·66	1·1	2·18	11·15
Water and loss	7·59		5·44	4·10
	100·00	100·0	100·00	100·00

II. *Copaiba Balsam, containing only neutral resins.* PARACOPAIBA BALSAM.—This variety, which is of recent introduction, is distinguished from the former by its much greater mobility. In odour and taste it agrees with the preceding, but, according to Posselt (Ann. Ch. Pharm. lxix. 67), behaves in a totally different manner with solvents and with bases. With alcohol, in any proportion, it forms a turbid mixture. Potash and ammonia also form with it turbid liniments, which, when left at rest, deposit the balsam in its original state. It does not thicken with magnesia. The volatile oil, *paracopaiba-oil*, which it yields by distillation with water, is distinguished from the copaiba-oil above-mentioned, by its viscidity, its sparing solubility in absolute alcohol, and especially by not forming a crystalline compound with hydrochloric acid. The resinous cake, brittle in the cold, which remains after the volatile oil has been distilled off, is resolved by cold alcohol into a soluble portion, which separates on evaporation of the alcohol, in drops that gradually solidify in amorphous masses, and another resin, which dissolves only in boiling alcohol and in ether, is difficult to fuse, and likewise uncrystallisable. Neither of these resins exhibits any acid reaction in the state of solution, or forms compounds with bases (see COPAIBA RESINS). One hundred pts. of the Brazilian balsam examined by Posselt, contained 82 pts. of volatile oil, and 18 pts. resin, the greater part of which was soluble in cold alcohol.

The two varieties of copaiba balsam just described, the first of which, from its behaviour with magnesia, is called *solidifiable balsam*, must be regarded merely as types—which are, perhaps, not the only ones—and may vary greatly in the proportion of oil and resin, and therefore in consistence. Oberdörffer (Arch. Pharm. [2] xlv. 172) found in three varieties of mobile copaiba balsam of the first variety:

	I.	II.	III.
Volatile oil	60	58	54
Resins	40	42	46

The following proportions of oil and resin have been found in several balsams of unknown origin:

	Ulex.§	Stockhardt.‖		Procter.¶				
	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.
Specific gravity	0·928			0·916	0·956	0·983	0·985	0·986
Volatile oil	90	58	56·5	80	65	50	35	34
Resins	11	42	43·5	20	35	50	65	64

The amount of volatile oil was estimated either by the loss of weight which the balsams suffered by boiling with water (I. to VI.), or by continued heating to 120° C. (248° F.), till the weight remained constant (VII. to XI). The balsams IV. to VI. were mobile and are not further distinguished; VII. and VIII. are mobile balsams of the second variety; IX. to XI. viscid balsams of the first variety.

According to Procter, the proportion of oil varies with the age of the trees, the youngest trees yielding the most liquid balsam. The acid resins appear to be formed in the plant itself, while the soft resin (β resin) is produced by the oxidation of the volatile oil, and consequently increases in amount with the age of the balsam, especially when it is kept in loosely closed vessels; this is in accordance with the results of Oberdörffer's analyses just quoted.

Copaiba balsam is used in the preparation of lac-varnishes and tracing paper; but its chief application is in medicine, as a remedy in diseases of the urinary passages. It is not known with certainty to which constituent of the balsam the peculiar physiological action is due; but it does not appear to reside especially in the volatile oil; for in many places, the resin completely freed from oil is successfully used in medical practice, instead of the balsam in its original state. Whether the more oleaginous variety, containing only neutral resins, which is of recent introduction, is capable of exerting the same action as the more viscid and acid variety, which has long been in use, is not yet known.

Copaiba balsam is often adulterated, especially with fixed oils and turpentines. Of

late years East Indian *wood-oil* (also called *Gurjun balsam*, or *capivi*), which closely resembles copaiba balsam in taste and smell, has been introduced as a substitute for it. This oil may be easily distinguished by its property of becoming gelatinous when heated to 130° C. (268° F.), whereas pure copaiba balsam becomes more fluid when heated.

The presence of fixed oils in copaiba balsam may be detected by the following methods:—1. By placing one or two drops of the balsam on paper, and evaporating it at a very gentle heat. The pure balsam then leaves a hard, sharply defined varnish-like spot, whereas if any fixed oil be present, the spot is soft and surrounded with a circle of fat (Berzelius).—2. The pure balsam, boiled for some hours with water in an open vessel, leaves a resin which becomes brittle on cooling: fixed oils render this residue soft or greasy.—3. The fixed oils remain behind when the balsam is dissolved in 8 pts. of alcohol of 90 per cent. (a smaller quantity of alcohol of that strength would leave some of the balsam undissolved, p. 493). This last method will not indicate the presence of castor-oil, which is itself soluble in alcohol; neither will it detect the presence of less than 10 per cent. of other fixed oils. Turpentine and oil of turpentine may be recognised by their odour, especially when the balsam is dropped upon a metal plate.

All other methods of testing copaiba balsam are founded on the amount of acid resins contained in it, and relate to the first variety (p. 493). This officinal balsam may be regarded as genuine when, besides exhibiting the characters above mentioned (p. 493), it forms a clear or nearly clear solution with alcohol, yields by distillation with water, not more than 45 per cent. of volatile oil; forms a clear solution with $\frac{3}{8}$ of its weight of aqueous ammonia of specific gravity 0·921, and when mixed with $\frac{1}{16}$ of its weight of calcined magnesia, gradually forms (in twenty-four to forty-eight hours) a plastic paste. (Handwört. d. Chem. 2te Aufl. ii. 634.)

Mecca Balsam or Balm of Gilead. *Opobalsamum verum s. gileadense. Baume de la Mecque, de Judée, ou du Caire.*—This balsam is the produce of the *Balsamodendron gileadense* or, *Amyris gileadensis*, a shrub belonging to the terebenthaceous order, native of Arabia Felix. There appear to be three varieties of it. The finest, which is used only in the East, and has a peculiarly fragrant odour, is said to exude from the flowers in clear colourless drops. An inferior sort exudes spontaneously, or from incisions in the young branches of the plant. It is mobile, pale yellow, turbid like almond syrup, has a very agreeable odour like rosemary and lemon, and a bitterish sharp taste. When exposed to the air, it gradually hardens and loses its transparency. The third sort, which is the most common, is obtained by boiling the wood and the branches with water. It is somewhat more viscid than balsam of copaiba, becomes white and soapy when rubbed in the hand, and when dropped upon water, forms a film which is easily removed by a quill feather. Ordinary spirit of wine dissolves it but partially, and leaves a transparent odorous substance, of which warm alcohol of specific gravity 0·815 dissolves about two-thirds. The residue is a flocculent substance, which may be drawn out into threads.

Trommsdorff (Trommsd. Neues Journal, xvi. 62) found in a sample of this balsam, 30 per cent. of volatile oil, 64 per cent. of hard resin, 4 per cent. of soft resin, and 0·4 per cent. of bitter principles. The *volatile oil* was mobile, colourless, fragrant, and had a rough taste; dissolved in alcohol and ether, and with deep red colour in sulphuric acid, whence it was precipitated by water as a resin. It was also resinised by nitric acid. The *hard resin* was honey-yellow, transparent, brittle, of specific gravity 1·333, softened at 44° C., and melted completely at 90°. It dissolved with difficulty in alcohol and ether at ordinary temperatures, easily with aid of heat; it was likewise soluble in oils, both fixed and volatile. It was altered by hot nitric and sulphuric acids, and appeared to combine with alkalis, forming compounds insoluble in free alkali. The *soft resin* was brown and very glutinous, inodorous and tasteless; melted, when dry, at 112° C. It was insoluble in alcohol and ether, but soluble in oils, both fixed and volatile. It was not attacked by alkalis or by strong sulphuric acid; with nitric acid, it swelled up and became friable.

According to Bonastre (Ann. Ch. Pharm. iii. 147), Mecca balsam contains in 100 pts.:

Fragrant volatile oil	10 pts.
Brown bitter extract, soluble in water and alcohol	4 „
Acid resin, soluble in alcohol, and not hardening	70 „
Stiff whitish-grey resin, sparingly soluble in alcohol . . .	12 „
Acid substance and impurities	4 „

Mecca balsam was formerly used in medicine, but has now fallen into disuse on account of its scarcity and dearness. In the East it is used internally as a tonic.

Balsams of the Second Group, containing Cinnamic Acid.

Liquidambar Balsam is the produce of *Liquidambar styraciflua*, a large tree growing in Louisiana, Florida, and Mexico. There are two varieties of it, viz.:

1. *Liquid liquidambar*, or *Oil of liquidambar*, which is obtained by making incisions in the tree, receiving the balsam immediately, in vessels which protect it from the action of the air, and afterwards decanting the liquid from a portion of opaque balsam, which settles to the bottom. It is a thick transparent oil of amber-yellow colour, has an odour like that of liquid storax, but more agreeable, and an aromatic taste, which irritates the throat. It contains a rather large quantity of benzoic or cinnamic acid, and reddens litmus paper strongly. Boiling alcohol dissolves it, with exception of a slight residue, and the filtered liquid becomes turbid on cooling.

2. *Soft* or *white liquidambar* is formed from the preceding by exposure to the air, as when it runs down the stem of the tree and is left there to thicken. It resembles very thick turpentine or soft pitch, is opaque and whitish, has a less powerful and more agreeable odour than the preceding, and a sweet, perfumed, but irritating taste. It contains a large quantity of benzoic or cinnamic acid. By continued exposure to the air, it solidifies completely, and becomes nearly transparent. It was formerly sold as white Peru balsam. (Gerh. iii. 386.)

Peru Balsam. *Balsamum peruvianum; Bals. indicum.*—This balsam is the produce of certain species of *Myroxylum*, or *Myrospermum*, growing on the Balsam coast near San Sonate, in the state of San Salvador, Central America. There are three varieties of it:

1. White Peru balsam.—Obtained from the fruit of the tree by removing the wings and the outer and middle integuments, and subjecting the inner coating, together with the seed, to pressure. The balsam thus obtained is pale yellow, somewhat thick, turbid and granular, and has an agreeable odour of melilot. When left at rest, it deposits a solid crystalline layer. Cold alcohol or ether dissolves it but imperfectly; the same liquids when hot dissolve the greater portion. The alcoholic solution, when left at rest, deposits crystals of myroxocarpin (*q.v.*), of which also the crystalline sediment above mentioned appears to consist. The ethereal extract of the balsam leaves when evaporated a mixture of resin and fixed oil. The balsam distilled with water, yields traces of a volatile oil and a volatile acid (Scharling). According to Guibourt, there is another kind of white Peru balsam, which is identical with liquidambar.

2. Dry Peru balsam, *Balsamum peruvianum siccum*, *Opobalsamum siccum*, is said to be produced from the preceding by hardening in contact with the air. According to Weddell, it exudes spontaneously from the stem of a myroxylum. It is reddish-yellow, translucent, hard, smells aromatic and like vanilla, melts when heated, and burns with a smoky flame; 100 pts. of it contain, according to Tromsdorff, 12 pts. benzoic (more probably cinnamic) acid, 0·2 volatile oil, and 88·0 resin.

3. Black Peru balsam. Black balsam of San Salvador or San Sonate. *Balsamum peruvianum s. indicum nigrum. Baume de Pérou noir.* This, which is the ordinary Peru balsam, has been known in Europe since 1580. It is said to be obtained by making incisions in the stem of the trees, partially detaching a portion of the bark in such a manner as to leave it still connected with the stem at the upper part, then thrusting woollen rags between the bark and the wood, and warming the tree by making a fire round it. Fresh incisions are then made higher and higher up, till the rags are saturated, the process occupying ten or twelve days. The cloths impregnated with balsam are then removed, and well boiled with water, and the balsam which sinks to the bottom is freed from water, which it retains somewhat firmly, by several hours boiling under water. It is then further purified by straining, and sent to Europe by way of Peru, whence its name. (Copious details of the history and preparation of this balsam, are given in *Muspratt's Chemistry*, i. 228; see also *Ure's Dictionary of Arts, Manufactures and Mines*, i. 248.)

Black Peru balsam is viscid but not glutinous, of dark brown colour, opaque in the mass, but in thin layers perfectly transparent, with brown-red colour. Specific gravity 1·15. In contact with the air, it gradually thickens, but does not solidify. It has an agreeable odour, like vanilla, a bitter, persistently irritating taste, and an acid reaction, 1000 parts of the balsam saturating about 75 of carbonate of sodium.

When heated, it takes fire and burns with a smoky flame. When distilled with water, it does not yield any volatile oil, but the distillate contains cinnamic acid, which exists in the balsam in the free state, and may be extracted by repeated boiling with water, or by carbonate of sodium. Peru balsam mixes in all proportions with *absolute alcohol*; but the solution is not quite clear, and deposits a flocculent substance when left at rest. Weaker alcohol dissolves it less easily, and leaves a residue of resin. It is also but incompletely soluble in *ether* and in *oils*, whether fixed or volatile. It mixes without turbidity with ⅛ of its weight of fixed oil, or with ¼ of its weight of balsam of copaiba; but if a larger quantity of either of these liquids be added, two layers are formed. *Sulphuric acid* converts it into a thick red mass, with evolution of sulphurous acid; *nitric acid* acts upon it only when heated, giving off nitrous fumes and hydrocyanic acid; after the evaporation of the mixture, there remains a brownish-yellow bitter substance, soluble in water. When 2 volumes of the balsam are gently heated with 3 volumes of *potash-ley*, of specific gravity 1·3, two layers of liquid are formed, the upper consisting of a brownish oil (oil of Peru balsam), and the lower, which is watery, containing cinnamic acid, resins, and colouring matters in combination with potash. 4 pts. of the balsam form a soapy mixture with 1 pt. hydrate of potassium and 1 pt. of water. When subjected to *dry distillation*, it begins to boil at 287° C. and yields, with continual rise of temperature, an oil coloured by products of decomposition, while a porous charcoal remains in the retort.

Black Peru balsam has been repeatedly analysed. The earliest examination of it was made in 1824, by Stoltze (Berliner. Jahrb. f. Pharm. xxv. 24), who found in 100 pts. 69·0 pts. of a peculiar volatile oil, 6·4 of acid (supposed at the time to be benzoic acid, but really consisting of cinnamic acid), 20·7 resin easily soluble in alcohol, 2·4 resin sparingly soluble in alcohol, 0·6 extractive matter, and 0·9 moisture.

According to Fremy (Ann. Ch. Phys. [2] lxx. 180), the balsam is composed of variable quantities of a volatile oil (*cinnamein* or *styracin*), a crystallisable substance (*metacinnamein*), isomeric therewith, *cinnamic acid*, and *resin*. On dissolving the balsam in alcohol, and adding alcoholic potash, the resin is precipitated in combination with potash, while the cinnamein remains dissolved, and may be precipitated by water, the cinnamic acid still remaining in solution. The oil is purified from resin by solution in rock-oil and evaporation; by exposing it to a low temperature, and redissolving in weak alcohol, the crystalline metacinnamein, which however is not always present, is separated (see CINNAMEIN). The resinous portion of the balsam appears to be a mixture of several distinct resins, one of which agrees in composition with the resin produced from cinnamein by the action of sulphuric acid; another differs from that just mentioned merely by containing a smaller amount of the elements of water. Fremy therefore regards cinnamein and metacinnamein as the original constituents of Peru balsam, the cinnamic acid as a product of oxidation, and the resins as hydrates of cinnamein. This view explains the variation in constitution of the balsam with age; also the fact that cinnamic acid is still present in the balsam after it has been boiled with water, and increases in quantity with the age of the balsam.

For Plantamour's results, which agree with those of Fremy, so far as regards the presence of cinnamein and cinnamic acid, see Ann. Ch. Pharm. xxvii. 329; xxx. 347. According to Scharling (*ibid.* xcvii. 168), the cinnamein obtained from different samples of Peru balsam is not of constant composition; but the formulæ which he assigns to them are improbable.

The resin of Peru balsam mixed with pumice and subjected to dry distillation, yields benzoic acid, together with an oily and a watery distillate. On distilling the former by itself, a lighter oil passes over at 175° C., and afterwards a heavy liquid, which sinks to the bottom. The light oil, repeatedly rectified with potash-ley, and finally over hydrate of potassium, yields pure cinnamene, C^8H^8. The heavier liquid appears to consist of benzoate of methyl and phenic acid: when distilled with potash-ley, it yields wood-spirit. (Scharling, *loc. cit.*)

Black Peru balsam is used in medicine as an application to wounds, and also as an internal remedy. It is also used in perfumery, and in the preparation of chocolate, as a substitute for vanilla. The white and dry balsams (p. 496) are scarce, and have not received any practical application.

Adulterations in Peru balsam may be detected as follows: *Fixed oils* remain undissolved on treating the balsam with strong alcohol; *volatile oils* lower the boiling point, and pass over on distilling the balsam with water; *copaiba balsam* and *turpentine* may be recognised by the odour which they give out when heated; also by yielding volatile oils on distillation with water; *sugar* and all substances soluble in water, by the diminution of volume which the balsam so adulterated undergoes when shaken up with water; syrup of sugar also renders the balsam turbid.

STORAX BALSAM.—This balsam is the produce of *Styrax officinalis*, a shrub growing in the Levant, Palestine, Syria, and Greece. It is imported into Europe from Trieste. There are two principal varieties of it, *Styrax liquidus*, and *Styrax calamita*.

a. *Liquid storax.*—This variety is sometimes transparent, of brownish-yellow colour, of the consistence and tenacity of Venice turpentine, and has a peculiar sweetish or vanilla-like odour; sometimes opaque, with grey colour, the consistence of bird-lime, and a strong oppressive odour, slightly mixed with that of benzene or naphthalene. Liquid storax is a mixture of styrol, cinnamic acid, styracin, and resins.

b. *Reed storax, Styrax calamita.*—This is imported in compact masses of fragrant odour and rich brown colour, interspersed with white tears, whence it has also been called *amygdaloïd storax*. According to Reinsch, it contains about 0·5 per cent of volatile oil, 33 to 54 per cent. resin, 1·1 to 2·6 benzoic acid, 8 to 14 gum and extract, 9·6 to 24 matter extracted by potash, 20 to 27 woody fibre, 5 water, and traces of ammonia. The drug sold under this name is, however, of very variable composition, often consisting of nothing but saw-dust or decayed wood, impregnated with coal-tar, or some similar substance, and bearing no resemblance whatever to the genuine storax.

Storax is used in medicine, as a stimulating expectorant, its operation being analogous to that of Peru balsam or benzoin. It is also used as a detergent, in the form of ointment. (Muspratt's Chemistry, i. 225.)

Tolu Balsam.—This balsam is obtained in large quantity from incisions in the stem of the *Myrospermum toluiferum* (Sprengel), *Myroxylum toluiferum* (Richards), a tree growing in various districts of Columbia, viz. in the mountains of Turbaco and Tolu, and on the Magdalena River. In the fresh state it is yellowish, transparent and liquid, like turpentine (*white tolu-balsam*) but changes rather quickly by keeping, acquiring a reddish-brown colour and stiff consistence (*black tolu-balsam*), and being ultimately converted into a friable substance of granular crystalline structure (*dry tolu-balsam*). It has an aromatic odour, like that of lemon and jasmine, and a sweetish, aromatic, somewhat irritating taste. It melts at a gentle heat; dissolves readily and completely in *alcohol*; less readily in *ether* and in *volatile oils*; not completely in *fixed oils*. Hot *water* extracts from it cinnamic acid (and, according to Deville and Scharling, likewise benzoic acid), together with volatile oil. Heated with strong *sulphuric acid*, it forms a red solution without giving off sulphurous acid. With *potash-ley* of specific gravity 1·17, it forms a clear solution having an odour of violets, and with drops of oil floating on the surface.

Tolu balsam is a mixture of volatile oil, free acid, and resin. The *volatile oil* is obtained by distilling the balsam with water, the quantity being always small, but varying according to the age of the balsam. Deville obtained 0·2 per cent., Scharling 1 per cent., and, by afterwards passing steam heated to 170° C. through the balsam, 0·2 per cent. more. This oil is, according to Deville, a mixture of *tolene*, $C^{12}H^{18}$, passing over betweeen 160° and 170° C., and *cinnamein*, $C^{16}H^{14}O^{2}$, which distils between 340° and 350° C. According to E. Kopp and Scharling, on the other hand, the oil consists wholly of tolene, which, according to Kopp, is isomeric with oil of turpentine, $C^{10}H^{16}$. The small quantity of volatile oil contained in Tolu balsam, and the rapidity with which it hardens by exposure to the air, are characters by which it is readily distinguished from balsam of Peru.

The free acid of Tolu balsam consists, according to Deville and Scharling, of *cinnamic* and *benzoic* acids; according to Fremy and E. Kopp, of cinnamic acid only. The balsam boiled with water, yields a solution which, on cooling, deposits crystals chiefly of cinnamic acid (Deville). The oil obtained by distilling the balsam with water, and cohobating the distillate several times, deposits benzoic acid when exposed to the air (Deville). Benzoic acid is likewise extracted, together with cinnamic acid, by treating the balsam with aqueous carbonate of sodium, or caustic potash, adding chloride of calcium to precipitate the resins, and supersaturating the filtrate with hydrochloric acid (Deville, Scharling). E. Kopp is of opinion that the benzoic acid is a product of decomposition, and does not pre-exist in the balsam.

Resins.—According to E. Kopp, Tolu balsam contains two resins, an α resin, easily soluble in alcohol, and a β resin, $C^{18}H^{20}O^{5}$, sparingly soluble in alcohol.

The α resin, $C^{18}H^{19}O^{4}$, according to Kopp, but more probably $C^{18}H^{18}O^{4}$, as suggested by Gerhardt (Traité, iii. 408), is obtained by treating the balsam with cold alcohol, after it has been freed from volatile oil and cinnamic acid by distillation and boiling with water. It is brown, translucent, and shining; friable in the cold; but the powder cakes together even at + 15° C., and the resin melts at 60° C. Strong sulphuric acid colours it purple-red. When dissolved in potash-ley, and exposed to the air, it oxidises readily, and is converted into β resin. By dry distillation it yields toluene and benzoic acid.

The β resin, $C^{18}H^{20}O^{5}$, is brownish, dull, and without taste or smell; melts at a temperature above 100° C. It is sparingly soluble in alcohol and ether, dissolves with brown colour in potash-ley, and is precipitated with violet colour by sulphuric acid. It is more permanent than the α resin.

The mixture of the two resins, treated with nitric acid, yields a number of volatile and gaseous products, consisting of carbonic anhydride, nitrous anhydride, nitric oxide, bitter-almond oil, hydrocyanic acid, and a small quantity of benzoic acid, and there remains a yellow mass, consisting of benzoic acid and a yellow resinous colouring matter, which prevents the benzoic acid from crystallising till it has been separated by sublimation. The resin thus treated yields about a third of its weight of pure benzoic acid.

According to Deville, Tolu balsam contains only one kind of resin, which has the composition of the β resin just described. To extract it, Deville dissolves the balsam in potash largely diluted with water, saturates the liquid with carbonic acid gas, whereby a small quantity of resin is precipitated, then adds chloride of calcium, which precipitates the carbonic acid and the rest of the resin as calcium-salts, leaving benzoic and cinnamic acids in solution. The rose-coloured mass, left after filtration, is then treated with hydrochloric acid, which dissolves out the lime and leaves the resin, and the latter is purified by solution in a small quantity of alcohol and precipitation by water. It then forms a rose-coloured powder, having a faint odour of vanilla, soluble in alcohol and in potash, very hygrometric, and varying considerably in colour from the effect of atmospheric influences, and perhaps also of light. Treated with fuming nitric acid, it takes fire and burns as in oxygen. By dry distillation, it yields a small quantity of water, benzoic acid, toluol, benzoate of ethyl, and a mixture of carbonic oxide and carbonic anhydride. (Deville.)

Scharling finds that, when the resins of Tolu balsam are mixed with half their weight of powdered pumice, and covered in the retort with a layer of pumice, the process of dry distillation goes on quietly and without tumefaction. 16 pts. of the resin heated in this manner, ultimately to redness, yield 2 pts. of a watery, and 5 pts. of an oily liquid, which is heavier than water, and is resolved by fractional distillation into toluol, phenic acid, and a portion boiling above 198° C. The latter was not obtained of constant boiling point, and yielded by analysis numbers intermediate between the composition of benzoate of ethyl, $C^7H^5(C^2H^5)O^2$, and benzoate of methyl, $C^7H^5(CH^3)O^2$. When distilled with potash, however, it yielded only methylic alcohol, without any common alcohol; hence it appears that the products of distillation of the resins are toluene, phenic acid, and benzoate of methyl.

The mode of formation of Tolu balsam is not known with certainty. If we regard cinnamein as the primary constituent, the resins α and β may be formed from it by absorption of oxygen and water:

$$\underset{\alpha\ \text{resin.}}{C^{18}H^{18}O^4} = \underset{\text{Cinnamein.}}{C^{18}H^{16}O^2} + O + H^2O$$

$$\underset{\beta\ \text{resin.}}{C^{18}H^{20}O^5} = C^{18}H^{16}O^2 + O + 2H^2O$$

or the α resin may be converted by oxidation into the β resin and cinnamic acid:

$$\underset{\alpha\ \text{resin.}}{2C^{18}H^{18}O^4} + O = \underset{\beta\ \text{resin.}}{C^{18}H^{20}O^5} + \underset{\substack{\text{Cinnamic}\\ \text{acid.}}}{2C^9H^8O^2}$$

Lastly, the β resin may split up into benzoic acid, water, and a hydrocarbon:

$$C^{18}H^{20}O^5 = 2C^7H^6O^2 + H^2O + C^4H^6$$

which hydrocarbon is supposed by E. Kopp to give rise to the formation of tolene. Scharling, on the other hand, supposes that all the constituents of the balsam are formed from tolene, inasmuch as this body, when exposed to the air, quickly becomes resinous and acquires an acid reaction. It must be observed, however, that the resins thus formed are very different in composition and properties from those of Tolu balsam, and the nature of the acid has not been determined.

Tolu balsam is used medicinally to facilitate expectoration in coughs and chronic catarrhs; also in perfumery. It is said to be often adulterated with liquid storax, liquidambar, and Canada balsam. Pure Tolu balsam may be known by its perfect transparency when fresh; by its odour; by its freedom from water; by its perfect solubility in potash-ley of 1·17, and in alcohol; and by its reaction with sulphuric acid.

BALSAMS, ARTIFICIAL. Pharmaceutical preparations, chiefly for external use, and somewhat resembling the natural balsams in their physical character, *e. g. Balsamum opodeldoc*, an alcoholic soap-solution containing ammonia; *Balsamum Arcæi*, a salve containing elemi-resin; *Balsamum sulphuris*, a solution of sulphur in linseed oil, &c.

BALTIMORITE. A variety of chrysotil, or fibrous serpentine, found at Baltimore in North America.

BAMLITE. A silicate of aluminium, found in microscopic linear or fibrous crystals, at Bamle in Norway. Specific gravity 2·984; hardness about equal to that of disthene; colour varying from white to pale greenish; lustre vitreous to silky; translucent, or in single individuals nearly transparent and colourless. According to Erdmann's analysis (J. pr. Chem. xxxi. 165) it contains 56·9 silica, 40·73 alumina, 1·04 ferric oxide, 1·04 lime, and traces of fluorine, numbers which correspond nearly to the formula $Si^9Al^{16}O^{30} = 4Al^4O^3.9SiO^2$; but it requires further examination. Kobell regards it as a mixture of disthene and quartz.

BARALITE or **BAVALITE.** A mineral from Baralon, Côte du Nord, containing silica, alumina, ferric oxide, lime, magnesia, and water. It is probably a mixture, the separate constituents of which are not distinguishable by the eye.

BARBATIMAO. A name applied to several Brazilian barks containing tannin, and used both as astringent medicines and in the tanning of leather.

BARDIGLIONE. A blue variety of anhydrite cut and polished for various ornamental purposes.

BAREGIN. *Glairin.*—A nitrogenous substance contained in sulphurous thermal springs, especially in France. It forms a deposit on the sides of the basins and conduits of the springs, which are sometimes filled with water and sometimes empty, never occurring in parts which are constantly full. The name baregin is derived from its occurrence at Barèges; it is also called *Plombierin*, from Plombières, another locality in which it is found in considerable quantity. Baregin is in the moist state a transparent, gelatinous, nearly colourless substance, destitute of taste and odour. It dissolves very sparingly in the cold, more readily at higher temperatures, in water, alcohol, aqueous acids, and alkalis, and in oil of turpentine; insoluble in ether. When dried, it forms a horny mass, and on heating this mass, it emits an odour like that of burnt horn, together with ammoniacal vapours. According to Bouis (Compt. rend. xli. 16) it contains from 44 to 48·7 per cent. of carbon, 6·7 to 7·7 hydrogen, 5·6 to 8·1 nitrogen, and 30·2 to 40·7 per cent. of ash, chiefly consisting of silica. It does not contain sulphur. According to Danberg, it consists for the most part of a mass of confervæ and oscillatoriæ.

Nearly allied to, if not identical with baregin, is a substance which is sometimes formed in the quick method of preparing vinegar (see ACETIC ACID, p. 7), and attaches itself in gelatinous shreds to the inside of the perforated casks. This substance when dried forms a parchment-like layer, containing 42 per cent. carbon and 6 hydrogen, besides nitrogen and oxygen, and leaving an alkaline ash. (Gerh. iv. 536; Handw. d. Chem. 2^{te} Aufl. ii. 643.)

BARILLA or **BARILLOR.** The term given in commerce to the impure soda imported from Spain and the Levant. It is made by burning to ashes different plants that grow on the sea shore, chiefly of the genus *Salsola*, and is imported in hard porous masses of a speckled brown colour. *Kelp*, a still more impure alkali, made in this country by burning various sea-weeds, is sometimes called *British barilla*. These substances were formerly the source of all the soda of commerce; but their use is now almost entirely superseded by the manufacture of soda from common salt.

BARIUM. *Symbol* Ba; *Atomic weight* 68·5.—(The name is derived from βαρύς, heavy, in allusion to the great density of its compounds.) This metal occurs abundantly as a sulphate and carbonate; also in the mineral *barytocalcite*, a carbonate of barium and calcium, in certain ores of manganese, in Harmotome and in Brewsterite; traces of it has also been found in mineral waters. It is never found native. The oxide, *baryta*, was first recognised as a peculiar earth, distinct from lime, by Scheele, in 1774; and the metal itself was first obtained by Davy, in 1808.

Preparation.—1. Hydrate of barium, or the carbonate, chloride, or nitrate, is made into a doughy mass with water, formed into a cup, and placed upon a platinum dish, which is connected with the positive pole of a voltaic battery of 500 pairs of plates, the cup being filled with mercury, into which the negative wire dips. The amalgam of barium thus obtained is heated in a tube of glass without lead, filled with the vapour of rock-oil, till all the mercury is sublimed (Sir H. Davy). If the hydrate of barium is mixed with oxide of mercury, the amalgam is obtained in larger quantity (Sir H. Davy.) Hare (J. pr. Chem. xix. 249) prepared the amalgam in a similar manner from moistened chloride of barium surrounded by a freezing mixture, using two batteries, each of 100 pairs, and containing more than 100 square feet of zinc. The mercury was expelled by heating the amalgam in an iron crucible provided with an iron cover, and exhausted of air.—2. Barium may be obtained in an impure state, according to Davy, by passing vapour of potassium over red-hot baryta or chloride of barium.—3. Pure baryta or the nitrate is placed in a hole made in a piece of charcoal or slate, and exposed to a burning jet of detonating gas, produced from three measures of hydrogen and one measure of oxygen gas. Effervescence takes place, and white, shining little globules of metallic barium are formed. The baryta must be anhydrous and the detonating gas must be passed through oil and not through water; otherwise a translucent vitreous or horny mass will be obtained. (Clarke, Ann. Phil. xvii. 419.)—4. Bunsen subjects chloride of barium, mixed up to a paste with water and a little hydrochloric acid, at a temperature of 100° C., to the action of the electric current, using an amalgamated platinum wire as the negative pole. In this manner, the metal is obtained as a solid, silver-white highly crystalline amalgam, which, when placed in a little boat made of thoroughly ignited charcoal, and heated in a stream of hydrogen, yields barium in the form of a tumefied mass, tarnished on the surface, but often exhibiting a silver-white lustre in the cavities (Pogg. Ann. xci. 619). Matthiessen has obtained barium by a method similar to that adopted for strontium (*q. v.*); but only in the form of a metallic powder.

Properties.—Barium, according to Davy, is a silver-white metal with less lustre than cast-iron; according to Clarke, it has the colour and lustre of iron; according to Matthiessen, it is a yellow powder. It sinks rapidly in strong sulphuric acid, even when surrounded by bubbles of gas. Its specific gravity, according to Clarke, is 4·0 or somewhat greater. It is ductile, and may be beaten flat, though with difficulty. It melts below redness, and does not volatilise at a red heat. It oxidises rapidly in the air, becoming heated at the same time, and decomposes water rapidly at ordinary temperatures. When heated in the air, it burns with a dark red light (Davy); before the oxy-hydrogen blowpipe it burns with a greenish flame (Clarke). Sulphuric acid rapidly converts it into sulphate, with evolution of hydrogen.

BARIUM, BROMIDE OF. $BaBr$. *Crystallised:* $BaBr.H^2O$.—Prepared by saturating baryta-water, or sulphide, or carbonate of barium with hydrobromic acid, or by decomposing the sulphide with free bromine, sulphur being at the same time precipitated. It is very soluble in water and crystallises with difficulty. Isomorphous with the chloride. It is soluble in strong alcohol, and may thus be separated from the chloride, which is nearly insoluble in that liquid.

BARIUM, CHLORIDE OF. $BaCl$. *Crystallised*, $BaCl.H^2O$.—The hydrated salt was formerly called *Terra ponderosa salita.* This salt is prepared either from the carbonate or from the sulphate of barium, both of which are natural minerals. The carbonate (witherite) is simply dissolved in hydrochloric acid, and the resulting chloride purified by recrystillation. From the native sulphate (heavy spar), the chloride may be prepared in two ways: 1. By igniting the sulphate in a crucible with pounded coal, whereby it is converted into sulphide, Ba^2S, extracting the sulphide by boiling water, and decomposing the filtered solution with hydrochloric acid:

$$Ba^2S + 2HCl = 2BaCl + H^2S;$$

The acid is added in sufficient quantity to produce a strong acid reaction, and the liquid is boiled for some time to drive off all the sulphuretted hydrogen, then filtered, evaporated, and cooled till it crystallises.—2. By heating a mixture of 2 pts. heavy spar, and 1 pt. fused chloride of calcium to redness for about an hour. Sulphate of calcium and chloride of barium are then formed ($SO^4Ba^2 + 2CaCl = SO^4Ca^2 + 2BaCl$), and the latter may be extracted by pulverising the fused mass, boiling with water, and filtering as quickly as possible; otherwise, a portion of the chloride of barium will be reconverted into sulphate, because the sulphate of calcium in the residue gradually dissolves in the water, and mixing with the dissolved chloride of barium, produces a reaction exactly the reverse of that which took place in the fused mass. The decomposition of the sulphate may be facilitated by adding to the mixture in the crucible a quantity of iron filings and charcoal. Sulphide of iron is then formed, together with an insoluble oxysulphide of calcium, from which the chloride of barium may be separated by water as above.

Commercial chloride of barium often contains small quantities of the chlorides of strontium and calcium; also chloride of aluminium, sesquichloride of iron, and sometimes traces of copper and lead. The chlorides of strontium and calcium may be removed by washing the crystals with alcohol; the latter also by digesting the aqueous solution with carbonate of barium, whereby the chloride of calcium is slowly decomposed and converted into carbonate; the same decomposition may be more quickly effected by adding baryta-water, and then passing carbonic acid gas into the liquid. Digestion with carbonate of barium also precipitates the aluminium and iron in the form of sesquioxides. Lead and copper may be precipitated by adding to the solution a small quantity of sulphide of barium.

Chloride of barium crystallises from its aqueous solution in transparent, colourless, four-sided tables, belonging to the trimetric or right prismatic system. The form of the crystals resembles that of heavy spar. The angles are $\infty P : \infty P = 93° 20'$; $oP : \frac{1}{3}\bar{P}\infty = 142° 35'$; $oP : \frac{1}{2}\bar{P}\infty = 140° 57'$. The crystals decrepitate in the fire. Their specific gravity is 2·66 (Filhol); cubical expansion from 0° to 100° C. = 0·00987 (Joule and Playfair). They have an unpleasant, bitter, and sharply saline taste, excite nausea, and are highly poisonous.

100 pts. of water at 0° C. dissolve 32·62 pts. of anhydrous chloride of barium, and

0·2711 pts. for every degree above 0° C.; 100 pts. of water at 15·6 dissolve 43·5, and at 105·5°, 78 pts. of the crystallised chloride (Gay-Lussac). One pt. of crystallised chloride of barium dissolves at 18·1° in 2·257 pts. of water, forming a solution of specific gravity 1·28251 (Karsten). Specific gravity of a saturated solution at 8° = 1·270 (Anthon). Water acidulated with hydrochloric acid dissolves less than pure water, and concentrated aqueous hydrochloric acid hardly any; so that a saturated solution in water is precipitated by it. Hot absolute alcohol dissolves only $\frac{1}{400}$ pt. of the crystals, but more if it contains water. According to Fresenius (Ann. Ch. Pharm. lix. 117), one pt. of the salt dissolves in 8108 pts. of alcohol of 99·3 per cent. at 14° C., and in 4857 pts. of the same alcohol at the boiling heat.

The crystals do not effloresce in the air: at 100° C. they give off the whole of their water, leaving the anhydrous chloride in the form of a white mass, which melts at a full red heat, and is translucent after solidification. Specific gravity of the anhydrous chloride = 3·7037 (Karsten), 3·8 (Richter), 3·86 to 4·156 (Pol. Boullay). Heated by itself, it does not become alkaline till after fusion; but when heated in aqueous vapour, it becomes alkaline below the melting point, and evolves hydrochloric acid. By ignition with sulphur it is partly changed into sulphide of barium (Karsten). It is not decomposed, at ordinary temperatures, by vapour of anhydrous sulphuric acid. According to H. Wurtz, it completely decomposes silicates when fused with them.

Chloride of barium in the state of concentrated solution, is decomposed by nitrate of potassium or sodium, yielding nitrate of barium and a chloride of the alkali-metal. It forms a crystalline compound with glycocol. Blood mixed with it remains fluid and does not putrefy.

The chief use of chloride of barium is as a chemical reagent, especially for the detection and estimation of sulphuric acid.

BARIUM, CYANIDE OF. See Cyanides.

BARIUM, DETECTION AND ESTIMATION OF. 1. *Reactions in the dry way.*—Barium-compounds, heated in the inner blowpipe flame, colour the outer flame green. They likewise impart a green colour to the flame of alcohol, and when this flame is examined with a prism by Bunsen and Kirchhoff's method (see Analysis, Inorganic, p. 214, and Light), a spectrum is seen, having several broad green bands, in the neighbourhood of Fraunhofer's lines *b*, *E*, a bright yellow band coincident with the line *D*, a bright orange band just beyond it, and two fainter orange-red bands, one of which nearly coincides with the line *C*.

Reactions in the wet way.—The hydrate, sulphide, chloride, nitrate, and many organic salts of barium, the acetate, for example, are soluble in water; most of the other salts are insoluble in water, but soluble in nitric and hydrochloric acid: the sulphate and the silicofluoride are insoluble in all acids. All barium-compounds are colourless, excepting those which, like the chromate, contain a coloured acid. The soluble salts of barium are poisonous. Solution of *potash* (free from carbonate), forms a precipitate of hydrate of barium, only in very concentrated solutions of barium-salts. *ammonia* forms no precipitate, even in the most concentrated solutions. *Alkaline carbonates* form a white precipitate of carbonate of barium, soluble, with efflorescence, in hydrochloric acid. *Phosphate*, *arsenate*, *borate*, and *iodate of sodium*, also form precipitates soluble in acids. *Free oxalic acid*, or acid *oxalate of potassium*, precipitates oxalate of barium, only from very concentrated solutions; neutral alkaline oxalates form a precipitate in all neutral solutions of barium-salts, which are not very dilute. *Neutral alkaline succinates* precipitate barium-salts quickly or slowly, according to the concentration of the solutions. *Ferrocyanide of potassium* forms a precipitate in moderately dilute solutions; *ferricyanide* only in strong solutions. *Sulphydric* acid, *sulphide of ammonium*, and *perchloric acid*, form no precipitates. *Sulphuric acid* and *soluble sulphates*, throw down sulphate of barium, from all solutions of barium-salts, whether neutral or acid. The precipitate is insoluble in nitric or hydrochloric acid, even at the boiling heat. A solution of nitrate of barium, containing only 1 pt. of baryta in 50,000 to 100,000 pts. of water, gives a very distinct cloudiness with sulphuric acid or sulphate of sodium; with 200,000 to 400,000 pts. of water, after some minutes only; and with 800,000 pts. of water, the reaction is no longer visible. (Lassaigne, J. Chim. méd. viii. 526.) According to Harting (J. pr. Chem. xxii. 58), a solution of chloride of barium containing 1 pt. of baryta in 71,000 pts. of water, becomes turbid with sulphate of sodium after the lapse of half an hour. Alkaline *chromates* form with barium-salts, a yellowish precipitate of chromate of barium, insoluble in dilute acids, soluble only in a large excess of nitric acid. *Hydrofluosilicic* acid forms with barium-salts, after a while, a white crystalline precipitate, nearly insoluble in nitric or hydrochloric acid. This reaction will detect 1 pt. of the chloride in 3800 pts. of water. The precipitation is accelerated by addition of alcohol.

This last reaction affords a complete distinction between barium and strontium;

the latter metal not being precipitated by hydrofluosilicic acid. The reaction with sulphuric acid distinguishes barium in solution from all other metals, except lead and strontium. From lead it is easily distinguished by its behaviour with sulphuretted hydrogen, which forms a black precipitate with lead, and by many other characters. Strontium and calcium are distinguished from barium by the greater solubility of their sulphates, so that a solution of sulphate of strontium, or calcium, added to a soluble barium-salt, forms a precipitate of sulphate of barium. Another distinction is afforded by the colour imparted to the flame of alcohol by the compounds of these two metals, barium-compounds colouring the flame pale green (p. 500), while strontium compounds colour it deep red. The tabular crystals of chloride of barium, which are nearly insoluble in alcohol, likewise afford a means of distinguishing barium from strontium and calcium, the chlorides of which form hygroscopic needle-shaped crystals, easily soluble in alcohol.

3. *Quantitative Estimation.*—Barium is always estimated in the form of sulphate. The precipitation is effected by means of dilute sulphuric acid. The acid must be added in excess, and to a hot solution of the barium-salt; otherwise a small quantity of the original salt, especially if it be nitrate, will be thrown down undecomposed together with the sulphate. The precipitate is washed with hot water, ignited at a moderate heat, together with the filter, and the amount of barium or of baryta calculated from its weight. 100 pts. of it correspond to 58·78 pts. of barium, and 65·64 of baryta.

This mode of estimating barium is very exact; but the precipitate, unless certain precautions are taken, is very troublesome to filter, sometimes passing through as a milky liquid, and sometimes completely stopping up the pores of the paper. To avoid these inconveniencies, the liquid must be heated, and the precipitate allowed to settle down completely, before the filtration is commenced. The clear liquid is then to be passed through the filter, the precipitate stirred up with boiling water, and again left to settle down, this clear liquid also poured through the filter, and the same process repeated three or four times. The result of this treatment is to render the precipitate dense and granular; it may then be poured on the filter, and washed with hot water as above-mentioned.

Recent experiments have shown that sulphate of barium is soluble to a perceptible extent in strong hydrochloric, and still more in nitric acid (Calvert, Chem. Gaz. 1856, 55.—Nicholson and Price, Phil. Mag. [4] xi. 169.—Noad, Chem. Soc. Qu. J. ix. 25). According to Seigle (J. pr. Chem. lxix. 144), it is also slightly soluble in dilute acids, but less in acetic than in hydrochloric or nitric acid. Care must therefore be taken that the liquid, from which the sulphate of barium is precipitated, does not contain too much free acid; and it must be washed with pure, not with acidulated water.

Barium may also be estimated as carbonate; but the method is less accurate than that just described, because carbonate of barium is not completely insoluble in water.

4. *Atomic Weight of Barium.*—The most exact estimations of this number have been made by determining the amount of chloride of silver obtained by precipitating pure chloride of barium with nitrate of silver. In this manner Marignac (Ann. Chem. Pharm. lxviii. 215), operating on chloride of barium purified by washing with alcohol, recrystallisation from water, and drying at a low red heat, found, as a mean of six closely agreeing experiments, that 1 pt. of silver corresponds to 0·96365 pt. of BaCl. Hence, the atomic weight of silver being 108, we have:

$$\begin{array}{lcl} \text{Atomic weight of BaCl} = 0{\cdot}96365 \times 108 & = & 104{\cdot}07 \\ \text{Whence deducting} \quad . \quad \text{Cl} \quad . \quad . & = & \underline{35{\cdot}50} \\ \text{There remains} \quad . \quad . \quad \text{Ba} \quad . \quad . & = & 68{\cdot}57 \end{array}$$

In like manner, the atomic weight of barium was estimated by Berzelius (Schw. J. xx. 1014) at 68·40, and by Pelouze (Compt. rend. xx. 1047) at 68·65.

Lastly, Dumas (Ann. Ch. Phys. [3] lv. 129), by numerous experiments made with chloride of barium, carefully purified and fused in a stream of hydrochloric acid gas, has obtained results varying between the limits 68·47 and 68·56; mean value = 68·5, which last number is here adopted.

The atomic weight of barium has likewise been estimated from the amount of sulphate produced from a given weight of chloride; but the results do not appear to be so trustworthy as those obtained by the method above described.

5. *Separation of Barium from other metals.*—The precipitation of barium by sulphuric acid affords the means of separating it from all other elements excepting strontium, calcium and lead. From *strontium* and *calcium* it may be separated by hydrofluosilicic acid, which throws down a crystalline precipitate of silicofluoride of

barium $2BaF.SiF^2$. This precipitate is somewhat soluble in water, but the separation may be rendered complete by adding alcohol and warming the liquid: from dilute solutions it takes some time to settle down. It must be collected on a weighed filter, dried at a moderate heat, and weighed. 100 pts. of it correspond to 49·01 of barium and 54·73 of baryta. For other methods of separation, see Calcium and Strontium.

The separation of *lead* from barium is easily effected by sulphydric acid, which precipitates the lead as sulphide.

BARIUM, FLUORIDE OF. BaF.—Obtained by neutralising baryta-water with hydrofluoric acid, by digesting the recently precipitated carbonate in that acid, or by decomposing nitrate of barium with fluoride of potassium or sodium. It is a white powder, or, when obtained by evaporating the acid solution, a granular crystalline crust. It is insoluble in water, but dissolves easily in nitric, hydrochloric, or hydrofluoric acid.

Fluoride of barium unites with the fluorides of boron and silicon, forming the compounds $BaF.BF^3$ and $2BaF.SiF^2$. The latter is nearly insoluble in water, and serves for the separation of barium from strontium and calcium, p. 502 (see Borofluorides and Silicofluorides). It also forms a crystalline compound with chloride of barium, BaCl.BaF, which is produced on mixing a solution of fluoride of potassium or fluoride of sodium with chloride of barium. This compound is more soluble than the fluoride itself, and remains as a granular mass when the solution is evaporated.

BARIUM, IODIDE OF. BaI.—Formed when hydriodic acid gas is passed over baryta at a red heat, the combination being attended with production of light. Protosulphide of barium dissolved in water is mixed with a saturated alcoholic solution of iodine [iodine without the alcohol might be preferable], as long as a precipitate of sulphur is formed; the colourless filtrate is boiled rapidly—so as to prevent the action of the air—almost to dryness; the mass is dissolved in a small quantity of water, and filtered quickly; and the filtrate is evaporated to dryness in as short a space of time as possible in a glass bolt-head. (O. Henry.)

On redissolving the mass in hot water and leaving the solution to cool, the hydrated salt crystallises in slender deliquescent needles containing, according to Croft (Chem. Gaz. 1856, p. 125), $2BaI.7H^2O$; they dissolve readily in alcohol. Heated out of contact with the air, they leave the anhydrous salt, which is not decomposed by heat in a close vessel, but in contact with the air, decomposes slowly at ordinary temperatures and quickly when heated, giving off vapours of iodine and leaving baryta.

BARIUM, OXIDES OF. Barium forms two oxides, a protoxide, Ba^2O, and a dioxide or peroxide, BaO; the first produced by the direct oxidation of the metal, or by heating certain of its salts; the second, by heating the protoxide to dull redness in contact with excess of oxygen.

Protoxide of Barium, or Baryta, Ba^2O, or *BaO*. *Barytes*, *Terra ponderosa*, *Terre pésante*, *Schwererde*.—Barium oxidises rapidly in the air, even at ordinary temperatures, and when heated, burns with a dark-red light and is completely converted into anhydrous baryta. This oxide is however more readily obtained by igniting the nitrate or carbonate of barium.

Preparation.—1. Nitrate of barium is heated in a porcelain crucible, or better in a porcelain retort, till it is completely decomposed, and no more red vapour or free oxygen is given off. The heat should be moderate at first, because the nitrate fuses and froths very much; but towards the end of the process, it must be raised to bright redness. If the heat is too long continued, the baryta is apt to absorb carbonic acid and oxygen from the fire.

It is not convenient to use a platinum crucible in this process, because baryta attacks platinum rather strongly at high temperatures, and if a Cornish or Hessian crucible be used, the baryta becomes contaminated with silica, alumina, oxide of iron, and other matters derived from the crucible. A porcelain vessel is attacked in the same manner, though less strongly, and the baryta prepared in it always contains small quantities of alumina and silica. This contamination, and likewise the inconvenience arising from the frothing of the mass, may be obviated in some cases by mixing the nitrate with rather more than its own weight of pounded sulphate of barium (heavy spar). Such a mixture does not fuse, and may therefore be heated in an earthen crucible without attacking it (Mohr, Ann. Ch. Pharm. xxvii. 27). This process is very convenient when the baryta is to be used for purposes for which the presence of the sulphate is not objectionable, as for preparing baryta-water or the hydrate.

2. On the small scale, baryta may be conveniently prepared by igniting the iodate of barium, which readily gives up all its iodine and $\frac{5}{6}$ of its oxygen without fusion or frothing ($2IO^3Ba = Ba^2O + I^2O^5$).—3. Carbonate of barium exposed to the strongest heat of a forge-fire is converted into baryta (Abich), and at an ordinary white heat, when mixed with $\frac{1}{10}$ of its weight of lamp-black or charcoal, and made into a thick

paste with oil; the mixture should be heated in an earthen crucible lined with lampblack, and having a close-fitting cover. Baryta is prepared by this process on the large scale from Witherite, to be used in separating crystallised sugar from molasses (Leplay and Dubrunfaut, Sill. Am. J. [2] xvi. 276). Baryta is also prepared on the large scale by igniting a mixture of the carbonates of barium and calcium in a current of aqueous vapour. (Jacquelain, Compt. rend. xxxii. 877.)

Properties.—Greyish-white, friable mass, of specific gravity 4·7 (Karsten); 5·54. (Filhol). It is strongly alkaline, caustic, and poisonous. It melts only at the strongest heat of a forge-fire, or in the flame of the oxyhydrogen blowpipe, forming a lead-grey slag. It is a non-conductor of electricity, but may be decomposed by the electric current, with the intervention of mercury, yielding barium and oxygen (p. 560). Potassium deoxidises it at a red heat. Heated in vapour of sulphide of carbon, it forms carbonate and sulphide of barium:

$$3Ba^2O + CS^2 = CO^3Ba^2 + 2Ba^2S.$$

With water, it forms a hydrate (see below). It unites with alcohol and wood-spirit, forming the compounds $Ba^2O.2C^2H^6O$ and $Ba^2O.2CH^4O$. It dissolves readily in dilute nitric and hydrochloric acid, and in some other acids; with many acids, it forms insoluble salts. When vapour of sulphuric anhydride is passed over baryta, heated to low redness in a glass tube, combination takes place attended with incandescence, and sulphate of barium, SO^4Ba^2, is produced.

OXIDE OF BARIUM and HYDROGEN; HYDRATE OF BARIUM, BaHO or *BaO.HO*. *Hydrate of Baryta, Caustic Baryta, Hydrated oxide of Barium.*—Formed by the action of water on anhydrous baryta ($Ba^2O + H^2O = 2BaHO$). When anhydrous baryta is sprinkled with water, the hydration takes place, with great evolution of heat and expansion of volume. Anhydrous baryta also rapidly absorbs water from the air. The hydrate is usually prepared by heating a solution of sulphide of barium (obtained by igniting the native sulphate with coal or charcoal) with oxide of copper, till a filtered portion of the liquid gives a white instead of a black precipitate with lead-salts.—Another mode of preparation is to decompose the nitrate of barium with caustic soda. A solution of soda of specific gravity 1·10 to 1·15, whose strength has been previously determined, is mixed with an equivalent quantity of finely pounded nitrate of barium, the liquid being kept in a state of ebullition, and water being added from time to time in small portions to facilitate the solution of the nitrate; and when the whole is dissolved, the boiling liquid is rapidly filtered, if necessary, through a folded filter into a bottle which can be well closed. On cooling, it deposits an abundant crop of crystals of the hydrate, which may be freed from the mother-liquor by draining, or better by means of a centrifugal machine. The crystals retain but a very small quantity of nitrate, and may be freed from it by recrystallisation. Chloride of barium may also be used in this preparation, instead of the nitrate, but the presence of small quantities of chloride of sodium in the product is more likely to be detrimental in the use of the baryta, than that of the nitrate. (Mohr, Arch. Pharm. [2] lxxxviii. 38.)

Hydrate of barium crystallises from its aqueous solution in transparent, colourless, four or six-sided prisms with four-sided summits. They contain 4 at. water: $BaHO.4H^2O$; dissolve in 20 pts. of water at 15° C. and in 2 pts. of boiling water. The aqueous solution, Baryta-water, has a strong alkaline reaction, is highly caustic, and rapidly absorbs carbonic acid from the air, forming a film of carbonate on the surface. The crystals are efflorescent, and in vacuo over oil of vitriol, give off $\frac{7}{8}$ of their water of crystallisation, leaving $2BaHO.H^2O$. At 100° C. they melt, giving off 1 at. water, and at a red heat, the remainder of the water of crystallisation is given off, leaving the pure hydrate BaHO (Bloxam, Chem. Soc. Qu. J. xiii. 49). This, when heated alone, is not reduced to anhydrous baryta below a red heat, but when heated in a stream of carbonic anhydride, it is easily converted into carbonate of barium, with elimination of water:

$$2BaHO + CO^2 = CO^3Ba^2 + H^2O.$$

Heated in a current of air, it takes up oxygen and is converted into peroxide of barium, also with elimination of water. (Boussingault.)

$$2BaHO + O = 2BaO + H^2O.$$

Hydrate of barium is extensively used as a chemical reagent, viz. for the estimation of carbonic acid, for precipitating metallic oxides, and especially for separating magnesia from the alkalis.

PEROXIDE OF BARIUM, BaO or *BaO²*.—Produced by heating anhydrous baryta or hydrate of barium to low redness in a current of pure oxygen, or of air free from carbonic acid. Pure anhydrous baryta absorbs oxygen with facility; the hydrate less readily, because it melts at the temperature required for the absorption;

the absorption may however be rendered rapid by mixing the hydrate of barium with lime and magnesia in sufficient quantity to prevent fusion, and keeping the mass in a porous state, so that the oxygen may penetrate it thoroughly. Peroxide of barium may also be produced by sprinkling red-hot baryta with four times its weight of pounded chlorate of potassium in successive small portions. Chloride of potassium is formed at the same time, and on washing out this salt with water, the peroxide remains in the form of a hydrate.

Peroxide of barium is a grey powder, somewhat more fusible than anhydrous baryta. At a strong red heat, it evolves oxygen and is converted into baryta, and when vapour of water is passed over it at a red heat, it likewise gives up half its oxygen and is converted into hydrate of barium. The absorption of oxygen by hydrate of barium at a red heat, and its subsequent evolution when the resulting peroxide is heated in a stream of aqueous vapour, has been proposed by (Boussingault, Ann. Ch. Phys. [3] xxx. 5) as a means of extracting oxygen from the air by a continuous process. Hydrate of barium mixed with lime and magnesia, as above described, is heated in a porcelain tube through which a current of air previously freed from carbonic acid is drawn by an aspirator: and as soon as the conversion of the hydrate into peroxide is complete, the current of air is stopped, the temperature is raised, and vapour of water is passed through the tube as long as oxygen continues to be given off. Anhydrous baryta may also be used instead of the hydrate, being first converted into peroxide as above, and the peroxide then decomposed by heating it to bright redness without passing aqueous vapour over it: but the temperature required for this decomposition is much higher; and moreover if the baryta contains small quantities of silica and alumina, which is often the case, it cakes into a very hard mass after frequent exposure to a high temperature, and will then no longer absorb oxygen with facility.

Peroxide of barium is readily decomposed by carbon, phosphorus, sulphur, hydrogen, and the metals, at a red heat, and by sulphydric acid at ordinary temperatures. Heated over a large spirit-lamp in a rapid current of carbonic oxide, it becomes white-hot, and at the same time small white flames burst out from its surface, probably arising from the evolution of oxygen from the still undecomposed peroxide. A similar but more brilliant appearance is presented when the peroxide is heated in sulphurous anhydride (Wöhler, Ann. Ch. Pharm. lxxxviii. 125). In contact with strong sulphuric acid, it gives off oxygen at ordinary temperatures or when gently heated. If the temperature of the mixture does not exceed 50° or 60° C., part of the oxygen is evolved in the form of ozone; but above 70° C., nothing but ordinary oxygen is evolved.

Peroxide of barium thrown into water diffuses itself through the liquid and forms a hydrate, probably containing $BaO.3H^2O$. The same hydrate is precipitated in crystalline scales when peroxide of hydrogen is added to strong baryta-water; it is slightly soluble in cold water, but decomposes at the boiling heat, yielding free oxygen and hydrate of barium.

Both the anhydrous peroxide and the hydrate dissolve in excess of water acidulated with hydrochloric acid, forming chloride of barium and peroxide of hydrogen, without evolution of oxygen ($BaO + HCl = BaCl + HO$). When the peroxide is mixed with acidulated water in presence of oxide of silver, peroxide of manganese, peroxide of lead, &c., oxygen is evolved, both from the peroxide of barium and from the other oxide, so that the peroxide of barium here acts as a reducing agent (see CHEMICAL AFFINITY and PEROXIDE OF HYDROGEN). Oxide, chloride, sulphate, or carbonate of silver, introduced into an acid solution of peroxide of barium, is partly reduced to metallic silver, the quantity thus reduced being, however, always less than that which is equivalent to half the oxygen in the peroxide of barium ($Ba^2O.O$). The quantity reduced increases with the amount of silver-salt present, and diminishes as the temperature is higher. A small quantity of the silver-compound, or of any similar substance, is capable of decomposing a large quantity of peroxide of barium. Iodine, on the other hand, decomposes an exactly equivalent quantity: $BaO + I = BaI + O$. (Brodie, Phil. Trans. 1850, 759.)

BARIUM, OXYGEN-SALTS OF. The general characters and reactions are described at p. 502. For the special descriptions, see the several ACIDS.

BARIUM, OXYSULPHIDES OF. A solution of sulphide of barium in boiling water, left to stand in a close vessel, first deposits crystals of hydrate of barium, and the liquid decanted therefrom yields scaly crystals, whose composition is nearly expressed by the formula $Ba^{14}S^2O^4.58H^2O$, and afterwards granular crystals, consisting of $Ba^4SO.10H^2O$. A moderately concentrated solution of the sulphide deposits, after about two months, large transparent tabular crystals, having the form of a hexagonal dodecahedron, with truncated summits, and containing $Ba^8S^3O.28H^2O$, or $Ba^2O.10H^2O + 3(Ba^2S.6H^2O)$ (H. Rose). These oxysulphides are very easily decomposible, being resolved by hot water into hydrate and sulphydrate of barium, of which, perhaps, they are merely mixtures.

BARIUM, PHOSPHIDE OF. BaP?—When vapour of phosphorus is passed over red hot baryta, a brownish-red mixture of phosphide and phosphate of barium is obtained, commonly called *phosphuret of baryta*, the reaction perhaps taking place in the manner represented by the equation:

$$4Ba^2O + 6P = 5BaP + PO^4Ba^3.$$

It is decomposed by water, forming a solution of hypophosphite of barium, and giving off a mixture of spontaneously inflammable phosphoretted hydrogen gas and free hydrogen.

BARIUM, SELENIDE OF. Ba^2Se, or *BaSe*.—Produced by exposing selenite of barium to a red heat in contact with hydrogen gas or finely divided charcoal (lamp-black). It is soluble in water, but decomposes at the same time, like the monosulphide, yielding hydrate of barium, and a higher selenide of barium, the solution of which is decomposed by acids, with evolution of selenhydric acid and precipitation of selenium.

BARIUM, SULPHIDES OF. The *protosulphide*, Ba^2S, or *BaS*, is obtained by passing sulphydric acid or vapour of sulphide of carbon over red-hot baryta, or by reducing pulverised sulphate of barium in a stream of hydrogen or carburetted hydrogen. Either of these processes yields a very pure product; but for preparation on the larger scale, the native sulphate of barium is heated to bright redness with carbonaceous matter. If charcoal is used, it must be thoroughly well incorporated with the heavy spar, otherwise the reduction will be imperfect, as no fusion takes place. The admixture of resin, oil, or starch is advantageous, to bind the mass together and produce partial fusion; but a much better method is to mix the powdered sulphate with about $\frac{1}{8}$ of its weight of bituminous coal, and heat the mixture in a crucible to full redness for an hour; the tarry matter of the coal then penetrates thoroughly into the mass, so that every particle of the sulphate comes well in contact with the reducing matter.

The mass thus obtained consists of sulphide of barium mixed with excess of carbonaceous matter and undecomposed sulphate; the sulphide of barium may be extracted by treating the mass with a sufficient quantity of hot water, and crystallised. Another method is to ignite a mixture of 100 pts. heavy spar, 200 common salt, and 15 pts. charcoal powder in a reverberatory furnace, and extract the sulphide of barium by hot water. The use of the chloride of sodium is to promote fusion. (Kuczinski, Repertory of Patent Inventions, 1835, p. 151.)

Pure sulphide of barium is a white mass, having a hepatic odour and alkaline taste, and easily soluble in water. Exposed to the air, it absorbs water and carbonic acid, and is converted into carbonate, with evolution of sulphuretted hydrogen. When heated in the air, it oxidises but slowly, but when heated to redness in an atmosphere of aqueous vapour, it is converted into sulphate of barium, with elimination of hydrogen.

Sulphide of barium dissolved in water is easily decomposed by boiling with *oxide of copper, oxide of iron, &c.*, forming hydrate of barium and sulphide of copper, &c. *Hydrochloric, nitric, carbonic acid, &c.* decompose it, eliminating sulphuretted hydrogen, and forming chloride, nitrate, &c. of barium. *Chlorine, bromine* and *iodine* decompose it, with formation of the corresponding salts and deposition of sulphur. Sulphide of barium is indeed the material most generally used for preparing the other compounds of barium.

A mixture of sulphide of barium with the sulphate, such as is obtained by igniting the sulphate with an insufficient quantity of carbonaceous matter (gum-tragacanth answers well, because it forms a paste with the heavy spar), acquires by exposure to the sun's rays the property of shining in the dark: it is called the *Bolognian phosphorus.*

With *water*, protosulphide of barium forms hydrate and sulphydrate of barium:

$$Ba^2S + H^2O = BaHO + BaHS.$$

The quantity thus decomposed varies with the quantity and temperature of the water. When crude sulphide of barium, prepared by igniting the sulphate with carbonaceous matter, is treated nine times in succession with a quantity of cold water less than sufficient to dissolve the whole, the mass being digested for twenty-four hours each time in a closed vessel, the first two solutions obtained are of a pale yellow colour; yield a large quantity of sulphuretted hydrogen and a precipitate of sulphur, when treated with hydrochloric acid; and form with chloride of manganese, a flesh-coloured precipitate of sulphide of manganese mixed with free sulphur, sulphuretted hydrogen being likewise evolved: hence these solutions contain sulphydrate of barium (BaHS) together with a polysulphide of barium. The third solution behaves like a solution of protosulphide of barium containing a slight excess of sulphuretted hydrogen. The fourth is of the same character, but contains a slight excess of baryta. This excess goes on continually increasing in the fifth, sixth and seventh solutions: and the eighth and ninth behave like pure baryta-water, yielding with chloride of manganese a white precipitate of manganous oxide. If the crude sulphide is at once treated with a quantity of water sufficient to dissolve the whole of the sulphide, the solution exhibits the characters of the pure protosulphide: it may however be a mixture of hydrate and sulphydrate of barium (see the above equation). A solution of sulphide of barium in not too large a quantity of water, kept for some years in a stoppered bottle, deposits, first crystals of hydrate of barium, then scales which are a mixture of crystallised hydrate of barium and the hydrated protosulphide ($Ba^2S.3H^2O$), and afterwards double six-sided pyramids containing the same substances, but much richer in sulphide of barium. The mother-liquor boiled down in a retort, evolves a continuous current of sulphuretted hydrogen, and on cooling deposits hydrated sulphide of barium in the form of a white powder, while sulphide of barium and hydrogen remains in solution.

Hydrated Sulphide of Barium, $Ba^2S.3H^2O$, is a white powder, which soon turns yellow. When treated at once with a quantity of water sufficient to dissolve it perfectly, it yields a solution which when mixed with a manganous salt, yields a precipitate of sulphide of manganese (Mn^2S) without evolution of sulphuretted hydrogen; but a smaller quantity of water extracts sulphydrate of barium and leaves hydrate of barium undissolved.

Sulphydrate of Barium, $BaHS$, or $BaS.HS$.—Baryta-water, or protosulphide of barium reduced to a paste with water, and warmed, is saturated with sulphydric acid, the solution evaporated apart from the air, and cooled, when crystals of baryta and yellow prisms are formed. The remaining liquid is either evaporated in a confined space, when white opaque prisms are obtained, or mixed with alcohol, filtered from the sulphur and hyposulphite of barium produced by air contained in the alcohol, and cooled down to —10° C.; in this way, colourless and transparent four-sided prisms are produced. Also when baryta or either of its hydrated compounds is allowed to crystallise, together with sulphide of barium, from an aqueous solution of protosulphide of barium, by evaporation in a retort and cooling, and the residual liquid (which is of a yellowish colour, from the air not being perfectly excluded) further evaporated and cooled, it solidifies to a crystalline mass of sulphydrate of barium (H. Rose). The crystals contain water, which they lose when heated, becoming white at the same time. When exposed to the air, they effloresce and turn white, while hyposulphite and sulphate of barium are formed. In a retort, they lose their water of crystallisation without fusing, and then evolve sulphydric acid as the temperature approaches redness, leaving dark yellow protosulphide of barium, which becomes white as it cools. An aqueous solution precipitates chloride of manganese, with escape of sulphydric acid gas (Berzelius, Pogg. Ann. vi. 441). The salt, when boiled, evolves sulphydric acid. With iodine, it forms iodide of barium and free hydriodic acid, sulphur being set free. It is insoluble in alcohol. (H. Rose.)

Trisulphide of Barium, Ba^2S^3, is said to be obtained, together with sulphate, by igniting 8 pts. of baryta with 6 pts. of sulphur, 1·78 pts. of the sulphur volatilising during the process. On treating the product with water, the trisulphide dissolves, and 2·8 pts. of sulphate of barium, remain behind (Vauquelin). When the moistened trisulphide is heated to redness and vapour of water is passed over it, sulphuretted hydrogen is given off, and sulphate of barium is formed. (Gay-Lussac.)

Pentasulphide of Barium, Ba^2S^5, is obtained in solution, by boiling the protosulphide or the sulphydrate with sulphur (H. Rose); also, together with hyposulphite of barium, by boiling baryta-water with sulphur. The solution is yellow, bitter, alkaline and caustic; leaves a pale yellow amorphous mass when evaporated in vacuo; and is decomposed by exposure to the air, with deposition of sulphur and formation of hyposulphite of barium.

BARLEY. See CEREALS.

BARNHARDTITE. A sulphide of copper and iron, $2Cu^4S.Fe^4S^3$, containing traces of silver, found in a mine in Barnhardt's Land, and other localities in North Carolina. Bronze-yellow, with metallic lustre, sometimes dull and opapue. Fracture conchoïdal; no cleavage. Specific gravity 4·521. Hardness = 3·5. Brittle. Streak greyish-black, somewhat shining. Tarnishes in the air, especially in contact with moisture, acquiring a brown or rose-red colour. Before the blowpipe, it gives the reactions of iron and copper. (Genth, J. pr. Chem. lxiv. 468.)

BAROCALCITE. Syn. with BARYTOCALCITE.

BAROLITE. Syn. with WITHERITE.

BAROMETER (*βαρος* weight and *μετρον* measure). The barometer is an instrument employed to measure the pressure or weight of the atmosphere. It consists essentially of a continuous body of liquid, generally mercury, from one part of the upper surface of which all pressure is removed, while the atmosphere still presses upon the remainder of the surface. It is a law of hydrostatics that, in a heavy fluid, the pressure at all points in a horizontal plane must be uniform, in order that there may be equilibrium. The surface of the mercury cannot, then, remain in one plane, as it does when the atmosphere presses equally on every part, but it must rise where protected from the atmosphere, until the pressure of the portion thus rising exactly balances and replaces the pressure of the atmosphere. Thus in *fig.* 92, the surface of mercury on which the atmosphere presses is at A, and the glass tube A B, having been perfectly emptied of air and every other fluid, the mercury has risen to B, so that the perpendicular column of mercury A B exerts a pressure at the horizontal plane A, exactly equal to the pressure of the atmosphere at A.

Now supposing mercury to be always of one specific gravity, the *length* of the barometric column will be exactly proportional to the *weight* or pressure of the atmosphere, and thus a length expressed in inches or parts of a metre becomes a convenient expression for a weight. It is well, however, to bear in mind the real pressures indicated, which are easily determined, as in the following example:—

29·872 inches = mean height of barometric column for noon at Greenwich.
13·568 = specific gravity of mercury at 60° F.
997·137 oz. avoirdupois = weight of one cubic foot of water at 62° F.

$$\frac{29\cdot872 \times 13\cdot568 \times 997\cdot137}{12 \times 12 \times 12} = 233\cdot879 \text{ oz.} = 14\cdot617 \text{ lbs.}$$

the average atmospheric pressure for noon at Greenwich on every square superficial inch.

Barometer at 28 inches	Atmospheric pressure 13·70 pounds
,, ,, 29 ,,	,, ,, 14·19 ,,
,, ,, 30 ,,	,, ,, 14·68 ,,
,, ,, 31 ,,	,, ,, 15·17 ,,

When any other liquid, is used, the height of the barometric column will be inversely as the specific gravity. Thus the height of a column of water corresponding to 29·872 inches of mercury at 60° F. is $29\cdot872 \times \frac{13\cdot568}{1\cdot000}$, or 405·3 inches or 33·77 feet; similarly a column of sulphuric acid would stand $29\cdot872 \times \frac{13\cdot568}{1\cdot85}$, or 219 inches high.

A full account of a water barometer constructed for the Royal Society by Professor Daniell will be found in Phil. Trans. cxxii. (1832), 539.

Construction of the Barometer.—All that is necessary to construct a barometer is to seal a glass tube about three feet along at one end, to fill it perfectly with mercury, and putting the finger over the open end, to invert the tube into a vessel of mercury. On withdrawing the finger, the mercurial column descends a few inches, and a measure being applied, the height of the column remaining is found. But to attain accuracy, great precautions are required at every step.

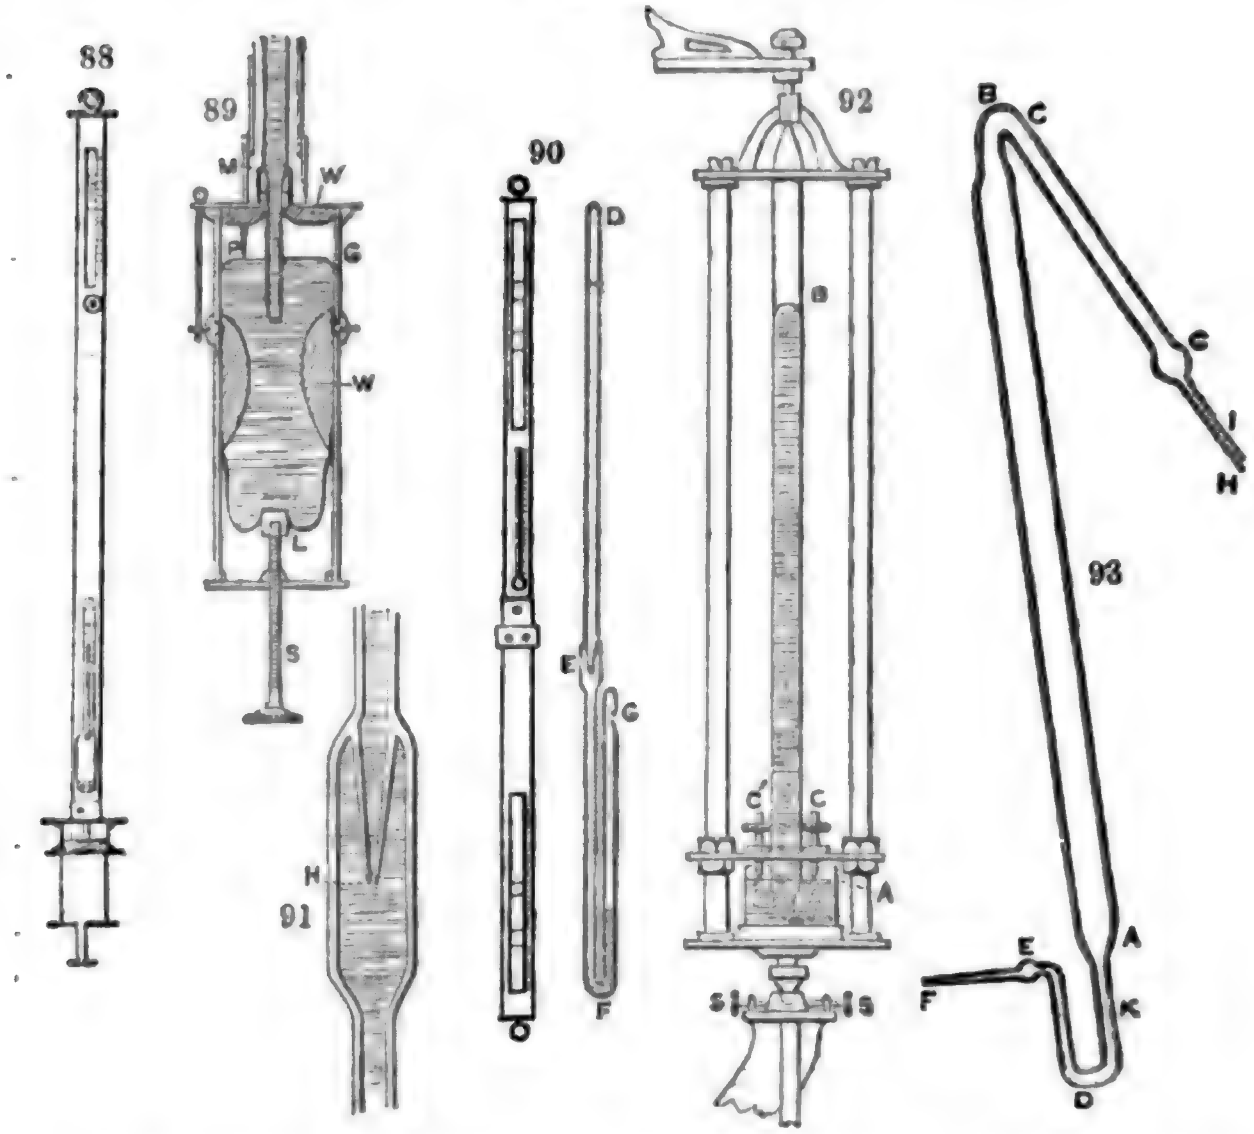
If any air remain in the tube, by adhering to the glass, it will rise into the space above the mercury, and its pressure, partly counteracting that of the atmosphere, will depress the barometric column. Most of the air may be got out by shaking the mercury in the tube, but some will certainly remain, to eliminate which, the tube must be boiled as follows:—Fill only about six inches of the tube with mercury, and gradually heat it over a strong flame or a charcoal fire until the mercury has boiled for a few moments. At the same time, heat another portion of mercury, that it may not crack the hot tube, and with it fill a few inches more of the tube. Expose this new part chiefly to the flame until it boils, and thus proceed, alternately pouring in a little mercury and then boiling, until the tube is almost full. It would be well to anneal the tube, if a large one, while cooling, to prevent fracture. When cold, fill it entirely with mercury, already boiled, and invert, with great precautions, to prevent entrance of air. Any kind of dirt entering also will prove very detrimental, and the tube, in the first place, before sealing, should be thoroughly sponged out with whiting and spirits of wine.

The mercury used must be perfectly pure, otherwise it will be thick, sluggish, and dirty, as well as somewhat false in specific gravity. To purify it, agitate with diluted nitric acid or sulphuric acid, and keep it under the acid, if possible, for a week or more, afterwards washing with fresh acid and distilled water. Carefully distilled mercury is pure enough, except that the dissolved oxide of mercury must be removed by treatment with sulphuretted hydrogen water, or dilute sulphide of ammonium.

Many forms of the barometer have been contrived since its first discovery by Torricelli; but, except in rendering the instrument portable and unalterable, no improvement has ever, or perhaps can ever be made on the original simple form. In fact, the most perfect barometer existing, the Great Standard at the Kew Observatory, mentioned further on, is also the most simple that could be imagined.

We shall, therefore, content ourselves with describing those forms of the barometer which can be recommended to the observer of the present day for their accuracy and convenience.

Figs. 88—93.



In *fig.* 88 is shown the PORTABLE STANDARD BAROMETER, as first invented by Fortin of Paris, and now made, amongst others, by Negretti and Zambra of Hatton Garden, London, at a cost of eight guineas.

The barometer tube has an internal diameter of ·39 or ·40 inch, and the air is perfectly driven out by the usual process of boiling. The cistern (*fig.* 89) is composed partly of a glass cylinder G, of boxwood sides and top, W and W′, and of a leather bag, L, the bottom of which can be raised or lowered by the finger-screw, S. The whole is, of course, held together by a brass casing, and the barometer tube, the lower end of which is contracted, is connected with the cistern by a leather joint at M.

To make an observation of this barometer, the lower surface of the mercury must first be adjusted so as just to touch the ivory fiducial point P (*fig.* 89), by turning the screw S. The moment of exact contact may be very accurately observed, if the mercury be properly clean and bright, by watching when the ivory point and its reflection just meet; if the mercury be even $\frac{1}{1000}$ of an inch too low, light will appear between the point and mercury; while, if too high, a small depression, instantly detected by reflected light, will be caused in the mercurial surface by the ivory point.

Next, the upper surface of the mercurial column is observed by adjusting the lower edge of a moveable brass cylinder, so that it shall visually be the tangent to, that is shall just touch, the curved surface of the mercury. To avoid the error of parallax, the line of vision must be exactly horizontal. The scale of inches, with the assistance of the vernier engraved on the moveable cylinder, then gives the actual height of the column, subject to index error, within the $\frac{2}{1000}$ part of an inch. But the observer, with a little practice, will soon discriminate the $\frac{1}{1000}$ part by the naked eye.

A Barometer should never be carried about in its ordinary upright position; for the mercurial column, being delicately balanced against the weight of the air, will be found to vibrate, or as it is said, to *pump* rapidly up and down when the barometer suffers any vertical disturbance. Not only might bubbles of air adhering to the lower part of the tube be thus carried up, but the mercury violently striking the sealed and vacuous end, might shatter a tube that was not very strong. To render this barometer portable, the handscrew at S must be screwed up, and the instrument gently inclined at the same time, until the mercury fills the whole of the tube, and *almost* the whole of the cistern; it is then to be inverted and kept or carried about as nearly as possible in this position until again safely suspended. A board and bracket, not shown in the figures, accompany this barometer, as also an arrangement of three screws, by which it may be secured motionless in the vertical position, which it of course assumes when free. Such a barometer is very suitable and quite good enough for a laboratory, or for a series of meteorological observations. It is the form of barometer most esteemed on the Continent.

Of **Mountain Barometers**, which require to be far more portable and secure from accident than that above described, the best is Gay-Lussac's form (see Ann. de Chimie, 1816, i. 113), as improved by Bunten, and drawn in *fig.* 90 from an instrument by Negretti and Zambra. Its tube is in the form of a syphon, of which the parts D E and F G have an uniform diameter of ·2 inch, while the part E F is a capillary tube, with a bore of about ·05 inch. The end of the tube at G is sealed, but a minute and somewhat sunken hole is pierced about an inch below the end, so that air may pass freely in or out, but not the mercury. At E is a pipette or air trap, shown on a larger scale in *fig.* 91, contrived by Bunten, so that even if air pass up the tube E F, it will collect at E, since it is scarcely possible that it should find its way through the capillary communication (H, *fig.* 91) into the upper part of the tube.

The tube is loosely packed in a brass tube-case, through two slits in which the upper and lower surface of the mercury may be observed in the same manner as the upper surface in the Fortin barometer. There are two divided scales, both 9 inches long, and measured from the lowest point of the lower scale, and the difference of the readings is the height of the barometric column. The verniers read to the $\frac{1}{1000}$ of an inch.

Newman's Standard Barometer is well known, and has long been relied upon in other countries as well as this. The tube has a diameter of ·5 or ·6 inch, and stands in a plain cylindrical glass cistern. The graduated scale is of brass, affixed to a brass rod passing down the inside of one of the upright supports, and terminating below in a conical ivory point, which by an endless screw and wheel is very accurately adjusted to contact with the mercury. In this respect the construction is superior to that of the Fortin barometer, because the mercury when raised or lowered, as in the latter, may not at once assume its true position, owing to adhesion. Mr. Newman has adopted a method of filling his barometer-tubes in vacuo, and of boiling them under diminished pressure, which obviates all oxidation and fouling of the tubes.

The Great Standard Barometer of the Kew Observatory, constructed by the late Mr. Welsh, has a tube 1·1 inch in bore, and as it was found impossible to fill so large a tube satisfactorily in the ordinary way, the following excellent method was adopted: — To the upper end of the barometer tube A B (*fig.* 93) was attached a capillary tube A D E F, much contracted at D, with a small bulb at E, drawn out at F to a fine point, and hermetically sealed. To the lower end of the large tube was attached 10 inches of a smaller tube B C G, having a bore of 0·3 inch, and to that again was added about 6 inches of capillary tube G H. A bulb of $\frac{3}{4}$ of an inch was blown at G, and the small tube finally bent into a syphon form at B. The end H of the capillary tube was now connected with a good air-pump, and the air very slowly extracted, at the same time that the whole tube was strongly heated by passing a large spirit flame along it. When the air had been as well as possible extracted, and whilst the pump was still in action and the heat still applied, the capillary tube G H was sealed at I by a blowpipe flame. When the tube had cooled, it was placed at a small inclination with the end F in perfectly pure mercury, which had been previously boiled, and the point being broken off, the mercury rose until the bulb at G was more than half filled. The point F was then again sealed, the capillary tube remaining quite filled with mercury. When the glass at F had cooled, the whole tube was inverted, the mercury now separating at the contracted part D, leaving the tube from D to F filled, or very nearly so, and from D to A perfectly vacuous. The operation was completed by sealing the tube at K, removing the portion K D E F, placing the bend B in the cistern of the barometer, and breaking off the tube C G at the point C.

The tube finally adopted at Kew, is perfectly free from air in the portion B, which is 9 inches long; it is mounted in an open brass frame (*fig.* 92), adjusted to verticality by screws at S; at C C′ are two steel rods, the first terminating below in a conical point, the second in a knife-edge, and both adjusted so as just to touch the surface of the mercury in the cistern. The height of the mercurial column is then easily observed by a cathetometer placed five feet off, the telescopic wire of which is made alternately to bisect a mark on the head of the rods C or C′, and to form a tangent to the mercurial surface at B. The difference of the readings on the divided scale of the cathetometer, added to the known length (3·515 for C) between the point and end of the steel rod, and the mark on its head, gives the actual length of the barometric column. The cistern of this barometer stands 33·9 feet above the mean sea-level. (Phil. Trans. [1856] p. 507.)

A very interesting account of the construction of the Royal Society's Standard barometer by Daniell, will be found in his Meteorological Essays, p. 353. See also Mr. Baily's Description of a New Barometer, Phil. Trans. cxxvii. 431; and Hudson, Phil. Trans. [1832] p. 575.

We will now consider the precautions and corrections necessary in obtaining the true atmospheric pressure with exactness.

Correction for Capacity.—It is obvious that in proportion as the barometer stands higher, so much more mercury there must be in the tube, and consequently so much less in the cistern. We should not then get the true variations in the length of the mercurial column, by noticing the top of the column only, since the base of the column also varies, and a correction must obviously be made for the amount of the variation.

This correction, indeed, is not required in any of the barometers above described, because observations or adjustments are made both at the upper and lower surfaces of mercury. But in many other barometers, the scale is measured truly from the lower surface of the mercury, only when the column is at one particular height, called the *neutral point*, usually determined by the barometer-maker, and marked on the instrument. When the column is higher or lower than this point, the mercury in the cistern must be lower or higher in a proportion depending on the sectional areas of the tube and cistern. If H be the height of the neutral point, and h the observed height of the barometer, the correction for capacity is

$$+\left\{\frac{\text{diameter of tube}}{\text{diameter of cistern}}\right\}^2(h-H)$$

In the marine barometer adopted by the Board of Trade, this correction is actually performed upon the divided scale, so that the inch divisions are about $\frac{1}{4}$ less than real inches. In any syphon barometer, like that of Gay-Lussac, in which both legs are of equal diameter, the correction for capacity is made by doubling the variations in height of one surface, and Gay-Lussac recommends this method when great nicety is not required; but measurements of both surfaces are evidently necessary for certainty.

Correction for Temperature.—The length of the barometric column is proportional to the pressure which it has to measure only so long as the specific gravity of mercury is constant. Now mercury expands $\frac{1}{10000}$ of its own volume when its temperature rises one degree (Fahr.), and its density of course varies inversely. Hence all readings of the barometer must be reduced to what they would be at one uniform temperature, that of 32° Fahr., when the specific gravity becomes 13·60. The brass scale by which the height is measured also expands by heat, and is only of the standard length when at a temperature of 62° F. (for the English yard).

To ascertain the temperature of the barometer, a thermometer is always attached. This should be placed half way up the barometer tube, with the bulb close to the tube, and well covered up from the atmosphere. The barometer should be placed in a room of which the temperature changes as little and as slowly as possible.

If h be the observed height of the barometer, and t its temperature in degrees Fahr., the height reduced to 32° F. is

$$h-h\times\frac{\cdot 0001001(t-32)-\cdot 000010434(t-62)}{1+\cdot 0001001(t-32)}$$

but it is quite exact enough to subtract (or *add* if t be less than 29° Fahr.) the following correction:

$$h\left\{(t-32)(\cdot 0001)-(t-62)(\cdot 00001)\right\}$$

The reader will observe that the *cubic*, not the linear, expansion of mercury is used in these formulæ, for it is on the cubic expansion that the specific gravity depends.

The correction is most conveniently obtained, however, from a table such as that on the following page, which applies to barometers with *brass scales*, extending from the cistern to the top of the mercurial column.

Table for the Temperature-correction of the Barometer.

60	·080	·082	·083	·085	·086	90	·156	·159	·162	·164	·167

The full tables, as originally calculated by Prof. Schumacher (Jahrbuch für 1837, Astron. Nach. t. ii.), will be found in the "Report of the Committee of the Royal Society on Physics," 1840. The Admiralty "Manual of Scientific Enquiry," and most works on Physics and Meteorology, also contain tables, often slightly differing from each other.

To obtain an approximate correction, multiply the number of inches in the height of the reading by the number of degrees Fahr. above 32°, and subtract ·0001 inch for every unit of the result. The following data are useful.

	For 1° Fahr.	For 1° Centigrade.
Coefficient of the cubic expansion of mercury (log. 1·0001001 = 0·0000435)	·0001001	·00018018
Coefficient of the linear expansion of brass	·00000956	·00001722
Coefficient of the linear expansion of brass adopted by Schumacher	·0000105	·0000188
Coefficient of the linear expansion of glass.	·0000048	·0000086

The last must be employed instead of the coefficient of brass, when the scale is engraved on the glass barometer tube, as often occurs on the Continent. Tables for glass metre scales and centigrade degrees, will be found in Bunsen's Gasometry, translated by Roscoe.

The Capillary Depression of the mercurial column is a formidable obstacle to the attainment of accuracy when the tube is of small bore. For this reason, important standard barometers, like that of Kew, have a large tube in which the capillary depression is inappreciable.

The cause of the depression is, that the particles of the mercury have a much stronger attraction for each other than for the glass; a slight resultant attraction thus arises, tending to draw each particle towards the general mass of mercury. The form which the surface of the mercury assumes is spheroïdal; the highest point of the surface is to be always taken, in adjusting the edge of the vernier for an observation.

To avoid any error from the capillary depression, it is far the best way to compare the barometer with an undoubted standard barometer in which the capillary depression is inappreciable. The correction for capillarity is then merged into that for index error.

If this be not done, the *bore* of the barometer tube must be ascertained from the barometer maker, or otherwise, and the correction then taken from the following table, which is the one generally adopted for the purpose in England.

Diameter of tube.	Add to the reading for		Diameter of tube.	Add to the reading for	
	Unboiled tubes.	Boiled tubes.		Unboiled tubes.	Boiled tubes.
0·60 inch.	0·004 inch.	0.002 inch.	0·30 inch.	0·028 inch.	0·014 inch.
0·50 „	0·007 „	0·003 „	0·25 „	0·040 „	0·020 „
0·45 „	0·010 „	0·005 „	0·20 „	0·060 „	0·029 „
0·40 „	0·014 „	0·007 „	0·15 „	0·088 „	0·044 „
0·35 „	0·020 „	0·010 „	0·10 „	0·142 „	0·070 „

Continental observers have attempted to attain greater accuracy by making the height of the meniscus or curved surface of the mercury an *argument* in the correction. M. Delcros has calculated an elaborate table on this principle of which a part is here given.

Bore of the tube. Millimetres.	Height of the meniscus in millimetres.								
	0·2	0·4	0·6	0·8	1·0	1·2	1·4	1·6	1·8
3·0	0·24	0·48	0·70	0·90	1·07	1·20	1·32		
4·0	0·12	0·24	0·35	0·46	0·55	0·63	0·71	0·77	
5·0	0·07	0·13	0·19	0·25	0·30	0·35	0·40	0·44	
6·0	0·02	0·06	0·09	0·13	0·18	0·20	0·23	0·25	0·27
7·0	0·01	0·03	0·06	0·09	0·10	0·12	0·14	0·15	0·16

For the full tables and for a very elaborate description of the principal standard barometers on the continent, the determination of their mean differences, and the errors to which barometers are subject, the reader should consult a paper by Bravais and Martius in Nouv. Mém. de l'Acad. Roy. de Bruxelles xiv. 31 (1841); see also Dove, Repertorium der Physik, i. 37.

The capillary depression of the barometric column has been investigated mathematically by Mr. Ivory in the Philosophical Magazine and Annals for 1828, vol. iii. p. 1. [This reference is usually wrongly given to the Philosophical Transactions.]

This correction is considered unnecessary to the Gay-Lussac, or any other syphon barometer, in which the two surfaces of mercury are of equal extent, and therefore subject to equal capillary action. But we think that the adhesion of the mercury in the lower limb of the Gay-Lussac tube, being much increased by the presence of air and dust, is liable to cause inaccuracy unless carefully attended to.

The Index Error is properly the error in the length of brass rod or scale extending between the two surfaces of mercury. Such error may usually be considered uniform for all parts of the divided scale, which is accurately divided by a machine, and the error probably arises, if at all, from the wrong adjustment of the ivory fiducial point.

But the index error, as usually determined by comparison with a standard barometer, comprises the capillary depression before mentioned, as well as any minute errors from impurity in the mercury, from imperfect vacuum in the upper part of the tube, error of the attached thermometer, and so on. Comparison with a standard, in short, secures the final accuracy of the result, and no observer of the present day who desires to be considered trustworthy should use an uncompared barometer. The purchaser of a barometer for scientific purposes should insist on receiving with it an authentic certificate of its index error from comparison with the Greenwich, Kew, or Royal Society Standard. The best barometer makers, Negretti and Zambra, Newman of Regent Street, or Barrow of Oxenden Street, the latter the maker to the British Meteorological Society, will readily procure such a certificate. Of course a fresh comparison is necessary if the barometer be in any way disordered or suspected of being disordered.

To compare two barometers, they should be suspended side by side, and a score of simultaneous readings of each taken at intervals, if possible when the barometric column is at various heights, and both rising and falling. The readings of each barometer are to be fully and carefully corrected for temperature, according to its own attached thermometer; the mean difference of all the readings, together with the known index error of the one barometer, is the index error of the other barometer.

From the uniformity of the readings, the observer may judge either of his own skill or of the character of the instruments. With good instruments and a careful observer, the differences should be uniform within about $\frac{2}{100}$ of an inch, and the whole index error, apart from capillary action, should not exceed $\frac{2}{100}$ or $\frac{3}{100}$; thus, in the comparison of the writer's barometer by Mr. Glaisher at Greenwich, the differences of twenty readings vary from $-0{\cdot}009$ to $-0{\cdot}020$, with a mean error of $-0{\cdot}014$, apart from the assumed capillary depression ·008 inch, making the whole correction $+{\cdot}022$ inch.

Treated according to the formulæ of the calculus of probabilities, the *probable error* of this determination from the mean of twenty observations is rather less than ·0015 inch. Assuming the Greenwich standard to be absolutely correct, this probable error of ·0015 inch is the only source of error which would not be eliminated by a proper use of the instrument, and in the taking of a number of observations, as is always the case in meteorology.

It is curious that a barometer maker, named Assier-Perricat, of Paris, as long ago as 1802, practised and advocated the method of ensuring the accuracy of barometers by comparison. (Assier-Perricat, Nouveau Traité sur l'Invention des Barometres, etc.)

It is important to be able easily to detect the presence of any air which might by accident get into the upper part of the barometer tube, where it would falsify the reading by a minute direct pressure, and probably also by increasing the capillary action. There happens to be a ready and perfect test as follows:—Incline the barometer so that the mercury may run up and strike the sealed end of the tube; if the sound be sharp and metallic, repeat the experiment several times, each time more gently. If the least trace of air be present, the sound will at last become soft and puffy; if, on the contrary, the vacuum be perfect, the sound will always remain beautifully clear and distinctly metallic.

If air be thus detected, uncover and examine the end of the tube, to see how large a bubble remains when the barometer is laid flat. Also invert the instrument and tap it, as sharply as is safe, near the bubble, which may sometimes be thus dislodged and eliminated. We do not think that a minute quantity of air can sensibly affect the reading of the barometer for ordinary purposes, but if there be more, the instrument must certainly be disused until refilled by the maker. If important observations have been made with a barometer containing air, they may be corrected, if the barometer be compared with a true one before its condition is altered. The simple difference of readings will be an approximate correction, but the exact correction is

$$\frac{e_1 e_3(h_2 - h_1)}{e_1(h - h_1) + e_2(h_2 - h)}$$

in which e_2 and e_3 are the errors of the readings h_1 and h_2 at different points of the scale, as determined by comparison, and h is the reading to be corrected.

If we suppose a bubble of air of $\frac{1}{50}$ of an inch diameter at the atmospheric pressure to enter the vacuous space of the Fortin barometer, described above, the depressing effect on the mercurial column may, by a simple calculation, be shown not to exceed $\frac{3}{10000}$ of an inch, apart, however, from any influence on the capillarity, a point probably of much greater importance than the direct effect.

DIRECTIONS FOR TAKING AN OBSERVATION OF THE BAROMETER.

1. Read and record the attached thermometer, making a correction for index error if necessary (see THERMOMETER).
2. Adjust the mercury below to exact contact with the fiducial point.
3. Slightly tap the tube near the upper end of the column, and adjust the edge of the vernier to exact tangential contact, the line of vision being horizontal.
4. Record the reading and work out the correct height as soon as convenient afterwards, as shown in the following example, which comprises all the corrections ever required:—

			Inches.
Attached thermometer . .	58·3 F.	Barometer reading . .	29·964
Data. Neutral point . .	28·861	Correction for capacity .	+·033
Capacity . . .	$\frac{1}{33}$	,, ,, capillarity	+·007
Diameter of the tube .	·4 inch		30·004
Index error to K. O. Standard (apart from capillarity) .	−·014 inch	,, ,, temperature	−·080
		,, ,, index error	−·014
		True height of the barometer	29·910

When many observations of one barometer have to be made, much labour will be saved by combining all these corrections into a special table, one reference to which furnishes the required correction. In important observations or comparisons, the adjustments and vernier readings should be made with a pocket lens.

It is much to be desired that the English should adopt the metre scale for the barometer, which is used all over the Continent; but although this may at once be done in chemical matters, it seems almost impossible at present in meteorology. For the easy reduction of the barometer scale from millimetres into English inches and *vice versâ*, we give the following tables. Negretti's portable barometer may be had with both millimetre and inch scales attached.

Millimetres	Inches.	Millimetres.	Inches.	Millimetres.	Inches.
700	27·560	751	29·567	762	30·000
705	27·756	752	29·607	763	30·040
710	27·953	753	29·646	764	30·079
715	28·150	754	29·685	765	30·119
720	28·347	755	29·725	766	30·158
725	28·544	756	29·764	767	30·197
730	28·741	757	29·804	768	30·237
735	28·938	758	29·843	769	30·276
740	29·134	759	29·882	770	30·315
745	29·331	760	29·922	771	30·355
750	29·528	761	29·961	772	30·384

1 millimetre = 0·03937 inch
0·1 „ = 0·00394 „
0·01 „ = 0·00039 „

1 inch = 25·39954 millimetres
0·1 „ = 2·53995 „
0·01 „ = 0·25400 „
0·001 „ = 0·02540 „

Uses of the Barometer.—The chemist requires to know the atmospheric pressure when very accurate weighings are made of light bodies, in order that the weight of the air they displace may be allowed for. On this subject, see Bessel's formulæ in the article Specific Gravity. Secondly, gases are usually weighed or measured, subject to the atmospheric pressure, and vary *directly in density* and *inversely in volume* with the pressure. Hence the atmospheric pressure must always be observed at the moment, in order that the weight or measure may be reduced, by a simple calculation, to what it would be at some standard pressure, which in England is 30·000 inches, and on the Continent 760 millimetres or 29·922 inches. Now $\frac{30{\cdot}000}{29{\cdot}922} \times 100 = 100{\cdot}261$ or 100 cubic inches of gas at the English standard pressure are equal to 100·261 cubic inches at the French standard pressure. It happens, however, that the English adopt 60° F. and the French 32° F., as the standard temperatures in these matters, and allowing for the expansion of mercury between these points, 29·922 inches become 30·006. Hence the true equivalent volume on the continental standard for 100 cubic inches of gas at 30·000 inch, 60° F., is $\frac{30{\cdot}000}{30{\cdot}006} \times 100 = 99{\cdot}98$ cubic inches, the difference being so trifling that it may almost always be neglected.

Determination of Altitudes.—Since the barometer measures the weight of the *superincumbent* air, the higher we rise in the atmosphere the lower the barometer must stand. At the surface of the earth, the barometer changes nearly ·001 inch for every foot in the change of altitude; but more exactly, the change of elevation corresponding to ·001 inch of the barometer, is:—

At temperature of 30°	0·865 foot
„ „ „ 40°	0·883 „
„ „ „ 50°	0·900 „
„ „ „ 60°	0·918 „
„ „ „ 70°	0·936 „
„ „ „ 80°	0·954 „

The difference of level (= x feet) of two barometers may be calculated by the following formula:

$$x = 60345{\cdot}7 \times \left\{ 1 + 0{\cdot}002837 \cos 2 \text{ lat.} \right\} \times \left\{ 1 + \frac{T + t}{900} \right\} \log \frac{B}{b}$$

in which B and b are the simultaneous corrected heights of the barometers at the higher and lower stations, and T, t the numbers of degrees Fahr. above 32°, at which the thermometers stand. (Biot, Traité de Physique, i. 100.)

If the height does not much exceed 3000 feet, the following more simple formula may be used:

$$x = 52494{\cdot}3 \times \frac{B - b}{B + b} \times \left\{ 1 + \frac{T + t}{900} \right\}$$

In meteorological observations, it is necessary to know the height of the barometer above the mean sea level, and to reduce the average results to that level accordingly, in order that they may be comparable with observations made at other places, and reduced in a similar manner.

Meteorology.—The chief use of the barometer is of course in meteorology, since changes of pressure in the atmosphere are the immediate cause of all winds. These changes are extremely complicated and interesting: for besides the irregular fluctuations, and extraordinary disturbances during storms, there is an average change, according to the season, and a semidiurnal oscillation, probably due to a kind of atmospheric tide, caused by the expansion of the atmosphere, where it is heated by the sun's rays (Phil. Mag. [4] xvii. 313). In keeping a register of the barometer, it should be observed every day at 9 A.M., the time of the daily maximum, and at 3 P.M., the time of daily minimum, or else at noon, when the pressure is near the mean.

The nightly maximum is about 9 P.M., the nightly mininum about 4 A.M. Almost every climate, however, is characterised by special laws of barometric fluctuation.

Aneroid Barometer. (α, priv. νηρος, liquid).—The essential part of this beautiful instrument is a small round metal box, exhausted of air, and with a thin circularly fluted lid, which the weight of the atmosphere more or less tends to press in. A complicated system of levers, causes an index, revolving over a dial, to mark the slightest movements of this metal lid. (Vidi, Compt. rend. xxiv. 275; Belville's Manual of the Mercurial and Aneroid Barometers.)

Bourdon's Metallic Barometer also consists of a vacuous metal box, but it is in the form of a flat tube bent almost into a circle. The two ends of the tube approach or recede as the atmospheric pressure increases or diminishes.

These metallic barometers are very sensitive and excellent as weather glasses, and they should be carried at sea or on exploring expeditions as a last resource in case the mercurial barometers, as often happens, become disordered. But they afford no independent measure of pressure, and are so much affected by variations of temperature as to be unsuitable for scientific use. The writer, however, has used an aneroid barometer with some success, and obtained an approximate correction for temperature by simply warming the instrument on various occasions, and noting the average change of reading (= ·0065 inch per degree F.) thus caused. An adjusting screw will be found at the back of the aneroid barometer, by which its reading may be made to agree at some one point and temperature with that of a mercurial barometer.

For a description of Macworth's "Underground barometer," see *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 255.) W. S. J.

BARRAS. The resinous incrustation in the wounds made in fir-trees.

BARSOWITE. A silicate of calcium and aluminium found near the river Barsowka in the Ural, in compact white masses or fine-grained aggregations, having a distinct cleavage in one direction. The granular variety has a faint mother-of-pearl lustre: the compact variety is dull and translucent on the edges. Sp. gr. 2·740 to 2·752. Hardness 5·5 to 6·0. Before the blowpipe, it melts with difficulty to a tumefied glass on the edges: with borax, slowly and quietly to a transparent colourless glass; likewise with phosphorus-salt, with separation of silica, the glass becoming opalescent on cooling if the proportion of the mineral is considerable. With an equal weight of carbonate of sodium, it melts to a tumefied glass, which with a larger quantity of soda, becomes snow-white and infusible. With solution of cobalt, it becomes blue on ignition. The powder is easily decomposed by hydrochloric acid, forming a thick jelly. According to Varrentrapp's analysis, it contains $3(2Ca^2O.SiO^2).(4Al^4O^3.3SiO^2)$ a small quantitiy of the lime being replaced by magnesia. (Handw. d. Chem. 2te Aufl. ii. 679.)

BARWOOD or **CAMWOOD.** A red dye-wood, the colouring matter of which appears to be identical with santolin (Preisser und Girardin, Ann. Ch. Pharm. lii. 375.) See also *Ure's Dictionary of Arts, Manufactures and Mines*, i. 255.)

BARYTA. See Barium, Oxides of.

BARYTES, BARYTINE, or **BAROSELENITE.** See Heavy Spar.

BARYTIC FLUORSPAR. A mixture of about equal parts of sulphate of barium and fluorspar, occurring on the slaty limestone of Derbyshire, where it forms a bed about an inch thick.

BARYTO-CALCITE, $BaCaCO^3$ or $BaO.CO^2 + CaO.CO^2$; a mineral found in Cumberland, of a slightly yellowish-brown tinge, translucent, with a waxy lustre, and sp. gr. 3·66. It contains cavities which are lined with crystals having the form of oblique rhombic prisms. The external surface is coated with sulphate of barium. (Brooke, Ann. Phil. N.S. viii. 114.)

The name baryto-calcite was also given by Thomson to a laminated mineral containing 71·9 p. c. sulphate of barium and 28·1 sulphate of calcium, found between Leeds and Harrogate in Yorkshire; also by Johnston to Alstonite, which is of the same composition but different crystalline form.

BARYTO-CŒLESTIN. This name is given to two minerals, both consisting of sulphate of barium and sulphate of strontium (cœlestin), one occurring near Kingstown in Canada, the other in the Binnenthal in Switzerland. The Swiss mineral forms orthorhombic crystals, containing, according to Waltershausen (Pogg. Ann. xciv. 134), 87·8 p.c. sulphate of barium and 9·1 sulphate of strontium. The Canadian mineral occurs in crystalline masses, containing, according to Thomson, $Ba^2Sr^4.3SO^4$. Allied to this is a mineral from the chalk marl of Moen, containing 40 p.c. Sr^2SO^4, 28·3 Ba^2SO^4, 15·5 Ca^2SO^4, 13·5 Ca^2CO^3, and 2·5 water.

BARYTOPHYLLITE. Syn. with CHLORITOÏDE.

BASALT. A rock of volcanic origin, occurring in amorphous masses, columnar, amygdaloïdal, and vesicular. Its colours are greyish-black, ash-grey, and raven-black. Massive, with dull lustre and granular structure. Fracture uneven or conchoïdal. Concretions columnar, globular, or tabular. It is opaque, yields to the knife, but is not easily frangible. Streak light ash-grey. Sp. gr. 3. Melts into a black glass and recovers its granular structure by slow cooling. It is found in beds and veins in granite and mica slate, the old red sandstone, and coal formations. It is distributed over the whole world, and is met with in great variety in Scotland.

The most remarkable variety of basalt is the columnar, which forms immense masses, composed of columns thirty, forty, or more feet in height, and of enormous thickness; those at Fairhead are two hundred and fifty feet high. These constitute some of the most astonishing scenes in nature, for the immensity and regularity of their parts. The coast of Antrim in Ireland, for the space of three miles in length, exhibits a very magnificent variety of columnar cliffs; and the Giant's Causeway consists of a point of that coast formed of similar columns, and projecting into the sea upon a descent for several hundred feet. These columns are, for the most part, hexagonal, and fit very accurately together; but most frequently do not adhere together, though water cannot penetrate between them. Another very remarkable formation of columnar basalt is the island of Staffa on the west coast of Scotland. The most extensive mass of basalt yet observed is that discovered by Colonel Sykes in the Deccan, where it occupies a surface of many thousand square miles.

Basalt is not a mineral of definite constitution, but a mixture of several minerals, generally of labradorite, augite, olivine, magnetic iron ore, and a zeolite. These minerals may however be replaced by others, namely labradorite by other varieties of felspar, and augite by amphibole: the zeolitic portion also varies greatly in composition. Some of the constituents of basalt viz. the olivine, the magnetic iron ore and the zeolite are decomposible by hydrochloric or sulphuric acid; the rest for the most part resist the action of acids; but the analytical results obtained by this mode of treatment are not very definite, inasmuch as the action of the acid varies with its strength, with the state of aggregation of the basalt, and with the nature of the individual minerals of which it is composed. The constituents of basalt, are silica (about 50 per cent.) alumina, protoxide of iron, lime, magnesia, potash, soda and water, the proportions of which differ considerably in the several varieties of basalt, as shown by the numerous analyses which have been made of it.

Basalt when calcined and pulverised, is said to be a good substitute for pozzolana in the composition of mortar, giving it the property of hardening under water. Wine bottles have likewise been manufactured with it, but there appears to be some nicety required in the management to ensure success. A mixture of 1 pt. basalt, 2 pts. broken glass, 2 soda, 1 wood-ash, and $\frac{1}{50}$ peroxide of manganese, has also been used for similar purposes.

BASALTIC HORNBLENDE usually occurs in opaque six-sided crystals, which sometimes act on the magnetic needle. It is imbedded in basalt or grauwacke. Colour velvet-black. Lustre vitreous. Scratches glass. Melts with difficulty to a black glass. Contains 47 per cent. silica, 26 alumina, 8 lime, 2 magnesia, 15 iron, and 0·5 water. It is found in the basalt of Arthur's Seat, in that of Fifeshire, and in the Isles of Mull, Canna, Eigg, and Skye; also in the basaltic and floetz traps of England, Ireland, Saxony, Bohemia, Silesia, Bavaria, Hungary, Spain, Italy, and France. U.

BASANITE. See JASPER.—**BASANOMELANE.** See ILMENITE.

BASE. This term is the correlative of ACID, and denotes the electropositive constituent of a salt. Its signification varies, however, to a certain extent, according to the view which is taken of the constitution of salts. In the dualistic system, which regards salts as formed by the union of two binary compounds of the first order, *e.g.* sulphate of copper = $Cu^2O.SO^3$; sulpharsenate of potassium = $3K^2S.As^2S^5$: hydrochlorate of ammonia = $NH^3.HCl$; nitrate of ethylamine = $NH^2(C^2H^5).HNO^3$, &c.; the base is the electropositive oxide, sulphide, selenide, or alkaloïd, which unites with the electronegative oxide, sulphide, &c., or hydracid; but in the unitary system, in which the salts of any acid are regarded as formed on the same type as the acid (or hydrogen-salt) itself, the base must be understood as the metal or other electropositive radicle by which the hydrogen of the acid is replaced: thus in the salts above-mentioned, regarded as Cu^2SO^4, K^3AsS^4, NH^4Cl, $NH^3(C^2H^5).NO^3$, the bases are the radicles Cu, K, NH^4, $NH^3(C^2H^5)$. (See ALKALIS, ALKALOIDS, AMINES, AMMONIUM-BASES, OXIDES, RADICLES.)

BASICERINE. See HYDROCERITE.

BASICITY. The power of an acid to unite with one or more atoms of base. See ACIDS, p. 46.

BASILICUM, OIL OF. The leaves of the *Ocymum basilicum*, a plant belonging to the labiate order, yield by distillation with water, an essential oil, which after a while deposits prismatic crystals, having the character and composition of hydrate of turpentine, $C^{10}H^{22}O^3 = C^{10}H^{16}.3H^2O$ (Dumas and Péligot). The oil itself has not been examined.

BASSIA LATIFOLIA. The seeds of this plant, which grows on the Himalayas, yield by pressure a yellowish oil, which gradually becomes colourless on exposure to light, has a faint odour, a density of 0·958, and a buttery consistence at ordinary temperatures; melts at 27° to 30° C.; dissolves sparingly in anhydrous alcohol, scarcely at all in spirit of ordinary strength, readily in ether. By saponification it yields, besides oleic acid and glycerin, two fatty acids, one which has not been obtained pure, but appears to have the composition $C^{15}H^{30}O^2$; the other, originally supposed to be a peculiar acid, and called *bassic acid*, is identical in composition and properties with stearic acid, $C^{18}H^{36}O^2$. (Hardwicke, Chem. Soc. Qu. J. ii. 231.)

BASSORIN. The principal constituent of *Gummi bassoræ*, *G. Toritonense*, or *G. Kutera*, a gum obtained from various species of acacia. This gum contains only about 5·6 per cent. of matter soluble in water (arabin), while the larger proportion, which is the bassorin, merely swells up in water. (See GUM.)

BASTARD CLOVER. *Trifolium hybridum.*—100 pts. of the fresh flowering plant yield 2·44 pts. of ash; 100 pts. of the dry plant 8·1 pts. of ash. The ash contains in 100 pts. 19·9 potash, 5·7 soda, 18·4 lime, 3·1 magnesia, 5·6 alumina (?), 3·9 sesquioxide of iron, 1·8 protoxide of manganese (?), 35·1 silica, 1·4 sulphuric anhydride, 4·5 phosphoric anhydride, 0·6 chlorine. (Sprengel, J. pr. Chem. x. 56.)

BASTITE. A mineral found at Basti in the Harz, and forming imperfectly defined individual crystals intergrown with serpentine. It cleaves very easily in one direction, less easily in another, making an angle of 87° with the first; there are also two imperfect cleavage-planes in the direction of the longitudinal and lateral faces. Fracture, uneven and splintery. Colour, leek to olive green, passing into yellow and brown. It has a metallic, glittering, nacreous lustre on the cleavage-faces; translucent on the edges. Specific gravity 2·6 to 2·8. Hardness 3·5 to 4·0. Gives off water when heated, and before the blowpipe becomes pinchbeck-brown and magnetic; it then splinters, melting to a brown glass on the edges. With borax and phosphorus-salt, it gives the reactions of iron and chromium, and with the latter a skeleton of silica. It is imperfectly decomposed by hydrochloric, completely by sulphuric acid. Its composition is nearly represented by the formula $4Mg^2H^4O^3 . 3(Mg^4 \text{ or } Fe^4)Si^3O^8$ which, if the hydrogen be regarded as basic, may be reduced to the general form $M^{36}Si^9O^{36}$, that is to say to the formula of an orthosilicate M^4SiO^4. Hermann regards the mineral as crystallised serpentine somewhat altered in composition by admixture of foreign minerals; but its form indicates rather a relation to the augite family. (Handw. d. Chem. i. 756.)

BASYL. Graham's name for the metal or other electropositive constituent of a salt (Elements of Chemistry, 2nd ed. i. 186).

BATATAS EDULIS. Sometimes called *Convolvulus batatas* or *Spanish potato*, a plant said to be indigenous in India, but extensively cultivated in America, and sometimes also in the south of Europe. The tubers resemble those of the potato, but have a sweeter taste. According to T. J. Herapath (Chem. Soc. Qu. J. iii. 194), they contain, in the fresh state, 66·7 per cent. water and other volatile matter, 31·8 vegetable matter, and 1·5 inorganic matter. The ash contains in 100 pts.: —

(*a.*) *Soluble in water.* — 8·7 CO^2, 7·1 SO^3, 0·9 P^2O^5, 29·3 K^2O, 12·4 KCl, and 11·4 NaCl.

(*b.*) *Insoluble.* — 6·2 CO^2, 7·1 P^2O^5, 12·0 Ca^2O, 1·4 Mg^2O, 1·3 Fe^4O^3, 2·1 SiO^2, with traces of sulphuric acid and alumina.

According to Henry (J. Pharm. xi. 223) the tubers contain in 100 pts. 13·3 starch, 0·9 albumin, 3·3 sugar, 1·1 fat insoluble in ether, 6·8 woody fibre, 1·4 malic acid, acid phosphates, chloride of potassium, &c., and 73·1 water, also 0·05 of a volatile poisonous matter.

BATH. The heat communicated from lamps and fires is subject to variation from many circumstances; and this variation not only influences the results of operations, but often endangers the vessels, especially if they are made of glass. To obviate these sudden changes of temperature, and at the same time to afford means of observing and regulating the degree of heat imparted, the vessel containing the substance operated upon is immersed in another containing water, oil, fusible metal, air, or other medium, which receives the heat directly from the source. The sand-bath and water-bath are most commonly used, the latter for maintaining a substance for any length of time at the constant temperature of 100° C., the former for higher temperatures, particularly when the exact observation of the temperature is not an object. In using the water-bath, the vessel to be heated may, according to convenience, be either immersed in the water or so placed above the vessel that its lower surface may be in contact with the steam. A ready method of constructing a water-bath for small operations is to place the basin containing the substance to be heated on the top of another of equal size, containing water and supported over a gas lamp.

The temperature of the water-bath may be raised above 100° C., by dissolving certain salts in the water. A saturated solution of common salt boils at a temperature of 7°·5 C. or 13°·3 F., above the boiling point of water; and by using a solution of chloride of calcium, a bath of any temperature between 100° and 125° C. or 212° and 252° F. may be conveniently obtained.

Liquid baths of higher temperature are obtained by the use of linseed oil or fusible metal heated in cast-iron pots. The oil-bath may be used for temperatures up to about 300° C., but it is dirty, and exhales an extremely unpleasant odour when strongly heated. Fusible metal is much cleaner and more pleasant to use, but its weight is an inconvenience where a large bath is required. A thermometer immersed in the liquid, as near the middle as possible, serves to indicate the temperature. The oil-bath is much used in the determination of vapour-densities by Dumas's method, also for heating volatile substances or mixtures in sealed tubes, so as to subject them to a higher tem-

Fig. 94.

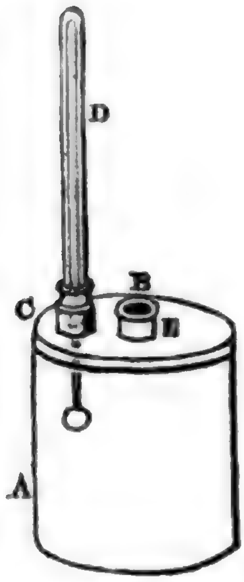

Fig. 95.

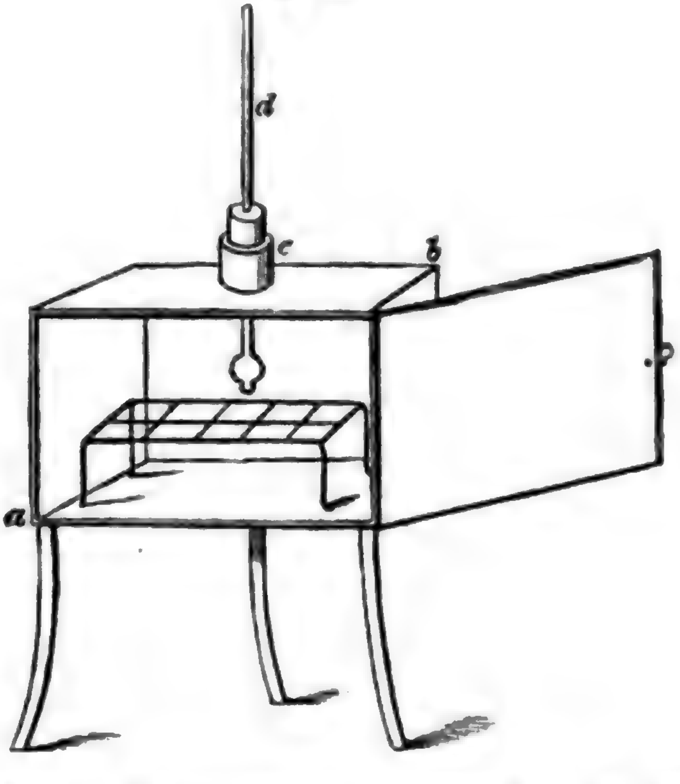

perature than that to which they could be exposed under the ordinary atmospheric pressure. The danger of explosion attending this operation may be obviated by enclosing the sealed glass tube in a strong tube of wrought iron, having a massive screw cap.

The air-bath is very convenient for many purposes, especially for desiccation. An air-bath may be extemporaneously constructed by placing an empty basin over a lamp, and another basin containing the substance to be dried on the top of it. The upper vessel is then heated by the air in the intervening space. A more convenient apparatus, which also serves to indicate the temperature, consists of a cylindrical copper vessel A, *fig.* 94, the cover of which is movable and has two apertures, the middle serving for the escape of vapour and the lateral one for the insertion of the thermometer. The vessel to be heated rests on a ring within the box, supported by a tripod. A larger air-bath serving to heat several small vessels at once is represented in *fig.* 95. Air-baths are sometimes surrounded with a jacket to hold water or oil. When water is used, the temperature of course cannot exceed 100° C. When oil is used, the temperature is indicated by a thermometer having its bulb immersed in the liquid.

High-pressure baths.—The danger of explosion in heating volatile liquids in sealed tubes is greatly diminished, when the tubes are at the same time subjected to a pressure from without. This may be effected by enclosing the tube containing the volatile liquid in a wider glass tube containing a less volatile liquid, and likewise sealed; the whole is then heated in an oil- or air-bath. In this manner, alcohol or ether may be heated to 360° C., the outer tube containing oil of turpentine (**Berthelot**). Greater security is obtained by enclosing the glass tube in a wrought iron tube, with a screw-cap, or by the use of a Papin's digester, or better, by the following apparatus invented by **Frankland** (Ann. Ch. Pharm. xcv. 30).

Fig. 96.

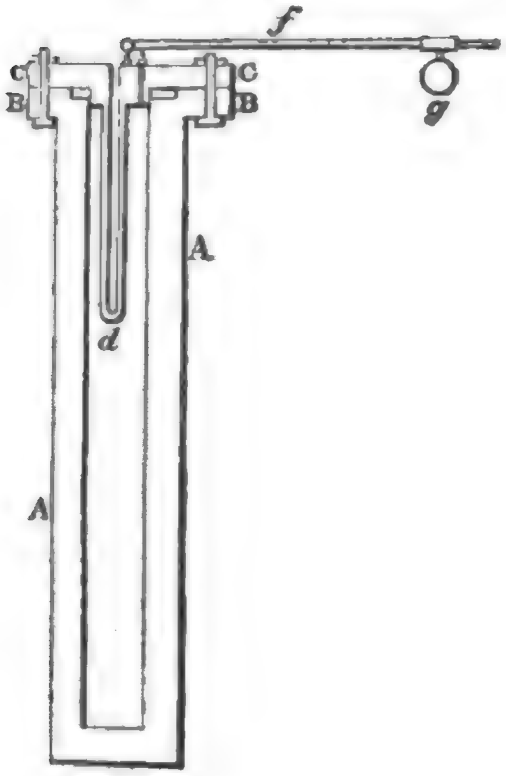

Fig. 97.

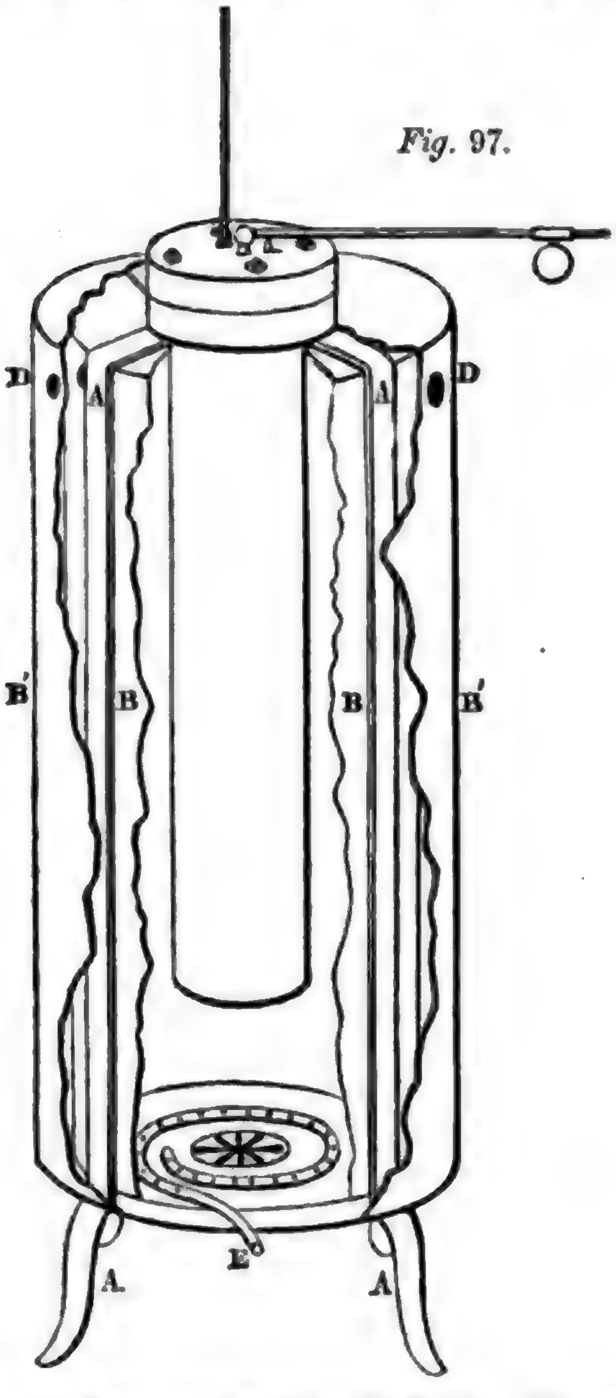

A A (*fig.* 96) is an iron cylinder 18½ inches long, 3 inches internal diameter, ⅝ inch thick in the side, and welded in one piece by the steam hammer. This cylinder has a flanch, B B, $1\frac{3}{8}$ inch broad, $\frac{5}{8}$ inch thick, turned true on the upper surface, and having an internal annulus sunk $\frac{1}{20}$th of an inch below the level of the surrounding surface. The cap C C, which is of the same diameter and thickness as the flanch, has a projecting face $\frac{1}{4}$ inch deep which fits exactly into the mouth of the cylinder. Within this projection the cap is pierced with two apertures, into one of which is fitted a cast-iron tube *d*, 6 inches long and $\frac{1}{2}$ inch in external diameter, filled with mercury and destined to receive a thermometer. The other aperture is bouched with brass, and serves as the bed of the safety-valve, which consists of brass wire $\frac{1}{8}$ inch thick, somewhat flattened on two sides, and furnished with a head accurately ground to the surface of the cap. The valve is loaded in the usual way with a lever *f* and weight *g*. The cap and flanch are fastened together by four screw-bolts, which are inserted from below and tightened by a lever-key, and the pressure thus exerted acts upon a lead washer $\frac{1}{8}$ inch thick, placed in the annular depression of the flanch. In this manner the apparatus may be made capable of bearing a pressure of 100 atmospheres without allowing any escape of gas. The cylinder A is about two-thirds filled with water, and the glass tube containing the volatile liquid is enclosed in it. In this manner, tubes of considerable width may be heated without danger of explosion.

The apparatus is heated in a gas-furnace (*fig.* 97). A A A A is a massive frame of wrought-iron, within which is fixed a cylinder B B, cf tin plate, closed at bottom and open at top to receive the apparatus above described. *c* is a regulator for the admission of air. The gas-burner is a copper tube *e*, $\frac{1}{4}$ inch wide and pierced with 18 or 20 apertures. To prevent loss of heat by radiation, the whole apparatus is enclosed in a cylinder B′ B′, of polished tin plate, separated from the inner cylinder by a space about $\frac{1}{2}$ an inch wide. The products of combustion escape by the apertures D D.

BATH-METAL. An alloy of copper and zinc containing a larger proportion of zinc than ordinary brass, and usually prepared by melting brass with zinc.

BATRACHITE. A mineral found on the Rizomberg in the Tyrol, generally massive, with a granular structure, rarely crystalline. It contains according to C. Rammelsberg (Pogg. Ann. li. 466), 37·69 silica, 35·45 lime, 21·79 magnesia, 2·99 protoxide of iron. and 1·27 water. Colour varying from light greenish-grey, like that of a frog (βάτραχος), to white; translucent with waxy lustre. Specific gravity 3·0 to 3·1. Hardness = 5·0. Melts before the blowpipe, assuming a pale red colour with solution of cobalt; is but slightly attacked by acids. The water appears to be unessential, and the composition of the mineral approaches to that of Monticellite. (Handw. d. Chem. ii. 757.)

BATRACHOLEIC ACID. An acid said to be contained, together with stearic acid, glycerin, and a peculiar yellow fat, in the oil obtained by pressure from the epiploon of the water salamander. (Rossignon, Compt. rend. xiii. 929.)

BAUDISSERITE. A dense variety of magnesite containing silica, found near Baudissero in Piedmont. As the amount of water contained in it is very variable, F. v. Kobell and Neumann regard it as a compact hydromagnesite intimately mixed with silica.

BAULITE, or *Krablite.*—A mineral found on the Krabla in Iceland, and likewise on the Baulaberg, either in short prismatic crystals belonging to the triclinic or doubly oblique prismatic system, or in crystallo-granular masses. Cleavage in two directions at right angles to each other. Fracture uneven and conchoïdal. Colourless, with glassy lustre; transparent or translucent. Specific gravity 2·5 to 2·7. Hardness 5·5 to 6·0. In the following table, *a* is the analysis of a specimen of baulite resembling pearlstone, from the Baulaberg, by Forchhammer (Ann. Min. viii. 644); *b* is that of a crystallo-granular variety of baulite, ejected by the volcano of Viti in Iceland, mixed with quartz-crystals and a black needle-shaped mineral, also by Forchhammer (Berzelius's Jahresb. xxiii. 261): *c* is Genth's analysis (J. pr. Chem. lxvi. 93), of crystallised baulite from the Krabla:

	SiO^2	Al^4O^3	Fe^4O^3	Fe^2O	Mn^4O^3	Ca^2O	Mg^2O	K^2O	Na^2O	Cl,	H^2O
a.	74·38	13·78	1·94		1·19	0·85	0·58	2·63	3·57	0·12	2·08
b.	76·65	11·57		0·63		0·05	0·20	3·26	3·73		
c.	80·23	11·34			trace	1·46	trace	4·92	2·26		

These analyses agree sufficiently well with the formula $(M^2O.3SiO^2).(Al^4O^3.6SiO^2)$, which (if $al = \frac{2}{3}Al$) may be reduced to $(M^2al^6)Si^9O^{22}$ or $2R^4SiO^4.7SiO^2$, the formula of an orthosilicate with $\frac{7}{2}$ at. silica; but it is probable, as Bunsen supposes, that the mineral is intimately mixed with orthoclase, Before the blowpipe, baulite is fusible in very thin splinters; with borax and phosphorus-salt it yields clear glasses, a skeleton of silica floating in the latter. It is insoluble in hydrochloric acid. (Handw. d. Chem. ii. 758.)

BAVALITE. See BARALITE.

BAY-SALT. See SODIUM, CHLORIDE OF.

BDELLIUM. A gum-resin of which there are two varieties, *African* and *Indian*. African bdellium is derived, according to Perrotet, from a shrub indigenous in Senegambia, the *Hendelotia africana* (Guillem and Perr); *Balsamadendron africanum* (Arnott); *Amyrès Nicattout* (Adanson), belonging to the amyredaceous order. It forms irregular, translucent masses, of a yellowish, reddish, or brownish colour, according to age; unctuous to the touch, brittle, but soon softening, and growing tough between the fingers. Specific gravity 1·371. It has a bitterish taste, and a moderately strong balsamic odour, not unlike that of myrrh. It does not easily take fire, and when set on fire soon goes out: in burning it gives off a balsamic odour, and sputters a little, owing to the presence of moisture. Alcohol dissolves about ⅗ of it, forming a golden-yellow tincture, from which water throws down a yellowish-white resin, and nitric acid a sulphur-yellow resin. Potash dissolves it completely. By dry distillation it yields ammonia, together with other products. According to Pelletier (Ann. Ch. Phys. [2] lxxx. 38), it contains 59 per cent. resin, 9·2 gum, 30·6 vegetable mucus, and 1·2 volatile oils (and loss).

The resin is transparent, but becomes white and opaque by boiling with water; melts between 58° and 60° C. According to Johnston (J. pr. Chem. xxvi. 145), it is $C^{40}H^{31}O^{5}$. The gum is yellowish-grey, and when treated with nitric acid, yields malic but no mucic acid. The vegetable mucus is also yellowish-grey, swells up with water, coagulates with alcohol, and is converted by nitric acid into a thin liquid. The volatile oil is heavier than water.

Indian bdellium is said to be obtained from *Balsamodendron Mukal* (Hooker), also an amyredaceous tree, growing in Scinde. It forms irregular, greenish-brown, or blackish masses, having a strong odour, and sharp bitter taste like myrrh. It becomes sticky between the fingers.

BEAN. Two species of bean are commonly cultivated in Europe, viz. 1. *Faba vulgaris*, or *Vicia Faba*, the common field or garden bean (*Feldbohne*, *grosse Bohne*, *Saubohne*), the most common garden varieties of which are the Windsor broad bean, the Toker, the long-pod, and the Mazagan, while for field cultivation, the Heligoland, or tick-bean, and the common horse-bean, are preferred as being more hardy.—2. *Phaseolus vulgaris*, the French, haricot, or kidney-bean, innumerable varieties of which are cultivated, some dwarf, others climbing. The scarlet-runner, *Phaseolus multiflorus* is closely allied to this species.

The seeds of these several species and varieties differ but little in chemical composition, as the following tables will show; but they are all remarkable for the large amount of nitrogenous matter (legumin) and phosphoric acid which they contain.

TABLE A.—*Composition in* 100 *parts of various kinds of Bean.*

	Legumin, &c.	Sugar.	Gum.	Starch.	Fat.	Pectin substances.	Woody fibre.	Ash.	Water.
1. Field-bean (*air-dried*)	24·2	—	44·2		1·4	—	12·6	3·6	14·0

1. Poggiale (J. Pharm. [3] xxx. 180). The shells amounted to 15 per cent. of the weight of the entire pods, and contained neither legumin nor starch.—2. Mean of earlier analyses by Braconnot, Horsford, and Krocker.—3. Mean of earlier analyses by Einhof, Boussingault, Horsford, and Krocker.—4, 5. Polson (Chem. Gaz. 1855, p. 211).—6. Poggiale (*loc. cit.*) The shells amounted to 7·5 per cent. of the weight of the entire pods, contained very little starch, 0·2 per cent. fat, 6·5 nitrogenous matter, and 5·8 ash.

Ward and Eggar (Jahresber. d. Chem. 1849, p. 708), obtained from several varieties of fresh beans grown on various soils: 2·4 to 3·6 per cent. nitrogen, 1·2 to 1·7 per cent. fat, and 11·0 to 17·0 per cent. water.—Way and Ogston obtained from the same varieties of bean (Heligoland and Mazagan), grown on various soils, in 100 pts. of the fresh seeds: 8·1 to 17·0 per cent. water, and in 1000 pts. of the dried seeds of five varieties, 2·5 to 2·9 per cent. sulphur, in a sixth kind, 4·6 per cent. sulphur.

* Cellulose and Shells.

† Cellulose.

Mayer (Ann. Ch. Pharm. ci. 144), obtained from 100 pts. of air-dried Mazagan beans, 11·8 to 12·5 per cent. water, 1·13 and 1·18 phosphoric anhydride, and 4·25 to 4·3 nitrogen. In dwarf haricot beans, he found 10·1 per cent. water, 1·06 phosphoric anhydride, and 3·32 nitrogen; in climbing haricot beans, 9·4 per cent. water, 0·95 phosphoric anhydride, and 3·17 nitrogen.

The sugar occurring in beans is usually regarded as grape-sugar. Vohl (Ann. Ch.

1. Analysed by Bichon (Handw. d. Chem. 2te Aufl. ii. [2], 259).—2. Boussingault (*ibid.*)—3. By Büchner (*ibid.*)—4–10 and 16–20. Way and Ogston (Journal of the Royal Agricultural Society, ix. pt. 1).—11. Levi (Handw.)—12. Boussingault (*ibid.*)—13. Thon (*ibid.*)—14. Richardson (Jahresber. f. Chem. 1847, 1848, p. 1075, Tafel C).—15. Hertwig (Handw.) This contained carbonic acid, which has been deducted.

The pods of *Phaseolus multiflorus* contain, according to T. J. Herapath (Chem. Soc. Qu. J. 4), 94·1 per cent. water; air-dried, they yielded 0·631 per cent., and, after drying at 100° C., 10·7 per cent. of ash, containing:—

Of matter soluble in water: 14·1 carbonic anhydride; 3·4 sulphuric anhydride; 1·5 phosphoric anhydride; 36·1 potash; 4·9 chloride of sodium.

Of matter insoluble in water: 22·2 carbonate of calcium; 3·8 carbonate of magnesium; 11·9 phosphate of calcium; and 2·1 silica.

BEAUMONTITE. A mineral found in the gneiss at Jones Falls near Baltimore, in North America, in square pyramids, having terminal dihedral angles of 147° 28′, and the lateral edges replaced by the square prism ∞ P.

Cleavage parallel to ∞ P. Yellowish-white to honey-yellow, translucent, with nacreous lustre. Specific gravity 2·24. Hardness 4·5 to 5·0. According to Delesse (Ann. Ch. Phys. [3] ix. 385), it contains 64·2 silica, 14·1 alumina, 4·8 lime, 1·7 magnesia, 1·2 protoxide of iron, 0·6 soda (and loss), 13·4 water. Alger and Dana are of opinion that the mineral thus characterised is merely stilbite, the form of which has been incorrectly determined, and the analysis made with impure material.

Pharm. xcix. 125), found, in the unripe seeds, another kind of sugar, which he at first regarded as a peculiar substance, designated by him as *phaseomannite*, from its resemblance to mannite. According to later investigations, however, it appears to be identical with inosite, the saccharine substance which Scherer obtained from muscular flesh.

The name *Beaumontite* is also given by Jackson to a variety of siliceous malachite, or an allied mineral containing silica, water, and oxide of copper.

BEBIRIC ACID. An acid contained, according to Maclagan, in the bark of the *Bebeeru* or *Sipeeri* (*Nectandra Rodiei*), a tree growing in British Guiana. To obtain the acid, the bark is exhausted with water acidulated with acetic acid; the alkalis, bebirine and sepirine, with which the acid is in combination, are precipitated by ammonia; the filtered liquid is precipitated by acetate of lead; the precipitate decomposed by sulphuretted hydrogen; the clear liquid evaporated over sulphuric acid; and the residue digested in ether, which dissolves the acid, but leaves the colouring matter. On evaporating the ethereal solution, bebiric acid remains as a white crystalline substance, having a waxy lustre. By exposure to the air, it is gradually reduced to a syrupy liquid. It melts a little above 200° C., and sublimes in tufts of needles. With potash and soda, it forms deliquescent salts soluble in alcohol; sparingly soluble salts with the alkaline earths; the lead-salt also is but sparingly soluble in alcohol.

BEBIRINE or **BEBEERINE.** $C^{19}H^{21}NO^3$ or $C^{38}H^{21}NO^6$.—An alkaloid discovered in 1834 by Dr. Rodie of Demerara, in the bark of the bebeeru tree (*vid. sup.*). Maclagan in 1843 (Ann. Ch. Pharm. xlviii. 106), showed that Rodie's bebirine was a mixture of two distinct alkaloids, which he denominated *bebirine* and *sepirine*. The former of these was more exactly investigated in 1845 by Maclagan and Tilley (Phil. Mag. xxvii. 186), who assigned to it the formula $C^{35}H^{20}NO^6$. But bebirine was first obtained perfectly pure by v. Planta (Ann. Ch. Pharm. lxxvii. 333), who assigned to it the formula above given.

Preparation.—1. The bark is exhausted with water containing sulphuric acid; the extract is concentrated, filtered, and precipitated by ammonia; and the precipitate, consisting of bebirine, sepirine, and tannin, is dried, dissolved in acidulated water, and decolorised with animal charcoal. The solution again decomposed by ammonia, yields a nearly colourless precipitate of bebirine and sepirine. As, however, the treatment with animal charcoal always occasions a certain loss of alkali, it is better to triturate the precipitate while yet moist with oxide of lead or milk of lime, dry the mixture over the water-bath, extract the two alkaloids by means of alcohol, and evaporate the alcoholic solution. To separate the two alkaloids, the product is exhausted with ether, which dissolves only the bebirine (Maclagan and Tilley). — 2. The bebirine prepared by the process just described, is not quite pure, and does not dissolve completely in ether. It may be purified by treating it with acetic acid, adding acetate of lead to the filtrate, precipitating the mixture with caustic potash, washing the precipitate with a large quantity of cold water, and redissolving in ether. The ethereal solution, when evaporated, leaves the bebirine in the form of a clear yellow syrup, which is dissolved in a small quantity of strong alcohol, and the solution is added drop by drop to a considerable quantity of water, with constant agitation: bebirine then separates in the form of a floculent precipitate. (v. Planta.)

Bebirine when dry, is a white, amorphous, odourless powder, which does not change by exposure to the air, and becomes electrical by friction. It melts at 198° C. to a vitreous mass, which decomposes at a higher temperature. — By boiling with strong nitric acid, it is converted into a yellow pulverulent substance. Heated with chromic acid, it yields a black resin. It does not yield chinoline when heated with caustic potash.

Bebirine is nearly insoluble in water, but dissolves readily in alcohol and ether, especially with the aid of heat. The solution has an alkaline reaction, and a very persistent bitter taste. It dissolves readily in acetic and hydrochloric acid, forming bitter uncrystallisable salts. It is precipitated from its solutions by dilute nitric acid.

Hydrochlorate of bebirine is very soluble in water; and the solution treated with caustic alkalis or their carbonates yields bebirine in white flakes, easily soluble in excess of the reagents. The *chloromercurate* is obtained by adding mercuric chloride to the solution of the hydrochlorate; a small quantity of hydrochloric acid or chloride of ammonium increases the precipitate; but an excess redissolves it. The *chloroaurate* is a brown-red precipitate. The *chloroplatinate*, $C^{19}H^{21}NO^{3}.HCl.PtCl^{2}$, is an orange-yellow amorphous precipitate, insoluble in hydrochloric acid. The *sulphocyanate* is a white precipitate; the *picrate* yellow.

Sulphate of bebirine in the impure state has been used as a remedy in intermittent fever.

The bark of the bebeeru tree, which has a bitter and astringent taste, contains about 2·5 per cent of bebirine and sepirine, together with bebiric acid and a peculiar tannin; the seed contains the same principles, together with about 50 per cent. of starch, which impedes the extraction of the bases and acid.

BECKITE. This name has been given to a mineral from Paynton in Devonshire, which, according to Kenngott, is merely a coral hardened into a chalcedonic or hornstone variety of quartz, intergrown with compact grey limestone.

BEECH. *Fagus sylvatica.*—Beech-wood recently felled, has a specific gravity of 0·982, and contains 40 per cent. water; after drying in the air, it has a specific gravity of 0·590, and contains 18 to 20 per cent. water. After drying at 100° C. it contains, according to Baer (Arch. Pharm. [2] lvi. 159), 46·1 to 48·3 per cent. carbon, 5·8 to 6·0 hydrogen, 46·6 to 45·1 oxygen, and 1·2 to 0·6 ash. According to Chevandier (Compt. rend. xxiv. 269), it contains 49·8 per cent. C, 6·0 H, 43·1 O, 1·1 N, and yields 1·06 per cent. ash. According to Sprengel (J. techn. Chem. xiii. 384), the air-dried wood yields 0·365 per cent. ash, containing 0·14 crude carbonate of potash; and the leaves which fall in autumn yield 6·695 per cent. ash.

The following table exhibits the composition per cent. of the ash of beech-wood, and of the leaves. *a*, *g*, *h* are by Sprengel (*loc. cit.*); *b*, *c* (Witting, Pharm. Centr. 1851, 104); *b*, of wood grown on sandstone (*bunter Sandstein*), near Marburg; *c* of wood grown on the Muschelkalk, near Morschen in Kurhessen; *d*, *e*, *f* (Heyer and Vonhausen, Ann. Ch. Pharm. lxxxii. 180). The wood was grown on a basaltic hill near Giessen. A hectare of surface produced yearly 2·672 cubic metres of stem-wood (*Scheitholz*); 0·965 c. m. large branch-wood (*Prügelholz*); 0·769 c. m. small branch-wood (*Stockholz*); and 1·878 c. m. of twigs (*Reisholz*); and these quantities of wood extracted from the soil, in all, 51·3 kilogrammes of ash, viz. the stem-wood 17·0 kil., the large branch-wood 9·9 kil., the small branch-wood 4·9 and the twig-wood 19·5 kil. Hence a cubic metre of the stem-wood yields 6·342 kilogrammes of ash; of large branch-wood 10·233 kil.; and of twig-wood 14·144 kil. The table shows also that, reckoning from the bottom upwards, the proportion of *alkali* diminishes, that of the *phosphoric* and *sulphuric acid* increases; while of *silica*, the twigs have more than the stem, and the thick branches least of all.

The *bark* of the beech contains, together with the usual constituents of vegetable substances, about 2 per cent. of tannin, also a peculiar red substance, and another which smells like vanilla. The latter is soluble in alcohol, insoluble in water and in ether; and by shaking up the alcoholic solution with hydrate of lead, and repeated precipitation by water, it may be obtained as an amorphous white powder, with an odour of vanilla and a bitter taste. It dissolves in acetic acid and in alkalis; nitric acid converts it into oxalic acid. (Lepage, J. Pharm. [3] xii. 181.)

Dry beech-bark yields about 0·6 per cent. crude potash. According to Hertwig (Ann. Ch. Pharm. xlvi. 97), it yields 6·6 per cent. ash, containing in 100 pts. 3·0 soluble salts, consisting of alkaline carbonates, sulphate of potassium, and a trace of chloride of sodium, and 97·0 pts. of insoluble salts, viz. 64·7 carbonate of calcium, 16·9 magnesia, 2·7 phosphate of calcium, 1·9 phosphates of magnesium, aluminium, and iron, and 9·0 silica.

The *ash of beech-nuts* yields in 100 pts. 18·1 K^2O, 7·5 Na^2O, 19·5 Ca^2O, 9·2 Mg^2O, 2·5 Mn^2O^2, 16·5 P^2O^5, 0·7 NaCl. 1·5 SiO^2, 9·1 CO^2, and 9·4 charcoal. (Handw. d. Chem. 2te Aufl. ii. [2] 549.)

BEECH-NUT OIL. *Huile de faine.* $C^{15}H^{28}O^2$.—Beech-nuts yield, by pressure, about 17 per cent. of a clear, light-yellow, viscid oil, inodorous, having a mild taste and a density of 0·9225 at 15° C. It solidifies at 17° C., and is coloured rose-red by nitric acid. It is a non-drying oil, and yields a white soap. It is used in cooking and for illumination. Mixed with eight or ten times its bulk of water, and treated at 60° or 80° C. with *chlorine* gas, it is converted into a chlorinated oil containing $C^{15}H^{26}Cl^2O^2$. *Bromine* acts on it with violence, but if the oil be cooled at the same time, the compound $C^{15}H^{26}Br^2O^2$ is produced. (Lefort, Compt. rend. xxxv. 734.)

BEER is the wine of grain, and is prepared from malt, or grain, generally barley, which has been allowed to germinate. The grain is steeped for two or three days in water, until it swells, becomes somewhat tender, and tinges the water of a bright reddish-brown colour. The water being then drained away, the barley is spread about two feet thick upon a floor, where it heats spontaneously, and begins to grow by first shooting out the radicle. In this state, the germination is stopped by spreading it thinner, and turning it over for two days; after which it is again made into a heap, and suffered to become sensibly hot, which usually happens in little more than a day. Lastly, it is conveyed to the kiln, where, by a gradual and low heat, it is rendered dry and crisp. This is malt, and its qualities differ according as it is more or less soaked, drained, germinated, dried, and baked.

Malt is distinguished by its colour, as pale, amber, brown, or black malt, according to the different degrees of heat to which it has been subjected. Pale malt is produced when the drying temperature does not exceed 90° to 100° F., amber-coloured malt when the heat has been raised to 120° to 125°, and brown malt at 150° to 170°. Black malt, commonly called patent malt, is prepared by roasting in cylinders like coffee, at a heat of 360° to 400° F.; it is used as colouring matter in the brewery of porter.

Indian corn, and probably all large grain, requires to be suffered to grow into the blade, as well as root, before it is fit to be made into malt. For this purpose, it is buried about two or three inches deep in the ground, and covered with loose earth; and in ten or twelve days it springs up. In this state, it is taken up and washed, or fanned, to clear it from dirt; and then dried in the kiln for use.

During the process of germination, the albuminous matter of the barley or other grain is brought into the peculiar state called *diastase*, in which it acts as a ferment on the starch contained in the grain, converting it into dextrin and sugar, and thereby rendering it soluble. A portion of the starch is, however, always left unchanged by the germinating process, and its conversion into dextrin and sugar is completed by the kiln-drying. The benefit of this latter process is, therefore, not confined to the mere expulsion of moisture from the grain; indeed kiln-dried malt always yields a larger quantity of saccharine extract than malt which has been left to dry in the air at ordinary temperatures.

The diastase of malt is capable of converting into sugar a much larger quantity of starch than that which the grain itself contains: hence in the preparation of the extract, the malt may be mixed with a certain quantity of unmalted barley or other grain. In Belgium, large quantities of beer are prepared from malt mixed with potato starch.

To make beer, the malt, after being ground or cut to pieces in a mill, is placed in a tun or tub with a false bottom; water at about 180° F. is then poured upon it; and the whole is well stirred about by suitable machinery. This operation is called *mashing*. After the infusion has been left for a few hours to clarify or *set*, the clear liquor or *sweet wort* is transferred to a copper boiler and boiled with hops, which give it a bitter aromatic taste, and perhaps also render it less liable to spoil by keeping. When the wort has been sufficiently boiled, it is drawn from the copper into large shallow vessels, so as to cool it as rapidly as possible to the temperature of the air, and thereby avoid an irregular acid fermentation, to which it would otherwise be liable. It is then transferred to the fermenting vats, which in large breweries are of great capacity, and mixed with yeast, the product of a preceding operation. The liquid is thereby brought into a state of commotion; the sugar is more or less converted into alcohol and carbonic acid, which escapes as gas; and the nitrogenous matter of the extract is converted into yeast, part of which is expended in keeping up the fermentation, while the rest rises to the surface. The fermentation is never suffered to run its full course, but is always stopped at a certain point, by separating the yeast and drawing off the beer into casks. A slow and almost insensible fermentation then takes place, whereby more of the sugar is converted into alcohol, and the beer is rendered stronger and less saccharine.

During this last process, the beer gradually becomes clear or fine, the solid particles of yeast which float about in it during the fermentation, and render it muddy, being gradually brought to the surface and discharged through the bung-holes of the casks, whence the yeast is conveyed into proper receptacles. A very effective arrangement for this purpose is adopted at the extensive breweries of Messrs. Bass and Allsopp at Burton-on-Trent, for a description and figure of which see *Muspratt's Chemistry*, vol. i. p. 276. Frequently, however, it is found necessary to assist the clarification by means of substances called *finings*, which lay hold of the suspended matter, and precipitate it to the bottom. Isinglass dissolved in sour beer is often used for this purpose, also gelatin, white of egg, serum of blood, Carragheen moss, and the dried stomach of the cod, called *sounds*. It is best, however, when the clarification takes place spontaneously, without the use of finings; for all these substances tend to make the beer flat, and prevent it from carrying a good head. The composition of the water used in brewing has a great influence on the result. Lime in particular appears to favour the clarification, by combining with the acids of the malt-extract, and forming insoluble salts, which carry down the suspended matter. The spring-water of Burton-on-Trent (not that of the river Trent) contains 19 per cent. of sulphate of lime, only a small portion of which is precipitated on boiling.

The strength and taste of beer are susceptible of endless variety, according to the quality and quantity of the malt and hops used, and the mode of conducting each stage of the process, but especially the fermentation. If the first fermentation be stopped at an early stage, the beer will contain a considerable quantity of sugar and comparatively little alcohol: it will be mild, and if bottled, will acquire the property of effervescing strongly when the bottle is opened, because the carbonic acid produced by the subsequent slow fermentation, remains dissolved in the liquid, and escapes with violence as soon as the pressure is removed. If, on the other hand, the fermentation be allowed to go on in the vat or in casks, till nearly all the sugar is converted into alcohol and the carbonic acid escapes, the beer then becomes more alcoholic; but if the process be allowed to go on too long, it loses its briskness and becomes flat and unpalatable. *Strong* beers are those which contain a considerable amount of alcohol; *substantial* beers are those which are rich in malt-extract; the latter are also said to possess *body*.

The malt-liquors consumed in this country are of two kinds, Ale and Porter. Ale is prepared from the paler kinds of malt, and in its preparation, the first fermentation is checked at such a stage as to leave a considerable quantity of saccharine matter in the liquor, which, by its subsequent conversion into alcohol and carbonic acid, may keep up the briskness. The ale is mild or bitter, according to the quantity of hops added to the wort. *Pale ale* is prepared from the palest malt dried in the sun or by steam heat, and from the best and palest hops. An essential point in its preparation is to keep the fermenting temperature as low as possible, never allowing it to rise above 72° F. By this means, the formation of acetic acid is prevented, as also the solution of the yeast by alcohol, which always communicates an unpleasant flavour to the liquor,—and the delicate flavour and aroma of the hop are preserved. *Scotch ale* is a sweet strong ale; it was formerly flavoured with honey, but that practice appears to be now abandoned.

Porter is a dark-coloured beer, prepared from a mixture of pale, amber, brown, and black malt. The following table (taken from Muspratt's Chemistry) exhibits the composition of the various mixtures employed:

Table of Porter Grists.

No.	Black.	Brown.	Amber.	Pale.	Total.
1	9	0	0	91	100
2	6	34	0	60	100
3	2	30	10	58	100
4	3	25	15	57	100
5	4	24	24	48	100
6	5	0	95	0	100

Of these the preference is given to the last two; in the others, the excess of black and brown malt introduces too much carbonaceous and useless matter, whence the porter acquires a disagreeable taste, as if liquorice were added to it. The fermentation of porter in the vats is carried on till the original gravity of the liquid is reduced to about one-third. *Stout* is merely a stronger kind of porter. *Small beer*, as its name implies, is a weaker liquor, and is made either by adding a large quantity of water to the malt, or by mashing with a fresh quantity of water, the residuum left after ale or porter has been drawn off.

The temperature at which the fermentation of beer is conducted, has a marked effect on its quality, and especially on its power of keeping without turning sour. When the fermenting temperature ranges from 65° to 90° F., as is the case with the beers of England, France, Belgium, and most parts of Germany, the beer gradually becomes sour by contact with the air, the alcohol being slowly converted into acetic acid. But Bavarian beer, which is fermented at a much lower temperature, 8° or 10° C. (46·5 to 50° F.), does not undergo this change. The difference arises from the manner in which the fermentation takes place, and is explained by Liebig as follows: Wort is proportionally richer in soluble gluten than in sugar, and when set to ferment in the ordinary way, it evolves a large quantity of yeast in the state of a thick froth, with bubbles of carbonic acid gas adhering to it, whereby it is floated to the surface of the liquid. Now the conversion of gluten into yeast is partly, at least, a process of oxidation; and when the liquor is covered with a thick scum, as just described, the gluten still dissolved in the liquid, not having free access to the air, appears to take oxygen from the sugar and other matters contained in the liquid, the formation of the yeast thus going on at the expense of the sugar, which is consequently destroyed before the whole of the gluten is converted into yeast. From this cause, a quantity of free gluten is left in the liquid, and on subsequent exposure to the air, this gluten acts as a ferment, inducing the conversion of the alcohol into acetic acid. In the Bavarian process, on the contrary, the carbonic acid, instead of escaping in large bubbles, which, carry the yeast to the surface, rises in minute bubbles in the same manner as from an effervescing mineral water; little or no scum forms on the surface, but the yeast, as it is produced, sinks to the bottom, and leaves the surface of the wort freely exposed to the air. The gluten is thus converted into yeast by atmospheric oxidation, and is at last wholly removed from the liquid without decomposition of the sugar. Beer thus fermented, is not liable to acidification by exposure to the air.

The kind of fermentation last described, is called *bottom fermentation* (*Untergahrung*), and the yeast produced by it *bottom yeast* (*Unterhefe*); while the ordinary fermentation process is called *top fermentation* (*Obergahrung*), and the yeast which it produces *top yeast* (*Oberhefe*). These two kinds of yeast differ essentially in their properties and mode of action. The top-yeast is gluten oxidised in a state of putrefaction, and the bottom yeast is the gluten oxidised by *eremacausis* or slow combustion. Each of them has a tendency to induce the particular kind of fermentation by which it was itself produced. (See FERMENTATION.)

For further details respecting the preparation and properties of beer, see the articles BEER and BREWING in the new edition of *Ure's Dictionary of Arts, Manufactures, and Mines;* also the article BEER in *Muspratt's Chemistry*, and in the *Handwörterbuch der Chemie*, 2te Aufl. ii. [1] 103·6

ANALYSIS OF BEER.—The normal constituents of beer are alcohol, carbonic acid, and extractive matters of malt and hops; acetic acid is also present, but its amount in good beer is very small.

The amount of carbonic acid in beer is but small, not exceeding 0·1 to 0·5 per cent. even in bottled beer, and of this small quantity the greater portion escapes as soon as the beer is opened. The strength of the frothing will give a very good idea of its relative amount. An exact estimation of the carbonic acid is indeed seldom necessary; but if desired, it may be made by boiling a known quantity of the beer in the flask-apparatus, represented in *fig.* 5, p. 119, (art. ALKALIMETRY.) The carbonic acid (anhydrous) then escapes as gas, while the vapours of water and alcohol given off at the same time are retained by the chloride of calcium in the drying tube.

The amount of acetic acid is estimated by the usual processes of ACIDIMETRY (*q. v.*)

The quantity of extractive matter in beer may be determined by evaporating 20 grammes of beer in a platinum or porcelain dish, and drying the residue in an air-bath (p. 520) at 100°—115° C. till it ceases to lose weight. Before weighing, it must be cooled under a bell-jar over chloride of calcium, as it is very hygroscopic.

It is seldom necessary to examine the extractive matter any further. It consists mainly of sugar, dextrin, albuminous matter, and lupulin, the bitter principle of the hop. The amount of dextrin and sugar may be determined by moistening the dried residue with water to a thin syrup, and gradually adding strong alcohol as long as dextrin is thereby separated. The clear sugar-solution may then be decanted, and the dextrin freed from the remaining sugar by repeated solution in water and precipitation by alcohol. The solutions of dextrin and sugar may then be evaporated to dryness, and the residues weighed. The albuminous matter may be estimated from a separate portion of the beer by boiling it so as to coagulate the albumin, collecting the precipitate on a tared filter, then washing, drying, and weighing it. Lastly the sum of the weights of the dextrin, sugar, and albuminous matter, deducted from the total weight of the extract gives the quantity of lupulin.

The inorganic constituents of beer are estimated by evaporating to dryness a known quantity of the beer, charring the residue, and then igniting it, as in the preparation of plant-ashes (p. 419). They consist chiefly of the phosphates of calcium and magnesium. Alkaline phosphates may likewise be found, but the greater part of them is dissolved out during the maceration of the barley for malting. Common salt, which is sometimes added to beer, will of course be found in the ash. Any considerable amount of alkaline carbonate may be attributed to alkali added to neutralise free acid in the beer.

The amount of alcohol in beer is ascertained by distilling 500 to 1000 grammes (15 to 30 ounces) in a somewhat capacious retort, having its neck inclined upwards and connected with a Liebig's condenser, receiving the distillate in a tared flask, weighing it, and determining its specific gravity at $15\frac{5}{9}$ C. (60° F.), that of water at the same temperature being assumed = 1·000; or the proportion of alcohol may be found by testing the distillate with a delicate alcoholometer. The weight per cent. of alcohol is then found by means of table A, which is an amplification of part of that given under ALCOHOLOMETRY (p. 81), and thence the total amount of alcohol in the given quantity of beer may be found.

Suppose, for instance, 1000 grms. of beer gave 615·38 grms. of distillate of specific gravity 0·98949 at 60° F.; then, according to the table, the distillate would contain 6·11 per cent. alcohol, and therefore the 615·38 grms. of distillate would contain 37·6 grms. alcohol. Now these 37·6 grms. of alcohol were obtained from 1000 grms. of beer; consequently the amount of alcohol in the beer is 3·76 per cent. The trouble of calculation may be saved by diluting the distillate till its weight becomes equal to that of the beer employed; the specific gravity will then at once give the percentage by weight of alcohol in the beer. If, for example, the distillate after dilution exhibited a specific gravity = 0·9932, the percentage of alcohol would be 3·76. If a Tralles' alcoholometer were used, it would show in the distillate, before dilution, a percentage by volume of 7·6, corresponding to 6·11 by weight. In using the alcoholometer, it is best not to dilute the distillate, unless the instrument is especially graduated for very weak liquids. If the observed specific gravity or alcoholometer-degree does not occur in the table, the weight per cent. of alcohol will be found by interpolation.

TABLE A.—*Specific Gravity and Strength of Spirits.*

Volume per cent.	Weight per cent.	Specific Gravity.	Volume per cent.	Weight per cent.	Specific Gravity.

			8·0	6·43	0·98900

The residue in the retort may be used for determining the amount of extractive matter in the beer. For this purpose it is diluted with water, after cooling, till its weight becomes equal to that of the beer before distillation, and the amount of extractive matter is then found from its specific gravity, by means of tables provided for the purpose.

The following is taken from a more detailed table in the *Handwörterbuch*, 2^{te} Aufl. ii. [1] 1081.

TABLE B.—*Specific Gravity and Strength of Malt-Extract.*

A more extended table of the specific gravity of pure syrup, which does not differ greatly from that of malt-extract, is given in *Ure's Dictionary of Arts, Manufactures, and Mines*, new edition, vol. ii. p. 610.

The amount of alcohol in beer may in most cases be calculated with sufficient accuracy for practical purposes, from the difference between the specific gravity of the boiled and unboiled beer, according to the following principle: *The specific gravity of the unboiled beer is less than that of the boiled beer, in the same proportion as the specific gravity of spirit of wine of equal alcoholic strength is less than that of water.* To determine the amount of alcohol in beer accordingly, the beer is first freed from carbonic acid by brisk agitation in a capacious flask, assisted perhaps by very gentle warming, and its specific gravity is accurately determined. It is then boiled to drive off the alcohol, and the residue is diluted with water, till its weight becomes exactly equal to the original weight of the beer; it is then filtered, if necessary, through a covered filter, and its specific gravity likewise determined. The amount of alcohol is then calculated, as in the following example. Suppose the specific gravity of the unboiled beer, freed from carbonic acid, to be 1·0250; and after boiling and dilution with water, to be increased to 1·0320. Then, according to the principle just stated, the specific gravity of pure spirit of the same alcoholic strength as the beer, will be to that of water as 1·0320 : 1·0250; that is to say, it will be $\frac{1\cdot0250}{1\cdot0320} = 0\cdot9932$, which, according to the table, page 531, corresponds to 3·8 per cent.

The empirical rule for finding the specific gravity of spirit of equal strength with the beer is: *Divide the specific gravity of the unboiled beer by that of the boiled beer, after its original weight has been restored by dilution.*

It is clear that the results obtained by this method (called in Germany the *Specific Beer-test*), will be more exact, in proportion as the composition of the beer differs less from that of pure spirit of equal strength, in other words, the smaller the amount of of the extractive matter contained in the beer. For beers like those of Bavaria, it answers very well; but for those which contain a larger amount of extract it cannot be relied on.

For **Balling's** *Saccharometric method* (*saccharimetrische Bierprobe*), and **Fuchs's** *Hallymetric method* (*hallymetrische Bierprobe*), which latter consists in determining the quantities of alcohol and extractive matter in beer by the quantity of common salt which it is capable of dissolving, see *Handwörterbuch der Chemie*, 2te Aufl. ii. [1] 1078; and *Handbuch der technisch-chemischen Untersuchungen* von P. A. Bolley, 2te Aufl. Leipzig, 1861, s. 350.

The following tables C and D, exhibit the composition of various kinds of beer.—See also *Jahresbericht für Chemie*, 1849, p. 708; 1850, p. 683; 1853, p. 758; 1855, p. 852.

* The blanks in this column indicate that the carbonic acid was not determined quantitatively in the corresponding samples.

Original Gravity of Beer-worts.—The conversion of sugar into alcohol by fermentation, is attended with a diminution of density in the liquid; consequently the specific gravity of beer is always less than that of the wort before fermentation. Now by the revenue-laws of this country, the brewer is allowed a drawback upon all beer that is exported, the amount being regulated according to the original gravity of the wort. Hence it is necessary that the revenue officer be possessed of a method of determining the original gravity, from the observed specific gravity and composition of the beer, whereby he may check the record kept by the brewer.

If the non-volatile matter of beer consisted entirely of starch-sugar (glucose), the determination of the original gravity would be a very easy matter: for it is found that every 1 per cent. of alcohol in beer corresponds very nearly to 2 per cent. of sugar in the wort before fermentation: hence it would merely be necessary to double the percentage of alcohol in the beer, add thereto the percentage of sugar as found by direct experiment, and the sum would be the total amount of sugar in 100 pts. of the unfermented wort; the specific gravity would then be given by a saccharometer-table, such as Table B, p 532.

For example, London porter (No. 1, of Table D), contains 6·0 per cent. of malt-extract (which we shall suppose to consist of starch-sugar), and 5·4 per cent. alcohol, the latter corresponding approximately to 10·8 per cent. starch-sugar. Hence the total quantity of extract in the unfermented wort would be 6·0 + 10·8 = 16·8, giving a specific gravity of 1·06.

But the actual problem to be solved is much less simple: for the wort contains several other substances, all differing more or less in specific gravity from starch-sugar. Hence the exact determination of original gravities can only be effected by special observations. The question has been examined by several foreign chemists, especially by Balling of Prague, in his great work on Brewing[*]; in this country it has been investigated by Messrs. Dobson and Phillips, of the Department of Inland Revenue, and more recently by Professors Graham, Hofmann, and Redwood, from whose "Report on Original Gravities,"[†] the following observations are extracted.

The substances contained in beer-wort, in addition to starch-sugar, are: 1. *Dextrin*, which has not been converted into sugar in the process of mashing. 2. In many instances, *cane-sugar*, the use of which is now permitted in breweries. 3. *Caramel*, arising either from high-dried malt, or from treacle or burnt-sugar, the use of which in the brewery of porter is also allowed by law. 4. A peculiar saccharine substance, called "extractive substance," resembling caramel, possessing decided acid properties, and not fermentable by yeast, even after boiling with sulphuric acid.[‡] 5. Azotised or albuminous matter, derived from the grain. 6. Alkaline and earthy salts.

The albuminous matter and the inorganic salts, have but little effect on the comparative densities of the wort before and after fermentation; but the dextrin, cane-sugar, caramel, and "extractive matter," all give solutions of less specific gravity than a solution of starch-sugar containing the same quantity of carbon, and therefore capable of yielding an equal amount of alcohol. The differences are exhibited in the following table.

TABLE F.—*Specific Gravities of Solutions of various* SACCHARINE SUBSTANCES, *and of* PALE *and* BROWN MALT *containing equal quantities of* CARBON.

Solution of Starch-sugar.	Solution of Cane-sugar.	Solution of Dextrin.	Solution of Extractive Substance.	Solution of Caramel.	Solution of Pale Malt.	Solution of Brown Malt.	Parts of Cane-sugar corresponding in 1000 Parts by Weight of Solution.

[†] Chem. Soc. Q. J. v. 229.

[‡] It probably contains glycerin and succinic acid, both of which substances have been shown by Pastour to be produced in alcoholic fermentation.

These numbers plainly show that if an unfermented wort contains cane-sugar and dextrin, and the gravity lost by fermentation is inferred from the quantity of alcohol contained in the beer, on the supposition that the fermentable matter consisted wholly of starch-sugar, the estimated gravity will be too high; and on the other hand the conversion of a portion of the fermentable sugar into unfermentable extractive matter, which gives a solution of lower specific gravity for the same amount of carbon, will cause the estimate of the original gravity to come out too low; indeed, the extractive substance indicates only about five-sixths of the saccharine principle from which it is derived.

To obviate these difficulties, the authors of the Report were led to propose,for the determination of original gravities, a purely empirical method, which consisted in fermenting solutions of cane-sugar, starch, sugar, and malt-extract, of known original gravity, and making, at ten or twelve stages of the process, two following observations: 1. Distilling a convenient quantity (4 fluid ounces) of the fermented liquid in a retort as described at page 530, diluting the alcoholic distillate with water, to the original volume of the liquid, and taking its specific gravity; this deducted from the specific gravity of water (= 1000) gives the spirit-indication of the beer: *e.g.* if the specific gravity of the alcoholic distillate after dilution is 985·95, the spirit-indication is 14·05. — 2. Diluting the boiled beer after cooling, to its original volume, taking its specific gravity, and subtracting this, which is called the extract-gravity, from the known original gravity of the wort before fermentation. The difference gives the number of *degrees of gravity lost*, corresponding to the spirit-indication previously observed. The results of a long series of determinations of this kind on liquids of known original gravity are given in the "Report" in the form of tables: of these we shall quote only those which embody the general result of the inquiry, and are intended for actual use in determining the original gravity of beer-worts.

Table G (p. 536) is to be used when the spirit-indication of the beer is found by *distillation* in the manner above-mentioned. The first column gives the integers of spirit-indication, the fractional parts (tenths) thereof being placed at the heads of the other columns; the numbers in these several columns are the degrees of gravity lost corresponding to the several spirit-indications. Thus, suppose that a sample of beer distilled as above, gives a spirit-indication = 9·4, and extract-gravity = 1030·6. On the ninth line of the table, and in the column headed ·4, is found the number 41·2, which is the *gravity lost*, and this added to the extract-gravity, gives 41·2 + 1030·6 = 1071·8 for the original gravity of the wort.

As the distillation of the beer in a retort, and collecting of the entire quantity of alcohol evolved, is an operation which occupies considerable time, and requires some experience in manipulation, it is often desirable to obtain the spirit-indication of the beer by an easier process. This may be done by first taking the specific gravity of the beer deprived of carbonic acid by agitation, then boiling it in a flask till all the alcohol is expelled, diluting it to its original volume, and again taking its specific gravity. The first result, the *beer-gravity*, deducted from the second, the *extract-gravity*, is the new spirit-indication: thus if the beer before boiling has a specific gravity of 1044·7, and after boiling of 1035·1, the spirit-indication is 9·6 degrees. By numerous experiments in which the beer was boiled in a retort, and the alcoholic distillate collected as above, it was found that the second method, the evaporation-method, gives a spirit-indication nearly equal to that resulting from the first or distillation-method, but always sensibly less; thus the spirit-indication of a particular sample was 9·9 degrees by the first method, and 9·6 by the second. The experiments in question were made on liquids of known original gravity, and thus a series of determinations were obtained of the *relation between* the spirit-indication as determined by the *evaporation-method*, and the degrees of gravity lost. The general results of the inquiry, as applied to malt-worts, are given in the Table H, the arrangement of which is the same as that of Table G.

The authors of the Report likewise suggest a rational method of determining original gravities, which is interesting in a scientific point of view, though not expeditious enough for practical use. It is as follows: First determine the amount of alcohol in the beer by distillation. Then treat the residual liquid, which generally contains both starch-sugar and unfermentable extractive matter, with yeast, to complete the fermentation, and determine the additional quantity of alcohol thus produced, making a correction for that which is introduced by the yeast itself. Lastly, make up the remaining spiritless liquor with water to the original volume of the beer, and take its specific gravity, a correction being also made for the increase of gravity caused by the yeast. The quantity of starch-sugar corresponding to the corrected gravity of this solution of extractive matter may now be found from a table provided for the purpose; and this, added to the amount of starch-sugar corresponding to the alcohol, gives the total quantity of starch-sugar, from which the original gravity may be found by the saccharometer tables.

TABLE G. — To be used in ascertaining Original Gravities by the DISTILLATION-PROCESS.

Adulteration of Beer.—The addition of extraneous substances to beer, to give it *colour* and *heading*, or to provide cheaper substitutes for the bitter of the hop, appears to have been formerly carried to a great extent in this country. Dr. Ure says, in his "*Dictionary of Chemistry*" 4th edition, 1831, p. 203: "As long ago as the reign of Queen Anne, brewers were forbid to mix sugar, honey, Guinea pepper, essentia bina, cocculus indicus, or any other unwholesome ingredient, in beer, under a certain penalty; from which we may infer, that such at least was the practice of some; and writers, who profess to discuss the secrets of the trade, mention most of these, and some other articles, as essentially necessary. The essentia bina is sugar boiled down to a dark colour, and empyreumatic flavour. Broom tops, wormwood, and other bitter plants, were formerly used to render beer fit for keeping, before hops were introduced into this country, but are now prohibited to be used in beer made for sale."

"By the present law of this country, nothing is allowed to enter into the composition of beer, except malt and hops. Quassia and wormwood are often fraudulently introduced; both of which are easily discoverable by their nauseous bitter taste. They form a beer which does not preserve so well as hop beer. Sulphate of iron, alum, and salt, are often added by the publicans, under the name of *beer-heading*, to impart a frothing property to beer, when it is poured out of one vessel into another. Molasses and extract of gentian root are added with the same view. Capsicum, grains of paradise, ginger root, coriander seed, and orange peel, are also employed to give pungency and flavour to weak or bad beer. The following is a list of some of the unlawful substances seized at different breweries, and brewers' druggists' laboratories, in London, as copied from the Minutes of a Committee of the House of Commons; *cocculus indicus multum* (an extract of the cocculus), colouring, honey, hartshorn shavings, Spanish juice, orange-powder, ginger, grains of paradise, quassia, liquorice, caraway seeds, copperas, capsicum, mixed drugs. Sulphuric acid is frequently added to *bring beer forward*, or make it hard, giving to new beer instantly the taste of what is eighteen months old."

This appears at first sight, a rather formidable picture of adulteration: nevertheless most of the articles enumerated are perfectly harmless, and of those which are really injurious, the use appears to have very much declined, partly perhaps in consequence of the improved taste of consumers. Formerly there was a preference for what was called *good hard beer*, that is to say beer in which nearly all the sugar and mucilage had been converted into alcohol by fermentation: hence the use of sulphuric acid, as above stated, to simulate the taste of beer thus advanced in fermentation. With regard to burnt sugar or treacle, which is added to porter to give colour and body, its use is now legalised, and therefore it can no longer be regarded as an adulteration.

Picric acid and *cocculus indicus* are sometimes added to give bitterness to beer, especially to bitter ale. The latter of these substances is especially objectionable, as it contains a very poisonous substance, viz. picrotoxin. Picric acid may be detected according to Lassaigne, by treating the liquid, evaporated to half or a quarter of its bulk, with subacetate of lead, or shaking it up with powdered animal charcoal. Pure beer is thereby almost wholly decolorised; but if picric acid is present, the filtered liquid retains a lemon-yellow colour. This reaction is very delicate, sufficing to detect 1 part of picric acid in 12,000 to 18,000 parts of beer. Subacetate of lead likewise precipitates the bitter principle of the hop, and thereby deprives pure beer of its bitterness; but beer containing picric acid remains bitter after being thus treated. According to Pohl (Wien. Akad. Ber. xii. 88), a still more delicate test for picric acid is obtained by immersing unbleached sheep's wool, or any fabric made therewith, in the beer, boiling for six or ten minutes, and then washing the wool. If the beer is pure, the wool remains white, but if picric acid is present, even to the amount of only 1 pt. in 125,000, the wool then appears of a canary-yellow colour, pale or dull according to the quantity.

Picrotoxin may be detected, according to T. J. Herapath, by mixing the beer with excess of acetate of lead; removing the lead from the filtrate by sulphuretted hydrogen; filtering again, boiling for a few minutes; then slowly evaporating the solution till it becomes thickish; shaking it up with pure animal charcoal; collecting the charcoal, which contains the picrotoxin, on a filter; washing it with the smallest possible quantity of water; then drying it at 100° C.; boiling it with alcohol; concentrating the alcoholic filtrate; and leaving it to evaporate. The picrotoxin then separates in well defined quadrilateral prisms; or if the solution be rapidly concentrated, in beautiful feathery tufts. (For figures of these crystals, see *Muspratt's Chemistry*, i. 283.)

Inorganic substances added to beer will be found in the ash. Chalk is sometimes added to sour beer to neutralise the acid; in that case, the ash will contain more lime than the normal quantity. If copperas has been added to promote the *heading*, the liquid will give the reaction of sulphuric acid with chloride of barium, and the ash will contain an abnormal quantity of oxide of iron.

BEGUIN'S VOLATILE SPIRIT, *Spiritus sulphuris Beguini*, consists essentially of sulphide of ammonium with excess of sulphur.

BELLADONNA, OIL OF. An oil expressed in Wurtemberg from the seed of deadly nightshade (*Atropa belladonna*), and used for illumination and for culinary purposes. It is limpid, of golden-yellow colour, of insipid taste, and without odour. Sp. gr. 0·9250 at 5° C. It thickens at −16° C. and solidifies at −25°. The vapours which it exhales during the process of extraction, intoxicate the workmen. The narcotic principle of the plant is retained in the marc, which cannot therefore be used as food for cattle. (Gerh. ii. 881.)

BELLADONNINE. An alkaloïd said to exist in *Atropa belladonna*.

BELL-METAL ORE. See Tin Pyrites.

BELMONTIN. A fatty substance prepared from Burmese naphtha.

BELONITE. Kobell's name for Needle-Ore.

BEN, OIL OF. The oil expressed from the fruits of *Moringa Nux Behen*, Desf.; *Guilandina moringa* Linn.; or *Moringa oleifera* Lam. It is colourless or slightly yellow, of specific gravity 0·912, thick at 15° C., solid in winter. It is odourless, and has a mild taste, is neutral to test-paper, and does not readily become rancid. It is used in perfumery to extract the odorous principle of fragrant plants. In India it is used as an embrocation for rheumatism. According to Völcker (Ann. Ch. Pharm. lxiv. 342), it is saponified perfectly by potash, 400 grammes yielding about 18 grammes of a mixture of solid fatty acids, together with oleic acid. The solid fatty acids are: 1. An acid soluble in strong alcohol, insoluble in ordinary alcohol, melting at 83° C. and containing 81·6 per cent. carbon and 13·8 hydrogen, numbers which approximate to the formula $C^{45}H^{90}O^2$; but the quantity obtained was too small for complete investigation.—2. Ordinary margaric acid.—3. An acid resembling stearic acid, and called by Völcker, *benic acid*.

Another kind of oil of ben, said to be obtained from the seeds of *Moringa aptera*, yields by saponification four fixed fatty acids, viz. stearic acid, margaric acid, and two peculiar acids, *benic acid* and *moringic acid*. (Walter, Compt. rend. xxii. 1143.)

BENIC ACID. This name has been applied to two different fatty acids, mentioned in the last article, both obtained from oil of ben, the one by Völcker, the other by Walter. For distinction, Völcker's acid, which has the higher melting point, may be called *benostearic acid*, and Walter's *benomargaric acid*.

Benomargaric Acid, $C^{15}H^{30}O^2$, crystallises from its alcoholic solution in very bulky nodules, melting at 52° or 53° C.

Benomargarate of ethyl is very soluble in alcohol, and separates from the solution in a crystalline mass. It melts at a very low temperature, even at the heat of the hand. (Walter.)

Benostearic Acid, $C^{21}H^{42}O^2$ according to Völcker, $C^{22}H^{44}O^2$ according to Strecker (Ann. Ch. Pharm. lxiv. 346).—The latter formula agrees with Völcker's analysis better than the former. It is a white crystalline fat, melting at 76° C. and solidifying at 70° C. to a shining white crystalline mass, composed of needles, which may be rubbed to powder; it is soluble in alcohol, and bears a strong resemblance to stearic acid.

Benostearate of sodium, $C^{22}H^{43}NaO^2$, is obtained by saponifying the acid with carbonate of sodium, and dissolving the dried soap in absolute alcohol. The alcoholic solution solidifies after a while to a gelatinous pulp, which is resolved into crystalline grains by drenching it with a large quantity of alcohol. The *barium*-salt, $C^{22}H^{43}BaO^2$, is precipitated on mixing an alcoholic solution of the sodium-salt with chloride of barium. The *lead*-salt, $C^{22}H^{43}BaO^2$, is a white precipitate obtained by mixing the soda soap with acetate of lead.

Benostearate of ethyl, $C^{22}H^{43}O^2.C^2H^5$, is obtained by passing hydrochloric acid gas through a solution of the acid in absolute alcohol. It is a crystalline mass, melting at 48° or 49° C. (Völcker.)

BENZALDIDE. Syn. with hydride of benzoyl. See Benzoyl, Hydride of.

BENZAMIC ACID. Syn. with Oxybenzamic Acid (*q. v.*)

BENZAMIDE. $C^7H^7NO = N.C^7H^5O.H^2$.—*Nitride of Benzoyl* and *Hydrogen*. Liebig and Wöhler, Ann. Ch. Pharm. iii. 268; Fehling, *ibid.* xxviii. 48; Schwarz, *ibid.* lxxv. 195; Laurent, Rev. Scient. xvi. 391; Gerhardt, Traité, iii. lxxv.

This body may be obtained in various ways. 1. By the action of ammonia on bromide, chloride, or cyanide of benzoyl. Chloride of benzoyl, when saturated with perfectly dry ammonia, evolves heat and solidifies into a white mass of benzamide and chloride of ammonium, which must be repeatedly broken up, lest any chloride of benzoyl be enclosed in it, and so escape the action of the ammonia. The sal-ammoniac is extracted with cold water, and the benzamide crystallised from boiling water. Gerhardt prefers pounding chloride of benzoyl in a mortar, with excess of commercial carbonate of ammonium, heating the whole gently, extracting with cold water, and crystallising the residue from alcohol or boiling water. Laurent prepares it by mixing an alcoholic solution of chloride of benzoyl with aqueous ammonia.—2. By the action of ammonia on benzoic anhydride.—3. By the action of ammonia on benzoate of ethyl. The reaction takes place slowly at the ordinary temperature, more rapidly when the ether is heated with aqueous ammonia over 100° C. in a sealed tube (Dumas).—4. By boiling hippuric acid with water and peroxide of lead (Schwarz, Fehling); or by heating it in a stream of dry hydrochloric acid. (Strecker.)

When its hot aqueous solution is cooled suddenly, benzamide separates in small pearly crystals, resembling those of potassic chlorate. When it is cooled slowly, it solidifies into a mass of white shining needles, in which cavities form after a time, containing one or more large crystals; the transformation extends gradually through the whole mass. The finest crystals are obtained from a solution containing a little potash or ammonia. The crystals belong to the trimetric system. Benzamide is inodorous, almost insoluble in cold water, soluble in hot water (especially if it contains ammonia), in alcohol, and in ether. It melts at 115° C., and solidifies on cooling to a crystalline mass; between 286° and 290° it volatilises undecomposed; its vapour smells slightly of bitter almonds, owing to the formation of some benzonitrile, is very inflammable, and burns with a smoky flame.

When vapour of benzamide is passed through a red-hot tube, it is but slightly decomposed, a small portion of a sweetish oil being formed, which, according to Gerhardt, is benzonitrile. It is decomposed at a moderate heat, when passed through a tube filled with pumice-stone, yielding hydrogen, nitrogen, carbonic oxide, and benzol (Barreswil). Benzamide is not decomposed by cold caustic potash; but on boiling, potassic benzoate is formed, and ammonia evolved. It is similarly decomposed by boiling with strong acids, the solution on cooling depositing benzoic acid, while it retains the ammonium-salt of the acid employed. When baryta is heated with benzamide, it undergoes a kind of fusion, and appears to be converted into hydrate of barium; ammonia is evolved, together with the oil which Gerhardt regards as benzonitrile. Benzamide, heated with potassium, yields cyanide of potassium and benzonitrile (cyanide of phenyl), but no ammonia. Heated with benzoic anhydride, or chloride of benzoyl, it yields benzonitrile and benzoic acid:

$$C^7H^7NO + \underset{\text{Benz. anhyd.}}{C^{14}H^{10}O^3} = \underset{\text{Benz. acid.}}{2C^7H^6O^2} + \underset{\text{Benzonitrile.}}{C^7H^5N}$$

$$C^7H^7NO + C^7H^5O.Cl = C^7H^6O^2 + C^7H^5N + HCl$$

Benzonitrile is also formed when benzamide is heated alone, or in a stream of dry hydrochloric acid (Handw.); or treated with phosphoric anhydride or pentachloride of phosphorus. Benzamide is not decomposed by boiling with water and peroxide of lead; but if hydrochloric or sulphuric acid be added, and the whole boiled, filtered, mixed with ammonia, and exposed to the air, it turns brown, and deposits a mould-like substance.

When benzamide is gently heated with fuming hydrochloric acid, it dissolves, combining with the acid, and forming *hydrochlorate of benzamide*, $C^7H^7NO.HCl$, which separates on cooling in long aggregated prisms. It is a very unstable compound; the crystals give off hydrochloric acid when exposed to the air, and in a few days have become opaque, and lost the whole of their acid. (Dessaignes, Ann. Ch. Phys. [3] xxxiv. 146.)

Benzamide is a primary amide, *i. e.* it represents 1 at. NH^3 in which 1H is replaced by benzoyl. The remaining 2H may be wholly or partially replaced by a metal, or an organic acid or basic radicle, secondary or tertiary amides or alkalamides being formed. Those alkalamides which contain organic radicles are described under the corresponding amine; the amides and those of the alkalamides which contain a metal will be described here.

Benzomercuramide. $C^7H^6HgNO = N.C^7H^5O.Hg.H$ (Dessaignes, Gerhardt, *loc. cit.*)—Aqueous benzamide dissolves mercuric oxide abundantly, and the saturated solution solidifies to a crystalline mass, which is coloured with excess of oxide. This is treated with hot alcohol, and the solution on cooling deposits benzomercuramide in white shining laminæ, which may be washed and dried at 100° C. It is readily soluble in alcohol and boiling ether. It is violently attacked by chloride of benozyl, yielding benzoic acid, benzonitrile, and chloride of mercury.

Aqueous benzamide also dissolves small quantities of cupric and argentic oxides; but the compounds have not been examined.

Benzacetosulphophenamide. $C^{15}H^{13}NSO^4 = N.C^7H^5O.C^2H^3O.C^6H^5SO^2$.—Produced by the action of chloride of acetyl on benzosulphophenylargentamide.

Benzocumylsulphophenamide, $C^{23}H^{21}NSO^4 = N.C^7H^5O.C^{10}H^{11}O.C^6H^5SO^2$, is obtained by the action of chloride of cumyl on benzosulphophenargentamide; it crystallises from ether in confused prisms.

Benzosalicylimide. $C^{14}H^9NO^3 = N.C^7H^5O.C^7H^4O''$ (Limpricht, Ann. Ch. Pharm. xcix. 250).—Obtained by heating benzosalicylamic acid (benzosalicylamide) in a small retort to 270° C., until about ⅓ has volatilised, and boiling the residue with small quantities of alcohol, to remove the undecomposed acid. The pulverulent benzosalicylimide is dissolved in a larger quantity of boiling alcohol, whence it separates on cooling in small yellowish needles. It is soluble in about 1000 pts. boiling alcohol.

Benzosulphophenamide. $C^{13}H^{11}NSO^3 = N.C^7H^5O.C^6H^5SO^2.H$ (Gerhardt and Chiozza, Ann. Ch. Phys. [3] xlvi. 145).—Obtained by heating equivalent quantities of chloride of benzoyl and sulphophenamide to 140°—145° C., as long as hydrochloric acid is evolved. The fluid mass crystallises on cooling, and is recrystallised from boiling alcohol. Forms shining, colourless, truncated, interlaced needles, which are slightly soluble in cold water or ether, readily in alcohol. It has a strong acid reaction, and is readily soluble in caustic alkalis. It melts between 135° and 140° C.; when quickly heated, it burns, gives off vapours of benzonitrile, and no longer solidifies on cooling. Its ammoniacal solution becomes syrupy when gently evaporated, and finally solidifies into a radiated mass, which Gerhardt states to be the acid ammonium-salt of *benzosulphophenamic acid*, $C^{26}H^{29}N^3S^2O^8 = NH^3.(C^{13}H^{13}NSO^4)^2$. This salt is very soluble in water and alcohol, but insoluble in ether. When an acid is added to its aqueous solution, an oily substance separates, which soon changes into needles of benzosulphenamide.

Benzosulphophenamide, like many other amides, behaves like a hydrate when acted on by pentachloride of phosphorus, forming the chloride of a peculiar body, which Gerhardt calls *benzosulphophenamidyl.*

$$C^{13}H^{11}NSO^3 + PCl^5 = \underset{\substack{\text{Chloride of benzo-}\\ \text{sulphophenamidyl.}}}{C^{13}H^{10}NSO^2.Cl} + PCl^3O + HCl.$$

The reaction does not take place till heat is applied. The new compound is decomposed by heat into benzonitrile and chloride of sulphophenyl. When it is triturated with carbonate of ammonium it forms an amide, *benzosulphophenamidylamide*, $N.C^{13}H^{10}NSO^2.H^2$, which crystallises from alcohol, and is very slightly soluble in ammonia. (Gerhardt, cited in Handw. ii. [1] 884.)

Benzosulphophenargentamide. $C^{13}H^{10}AgNSO^3 = N.C^7H^5O.C^6H^5SO^2.Ag$.—When nitrate of silver is added to a boiling aqueous solution of benzosulphophenamide containing a little ammonia, there is no precipitate; but on cooling, this compound separates out in colourless needles. It is but slightly soluble in cold water, readily in alcohol. It is decomposed by heat, giving off sulphurous anhydride and benzonitrile, and leaving a residue of metallic silver and carbon. Its solution in strong ammonia yields on evaporation, fine rose-coloured crystals, which contain the elements of 1 at. benzosulphophenamide + 1 at. ammonia. They are readily soluble in boiling water; the solution on boiling deposits crystals of benzosulphophenargentamide; the addition of an acid separates benzosulphophenamide. Gerhardt regards this compound as a diamide, $N^2.C^7H^5O.C^6H^5SO^2.Ag.H^3$, a view which the absence of a diatomic radicle renders improbable.

Benzosulphophenylsodamide. $C^{13}H^{10}NaNSO^3 = N.C^7H^5O.C^6H^5SO^2.Na$.—Benzosulphophenamide dissolves in sodic carbonate with evolution of carbonic anhydride; the solution is evaporated to dryness, and the residue exhausted with boiling alcohol, which deposits the compound on cooling in opaque nodules. It is soluble in water; acids separate from it benzosulphophenamide. (Gerhardt, cited in Handw. ii. [1] 884.)

Dibenzosulphophenamide. $C^{20}H^{15}NSO^4 = N.(C^7H^5O)^2.C^6H^5SO$. (Gerhardt and Chiozza, *loc. cit.*)—Obtained by the action of chloride of benzoyl on benzosulphophenargentamide. Chloride of silver is formed, together with a viscid mass, which dissolves in ether, and crystallises in large brilliant prisms. It melts at 105° C., and is slightly soluble in ammonia. It cannot be obtained by the action of chloride of benzoyl on benzosulphophenamide.

Benzoyl enters into the composition of certain biamides and triamides, forming compounds, which will be described under the original diamides and triamides referred to.

Substitution-products of Benzamide.

Bromobenzamide is not known.—Benzamide dissolves in bromine, without evolution of hydrobromic acid; the solution, after some days, deposits deep-red crystals, having the composition $C^7H^7NOBr^2$, which may be regarded as the hydrobromate of bromobenzamide, $C^7H^6BrNO.HBr$. The crystals are decomposed slowly by water, immediately by ammonia, with separation of benzamide. (Laurent.)

Chlorobenzamide. $C^7H^6ClNO = N.C^7H^4ClO.H^2$ (Limpricht and Uslar, Ann. Ch. Pharm. cii. 263).—Obtained by dissolving chloride of chlorobenzoyl in strong aqueous ammonia; the solution deposits yellow laminæ of chlorobenzamide, which are purified by recrystallisation from hot water or alcohol. It is insoluble in cold water; it fuses at 122° C., and sublimes in small quantities. The compound obtained by Gerhardt and Drion (Ann. Ch. Phys. [3] xlv. 102), by triturating chloride of chlorobenzoyl with carbonate of ammonium, has the same composition with the above, but differs from it slightly in properties, being insoluble in water, soluble in alcohol or ammonia, whence it crystallises in fine needles. It evolves ammonia when boiled with potash.

Nitrobenzamide. $C^7H^6N^2O^3 = N.C^7H^4(NO^2)O.H^2$. (Field, Ann. Ch. Pharm. lxv. 45. Chancel, Compt. Chim. 1849, 180.)—Obtained in small quantity by fusing nitrobenzoate of ammonium. Better, by adding aqueous ammonia to a solution of nitrobenzoic ether in a rather large quantity of alcohol, and allowing the mixture to stand for some days till it is not rendered turbid by water. It is then evaporated on the water-bath till it crystallises on cooling; and the crystals are purified by recrystallisation from mixed alcohol and ether. It is also formed by the action of ammonia on chloride of nitrobenzoyl. Nitrobenzamide is slightly soluble in cold, readily in hot water; also in alcohol, ether, or wood-spirit. From these latter solutions it crystallises in long needles, or, by slow evaporation, in large tables resembling gypsum. It fuses above 100° C., and crystallises on cooling. When boiled with strong potash, it forms potassic nitrobenzoate. Its aqueous solution is decomposed by sulphide of ammonium, as follows:

$$C^7H^6N^2O^3 + 3H^2S = \underset{\substack{\text{Phenyl-}\\\text{carbamide.}\\\text{(Phenyl-urea.)}}}{C^7H^8N^2O} + 2H^2O + S^3$$

Dinitrobenzamide. $C^7H^5N^3O^5 = N.C^7H^3(NO^2)^2O.H^2$ (Voit, Ann. Ch. Pharm. xcix. 105.)—When dinitrobenzoic ether is digested for some days with alcoholic ammonia, it forms a blood-red solution, which deposits dinitrobenzamide in yellowish laminæ and prisms. It has a bitter taste, and dissolves sparingly in cold, more readily in hot water; the solution is neutral. It melts at 183° C., and is decomposed by further heat. Its ammoniacal solution is not precipitated by nitrate of silver.

Thiobenzamide. Schwefelbenzamid. Benzamide sulfuré. $C^7H^7NS = N.C^7H^5S.H^2$ (Cahours, Compt. rend. xxvii. 329).—When a solution of benzonitrile in slightly ammoniacal alcohol is saturated with sulphuretted hydrogen, the liquid becomes brownish-yellow; and if, after some hours, it is boiled down to ¼ its volume, and water added, it deposits yellow flakes, which dissolve in boiling water, and separate on cooling in long yellow silky needles of thiobenzamide. It is decomposed by mercuric oxide, yielding mercuric sulphide, water, and benzonitrile; by potassium, yielding potassic sulphide and cyanide. F. T. C.

BENZAMIL. $C^{28}H^{20}N^2O^2$ (?) (Laurent, Rev. scient. xix. 446.)—Crude bitter-almond oil, shaken up with potash, is distilled till about ⅓ has passed over, the residue dissolved in ether-alcohol, and ammonia passed into the solution. The deposit which forms is separated and boiled with a large quantity of ether; and the solution on cooling deposits silky crystals and a white powder: the latter is benzamil. It is nearly insoluble in alcohol, difficultly soluble in ether. It melts at 170° C., and solidifies very slowly. On dry distillation, it yields a substance soluble in ether. It dissolves in alcoholic potash, and the solution, on cooling, deposits crystals which have not been examined. F. T. C.

BENZANILIDE. Syn. with Phenylbenzamide. See PHENYLAMINE.

BENZENE or **BENZOL.** C^6H^6, or $C^{12}H^6$.—*Benzine, Hydride of phenyl, Bicarburet of hydrogen.* (Faraday, Phil. Trans. 1825, 440. Mitscherlich, Ann. Ch. Pharm. ix. 39. Péligot, Ann. Ch. Phys. [2] lvi. 59. Mansfield, Chem. Soc. Qu. J. i. 244.) —Discovered by Faraday. It is a product of the decomposition of many organic compounds, being formed: 1. When benzoic acid is heated with caustic lime or baryta (Mitscherlich), or when its vapour is passed over red-hot iron (Darcet, Ann. Ch. Phys. [2] lxvi. 99).—2. When phtalic acid is heated with caustic lime (Marignac, Ann Ch. Pharm. xlii. 217), or insolinic acid with baryta (Hofmann). 3. By dry distillation of quinic acid (Wöhler).—4. By passing vapour of bergamot-oil over red-hot lime (Ohme, Ann. Ch. Pharm. xxxi. 318).—5. By passing fats through red-hot tubes (Faraday).—6. By dry distillation of coal (Hofmann, Mansfield).—7. In small quantity, when acetic acid or alcohol is passed through a red-hot tube (Berthelot, Compt. rend. xxxiii. 210). It is also found in Rangoon tar. (De La Rue and Müller.)

The readiest method of preparing pure benzene, is to distil 1 pt. benzoic acid with 3 pts. slaked lime at a gently increasing heat; the mixture of benzene and water which passes over is shaken up with a little potash, the benzene decanted, dried over chloride of calcium, and rectified on the water-bath. 3 pts. benzoic acid yield 1 pt. benzene. The most abundant source of benzene is coal-tar; but the product obtained from this source is very impure, containing several higher hydrocarbons, volatile alkaloids, and other substances. To obtain benzene pure, Mansfield shakes up the light oil obtained by the distillation of coal-tar with dilute sulphuric acid, then with water, and then with potash, in order to remove all the acids and alkaloids that it contains, and submits the washed oil to repeated fractional distillation; the portion which passes over at 80°—90° C. is cooled to −12°, when the benzene crystallises, and is purified from liquid substances by pressure. A better method is to distil the washed light oil in a metal still, and to pass the vapour upwards through a tube surrounded with boiling water, and then into a cooled receiver; thus the oils which boil above 100° C. are condensed and run back into the still. The distillate is similarly treated, the water round the condensing-tube being kept at 80° C. and the distillation stopped when the heat in the retort rises to 90°. This second distillate, (only half of which solidifies at 20°), is shaken up with $\frac{1}{16}$ vol. strong nitric acid, decanted, and shaken up with $\frac{1}{2}$ vol. strong sulphuric acid, rectified without decantation, and the product purified as before by cooling and pressure. Commercial benzene is always very impure, containing many higher hydrocarbons; it may be approximately purified by distillation in the water-bath.

At the ordinary temperature, benzene is a limpid, colourless, strongly refracting oil, of specific gravity 0·85 at 15°·5 C. (Faraday, Mitscherlich), 0·8991 at 0° (Kopp). When cooled, it solidifies into fern-like tufts, or into hard masses like camphor, which melt at 5°·5 C., expanding in bulk at the same time, and solidify again at 0°. At −18°, it is hard, brittle, and of specific gravity 0·956. It boils at 80°·4 at 776 m m. (Kopp), at 86° (Mitscherlich), and volatilises undecomposed. Its vapour-density is (expt.), 2·77 (calc.), 2·704. It has a pleasant smell. It is scarcely soluble in water, but imparts a strong odour to it; readily soluble in alcohol, ether, wood-spirit, and acetone. It dissolves sulphur, phosphorus, and iodine, especially on heating; fixed and volatile oils, camphor, wax, mastic, caoutchouc, and gutta-percha, abundantly; gum-lac, copal, anime, and gamboge, in small quantity; quinine, somewhat readily; strychnine and morphine in small quantity; cinchonine, not at all (Mansfield). Impure benzene is much used to remove stains from silk, &c.

Benzene is very inflammable, and burns with a bright smoky flame. A mixture of 1 vol. benzene with 2 vols. alcohol of 0·85, forms a very good lamp-oil; a larger proportion of benzene gives a smoky flame. When vapour of benzene is passed through a red-hot tube, carbon is separated, and a gaseous hydrocarbon formed. *Chlorine* and *bromine* (not *iodine*), act upon it in the sunshine, forming substitution-products (see below). Strong *nitric acid* converts it into nitrobenzene; according to Abel, the same result is obtained by repeated distillation with dilute acid. *Sulphuric anhydride* or *fuming sulphuric acid* converts it into sulphobenzide and sulphophenylic acid; strong non-fuming sulphuric acid into the latter product only (Gerhardt). According to Mansfield and Mitscherlich, the non-fuming acid has no action upon it. *Potassium, aqueous alkalis*, and *perchloride of phosphorus*, do not act upon benzene, even when heated to its boiling point; neither does aqueous chromic acid (Abel), or phosgene gas in sunshine. (Mitscherlich.)

Church (Phil. Mag. [4] xiii. 415) describes, under the name of *Parabenzene*, a hydrocarbon obtained by him from the light oil of coal-tar, which is isomeric with benzene, but has a different smell, boils at 97°·5 C. and does not solidify at −20°. Nitric acid converts it into nitrobenzene; fuming sulphuric acid into an acid isomeric with sulphophenylic acid, but whose copper- and barium-salts are somewhat different in properties from those of that acid.

Hofmann (Ann. Ch. Pharm. lv. 201) gives a good process for the detection of benzene in a mixture of volatile oils, founded on the facility with which benzene is converted into nitrobenzene by nitric acid, and nitrobenzene into phenylamine by reducing agents. The liquid to be examined is warmed in a test-tube with fuming nitric acid, diluted with water, and shaken up with ether, which dissolves the nitrobenzene. The ethereal solution is separated by a pipette, and mixed with equal volumes of alcohol and hydrochloric acid, and granulated zinc added. After five minutes, the mixture is saturated with potash, again shaken up with ether, which dissolves the liberated phenylamine, and the ethereal solution evaporated on a watch-glass; the addition of a drop of hypochlorite of calcium to the residue gives the intense purple colour characteristic of phenylamine.

Substitution-products of Benzene.

Bromine dissolves in benzene, forming compounds in which 1, 2, and 3 at. H are respectively replaced by Br.

Bromobenzene. Monobromobenzid. Bromide of phenyl, C^6H^5Br (Couper, Ann. Ch. Phys. [3] lii. 309).—The vapour of an equivalent quantity of bromine is passed into a large flask in which some benzene is heated to boiling; the product is washed with potash, dried, and distilled; most of it passes over about 150° C. It is a colourless liquid, smelling like benzene; it does not solidify at − 20° C.; its vapour-density is 5·631. It is not decomposed when heated to 200° C. with acetate of silver, or with a solution of sulphate of silver in strong sulphuric acid. Heated with potassium in a sealed tube, it explodes; with sodium, it yields benzene and a crystalline body. Fuming nitric acid converts it into *bromonitrobenzene*, $C^6H^4BrNO^2$, a crystalline body which melts below 90°, and distils undecomposed. Fuming sulphuric acid dissolves it, forming *bromosulphophenylic acid*.

Dibromobenzene. Bibromobenzid. $C^6H^4Br^2$ (Couper, *loc. cit.*)—When monobromobenzene is acted on for some time by excess of bromine, hydrobromic acid is evolved, and crystals separate, which, by recrystallisation from ether, are obtained in large oblique prisms, which melt at 89° C. and boil at 219° without decomposition.

Tribromobenzene. Terbromobenzid. $C^6H^3Br^3$ (Mitscherlich (1835), Pogg. Ann. xxxv. 374. Lassaigne, Rev. scient. v. 360).—A mixture of benzene and bromine exposed to sunlight gradually forms a solid crystalline body, which is purified by washing with boiling ether. This is the *hydrobromate of tribromobenzene*, $C^6H^6Br^6 = C^6H^3Br^3.3HBr$. It forms a white inodorous tasteless powder, insoluble in water, sparingly soluble in boiling alcohol or ether, whence it crystallises in microscopic oblique rhombic prisms. It is fusible, and crystallises on cooling. When heated, it partly sublimes undecomposed, and is partly resolved into tribromobenzene, hydrobromic acid, bromine, and hydrogen. Heated with hydrate of calcium, it yields *tribromobenzene*. This compound is best obtained by boiling the hydrobromate with alcoholic potash, adding water, dissolving the precipitated oil in ether, and evaporating the solution; it forms silky, very fusible needles, soluble in alcohol and ether, and volatile without decomposition.

Monochlorobenzene. See PHENYL, CHLORIDE OF.

Trichlorobenzene. Chlorobenzid. $C^6H^3Cl^3$ (Mitscherlich, *loc. cit.* Péligot, Ann. Ch. Phys. [2] lvi. 66. Laurent, *ibid.* lxiii. 27).—The action of chlorine in sunshine upon benzene is similar to that of bromine, resulting in the formation of crystals of *hydrochlorate of trichlorobenzene*, $C^6H^6Cl^6 = C^6H^3Cl^3.3HCl$, which are washed with ether or recrystallised from boiling alcohol. It forms colourless shining laminæ, or rhombic prisms with truncated lateral edges, insoluble in water, soluble in alcohol or ether: melts at 132° C. (Mitscherlich); 135°—140° (Laurent); distils completely at 288°, with partial decomposition, without leaving any residue. In its decompositions, it resembles the corresponding bromine compound. *Trichlorobenzene* is obtained by the repeated distillation of the hydrochlorate alone (Mitscherlich): or by heating it with hydrate of barium or calcium, washing the distillate with water, and rectifying it over chloride of calcium; or by boiling it with alcoholic potash (Laurent). It is a colourless oil, of specific gravity 1·457 at 7° C.; boils at 210°; vapour-density 6·37; insoluble in water, soluble in alcohol, ether, or benzene. It is not attacked by chlorine, bromine, acids, or alkalis.

Chlorodinitrobenzene. See CHLORIDE OF DINITROPHENYL, under PHENYL, CHLORIDE OF.

Nitrobenzene. Nitrobenzol. Nitrobenzid. $C^6H^5NO^2$ (Mitscherlich (1834), Pogg. Ann. xxxi. 625).—Formed by the action of fuming nitric acid on benzene, or by the dry distillation of nitrobenzoates. Prepared by gradually adding benzene to warm fuming nitric acid; the nitrobenzene separates as an oil on cooling, is washed with water, and rectified over chloride of calcium. It is a yellowish liquid, with a very sweet taste, and a smell like bitter-almond oil; specific gravity 1·1866 at 14°·4 C. (Kopp); boils at 213° C. (Mitscherlich), 219°—220° (Kopp); vapour-density 4·4. Below 3° C. it crystallises in needles. It is insoluble in water, readily soluble in alcohol and ether. It is much used by perfumers, under the name of *Essence de mirbane*. It is not attacked either by chlorine or bromine at the ordinary temperature; but its vapour is decomposed when passed with chlorine through a red-hot tube, yielding hydrochloric acid. Fuming nitric acid dissolves it, and on heating converts it into dinitrobenzene. Strong sulphuric acid dissolves it, and on heating decomposes it, forming a dark-coloured solution, and evolving sulphurous anhydride. Dilute nitric or sulphuric acid does not attack it, even at 100° C. It is scarcely attacked by boiling with aqueous potash or ammonia, or by distillation over caustic lime; when boiled with alcoholic potash, it yields azoxybenzide (p. 479); and when distilled with alcoholic potash, azobenzide. When a solution of nitrobenzene in alcohol is mixed with ammonia, and saturated with sulphuretted hydrogen, sulphur is deposited, and the product, when cooled to 0° C., solidifies to a mass of yellow needles, which are soluble in water or alcohol and have a biting taste; on driving off the alcohol by heat, more sulphur is deposited, and phenylamine is finally left:

$$C^6H^5NO^2 + 3H^2S = C^6H^7N + 2H^2O + S^3.$$

Other reducing agents, *e.g.* zinc with a mixture of alcohol and hydrochloric acid, iron filings and acetic acid, and arsenite of potassium, convert nitrobenzene into phenylamine.

Dinitrobenzene. $C^6H^4N^2O^4 = C^6H^4(NO^2)^2$ (Deville (1841), Ann. Ch. Phys. [3] iii. 187. Muspratt and Hofmann, Ann. Ch. Pharm. lvii. 214).—Formed very slowly by boiling nitrobenzene with fuming nitric acid; rapidly when nitrobenzene is dropped gradually into a mixture of equal vols. fuming nitric and strong sulphuric acid as long as solution takes place. The mixture is boiled for some minutes, and the crystalline magma which forms on cooling is washed with water and recrystallised from boiling alcohol. It forms long shining needles or laminæ, which melt below 100° C. and solidify into a radiated mass. It is insoluble in water, soluble in warm alcohol. Sulphide of ammonium converts it into nitrophenylamine, and separates sulphur. Zinc and hydrochloric acid convert it into nitrosophenylin (*q. v.*) According to Hilkenkamp (Ann. Ch. Pharm xcv. 86), sulphite of ammonium converts it into a peculiar acid, *dithiobenzolic* or *phenyldisulphodiamic acid*, $C^6H^8N^2S^2O^6$. He obtained this compound by the action of sulphite of ammonium on nitrobenzene, as follows; but he attributes its formation to the presence of dinitrobenzene. He heated 80 grms. nitrobenzene with 240 grms dry sulphite of ammonium, 1 litre absolute alcohol, and some carbonate of ammonium, for 8 or 10 hours on a water-bath. The liquid was filtered from the sulphate of ammonium which separated on cooling, and evaporated to a syrup, when it deposited at first abundance of fine white laminæ, which quickly decomposed, and then a smaller quantity of hard needles, which are the ammonium-salt of this acid.

$$\underset{\text{Dinitrobenzene.}}{C^6H^4N^2O^4} + 6SO^3N^2H^8 = \underset{\substack{\text{Dithiobenzolic}\\ \text{acid.}}}{C^6H^8N^2S^2O^6} + 4SO^4N^2H^8 + 4NH^3.$$

It is readily soluble in water or dilute alcohol, slightly in absolute alcohol, insoluble in ether. Nitric acid colours its solution yellow; chlorine forms with it abundance of chloranil, with traces of a brown resinous substance. The barium-salt is crystalline, soluble in water, insoluble in alcohol. The acid has not been obtained in the free state. F. T. C.

BENZHYDRAMIDE. *Hydride of Cyanazobenzoyl.* $C^{22}H^{18}N^2O$ (Laurent, Ann. Ch. Phys. [2] lxvi. 180; Laurent and Gerhardt, Compt. Chim. 1850, 114).—A product of the action of ammonia on crude bitter-almond oil; or of cyanide of ammonium on hydride of benzoyl.

$$3C^7H^6O + NH^4CN = C^{22}H^{18}N^2O + 2H^2O.$$

Crude bitter-almond oil heated to 100° C., is saturated with dry ammonia, and the product dissolved in ether-alcohol: after twenty-four hours, the solution begins to deposit crystals, which go on increasing for three or four days. The mother-liquor is decanted, and the crystals treated with boiling alcohol, which leaves a white residue, *benzoylazotide*. The solution, on spontaneous evaporation, deposits small needles, mixed with drops of oil: these are washed quickly with a little ether-alcohol, and recrystallised from boiling alcohol. It is also formed in the process for the preparation of azobenzoyl (*q. v.*)

Benzhydramide forms colourless, microscopic, rectangular prisms, with two terminal faces intersecting at an obtuse angle. It is insoluble in water, sparingly soluble in cold alcohol, readily in hot alcohol or in ether. It is very fusible, and solidifies on cooling to a resinous mass, without decomposition: when further heated, it gives off hydrocyanic acid, and yields an oil, a crystalline sublimate, and a little carbon. It is not decomposed by cold dilute hydrochloric acid; but, on boiling, it yields hydride of benzoyl, hydrocyanic acid, and chloride of ammonium. F. T. C.

BENZHYDROCYANIDE. Syn. with Benzimide (*q. v.*)

BENZHYDROL. BENZHYDROLIC ACID. Rochleder and Hlasiwetz gave the name of benzhydrol to a camphor obtained by them from oil of cassia. Further investigation by Rochleder and Schwarz, has shown that this camphor contains two substances, one richer in hydrogen, the other in oxygen: they call the former *benzhydrol*, the latter, *benzhydrolic acid.* F. T. C

BENZIDAM. Syn. with Phenylamine (*q. v.*)

BENZIDINE. $C^{12}H^{12}N^2 = N^2.\overset{\prime\prime}{C^{12}}H^8.H^4$ (Zinin, J. pr. Chem. xxxvi. 93; lvii. 173; Ann. Ch. Pharm. lxxxv. 328.)—An organic alkali formed by the reduction of azobenzene or azoxybenzene. It is obtained by saturating with sulphuretted hydrogen a solution of azobenzene in alcoholic ammonia: the liquid turns brown, and, when heated, deposits sulphur abundantly, which is filtered off. The filtrate, on cooling, deposits crystals of benzidine, which are purified by dissolving them in boiling alcohol, adding dilute sulphuric acid as long as a precipitate forms, washing the precipitate with alcohol, and dissolving it in boiling aqueous ammonia: the solution, on cooling, deposits benzidine in white shining scales. When an alcoholic solution of azobenzene or azoxybenzene is treated with sulphurous acid, sulphate of benzidine is at once precipitated.

Benzidine is inodorous; scarcely soluble in cold water, readily in hot water, alcohol, or ether; its solution has a bitter burning taste. It melts at 108° C., and cools to a crystalline mass: further heated, it partly sublimes, and is partly decomposed. When a solution of benzidine, or its salts, is treated with chlorine, it becomes first blue, then dark brown, and deposits scarlet crystals, scarcely soluble in water, more readily in alcohol (probably azobenzene). Nitrous fumes attack it violently at a gentle heat, and convert it into azobenzene (Noble). It is decomposed by strong nitric acid.

Benzidine combines with acids, forming definite salts, which are mostly readily crystallisable: their solutions are precipitated by caustic alkalis or alkaline carbonates. The *hydrochlorate*, $C^{12}H^{12}N^2.2HCl$, crystallises in white, pearly, rhombic prisms, soluble in water or alcohol, almost insoluble in ether. The *chloroplatinate*, $C^{12}H^{12}N^2.2PtCl^3H$, is a yellow crystalline precipitate, obtained by adding dichloride of platinum to the aqueous or alcoholic solution of the foregoing salt. It is slightly soluble in water, insoluble in alcohol or ether. When boiled with water (more readily with alcohol or ether), it is converted into a dark-violet powder. The *nitrate* forms rectangular prisms, soluble in water. The *acid oxalate*, $C^{12}H^{12}N^2.C^2O^4H^2$, forms white, silky, radiated needles, slightly soluble in water or alcohol. The *acid sulphate*, $C^{12}H^{12}N^2.SO^4H^2$, separates as a dull white powder, when sulphuric acid is added to a solution of benzidine: from a very dilute solution it separates in crystals. It is scarcely soluble in boiling water or alcohol. The *benzoate*, *acetate*, *tartrate*, and *phosphate* are all crystalline. With mercuric chloride, benzidine forms a crystalline double-salt, soluble in water and alcohol. F. T. C.

Diethylbenzidine, $C^{16}H^{20}N^2 = N^2.C^{12}H^{8\prime\prime}.(C^2H^5)^2.H^2$.—The hydriodate of this base, $C^{16}H^{20}N^2.(HI)^2$, or *iodide of diethyl-benzidammonium* $[N^2.(C^{12}H^8)''(C^2H^5)^2.H^4].I^2$, is obtained in crystals by digesting benzidine with alcohol and iodide of ethyl, in a sealed tube at 100° C. for two hours. Treated with ammonia, it yields the free base, which unites with acids forming well crystallised salts. The chloroplatinate, $C^{16}H^{22}Cl^2.2PtCl^2$ is sparingly soluble. (P. W. Hofmann, Proc. Roy. Soc. x. 585; Ann. Ch. Pharm. cxv. 362.)

Tetrethylbenzidine, $C^{20}H^{28}N^2 = N^2.(C^{12}H^8)''.(C^2H^5)^4$, is obtained as a hydriodate by treating the diethylated base with iodide of ethyl. The free base melts at 83° C. resolidifies at 80°, and forms crystalline salts with acids. *Iodide* of ethyl acts but slowly on it, but when treated with *iodide of methyl*, attacks it with energy, forming:

Iodide of Dimethyl-tetrethyl-benzidammonium, $C^{22}H^{34}N^2I^2 = [N^2.(C^{12}H^8)''.(C^2H^5)^4.(CH^3)^2].I^2$. This salt dissolves sparingly in alcohol, but easily in boiling water, whence it crystallises in long beautiful needles. Its solution is not precipitated by ammonia, but yields with oxide of silver, a strongly alkaline solution containing the hydrate $\left.\begin{matrix}N^2(C^{12}H^8)''(C^2H^5)^4(CH^3)^2\\ H^2\end{matrix}\right\}O^2$. This base unites readily with acids, forming beautifully crystalline salts. The *chloroplatinate* $C^{22}H^{34}N^2Cl^2.2PtCl^2$, is almost insoluble in water, but dissolves sparingly in boiling hydrochloric acid, whence it crystallises on cooling in beautiful needles. (P. W. Hofmann, *loc. cit.*)

BENZIL. *Sousoxide de Stilbèse*, $C^{14}H^{10}O^2$. (Laurent. Ann. Ch. Phys. [2] lix. 402. Liebig. Ann. Ch. Pharm. xxv. 25. Zinin, Ann. Ch. Pharm. xxxiv. 190. Gregory, Compt. Chim. 1845. 308.)—Formed by the action of oxidising agents on benzoin. Laurent prepares it by passing chlorine over fused benzoin as long as hydrochloric acid is evolved, and crystallising the product from hot alcohol. Zinin heats gently 1 pt. benzoin with 2 pts. concentrated nitric acid; the reaction is complete when no more nitrous fumes are evolved, and when the yellow oil which rises to the surface is quite clear. This oil solidifies to pure benzil on cooling.

It crystallises by spontaneous evaporation of its alcoholic or ethereal solution in long yellowish six-sided prisms, which are commonly hollow. Observed faces, $\infty P . oP . P$. It is without smell or taste, insoluble in water, soluble in alcohol, ether, and warm sulphuric acid, and reprecipitated from the last by water. It fuses between 90° and 92° C. and solidifies to a fibrous mass: at a higher temperature, it volatilises undecomposed.

It burns with a red sooty flame. It is not altered by boiling with nitric acid or with aqueous potash: but when boiled with alcoholic potash, it turns blue and forms benzilic acid. With ammonia, an alcoholic solution of benzil forms various products, according to the concentration and the duration of the reaction (see AZOBENZIL, BENZILAM, BENZILIM, IMABENZIL). With sulphuretted hydrogen, it deposits sulphur, and forms a yellow oil, smelling of garlic: this oil is more readily obtained by distilling benzil with alcoholic sulphide of ammonium. With sulphide of ammonium, it yields two or three different products, among which is *hydrobenzil* (*q. v.*) Fused with potassium, it gives off violet vapours and leaves a carbonaceous residue.

Benzil is polymeric with the hypothetical radicle benzoyl, C^7H^5O.

Hydrocyanate of Benzil. $C^{16}H^{12}N^2O^2 = C^{14}H^{10}O^2,2HCy$ (Zinin).—When benzil is dissolved in boiling alcohol, and an equal weight of nearly anhydrous prussic acid is added, the mixture gradually deposits white shining rhombic tables of hydrocyanate of benzil. This compound melts and decomposes when heated, leaving pure benzil. It is not attacked when boiled with water or strong hydrochloric acid: when heated with nitric acid or ammonia, it yields benzil. Its alcoholic solution gives with nitrate of silver a precipitate of cyanide of silver, and benzil crystallises from the solution. When its alcoholic solution is heated with mercuric oxide, mercury is reduced, and the smell of benzoic ether becomes distinctly perceptible. F. T. C.

BENZILAM. $C^{14}H^9N$. (Laurent, Rev. scient. xix. 443.)—Formed, together with imabenzil and benzilim, by the action of ammonia on benzil. It is best prepared by dissolving imabenzil or benzilim in sulphuric acid, and adding water, when an oil separates out which speedily solidifies: this is washed with water and a little alcohol, and crystallised from ether-alcohol. It forms colourless rhombic prisms readily soluble in alcohol or ether. It melts at 105° C.: if imperfectly fused, it quickly crystallises on cooling, but if perfectly fused, it solidifies much more slowly, without crystallisation. It is volatile without decomposition. Boiling alcoholic potash has no action upon it: nitric acid decomposes it, yielding an oil which crystallises on cooling, and is insoluble in ether: it is soluble in sulphuric acid, and is reprecipitated by water. F. T. C.

BENZILIC ACID. *Stilbic Acid.* $C^{14}H^{12}O^3$. (Liebig [1838], Ann. Ch. Pharm. xxv. 25. Zinin, *ibid.* xxxi. 329.)—Formed by the action of alkalis on benzil or benzoin. Benzil is dissolved in boiling alcoholic potash, in such quantity that the solution remains distinctly alkaline, and the whole is boiled until a sample of it gives no turbidity when mixed with water. The solution is then evaporated to dryness on the water-bath, the residue powdered, and exposed to an atmosphere of carbonic anhydride till all the potash is converted into carbonate; it is then extracted with alcohol, the solution mixed with water, and, after distilling off the alcohol, decolorised with animal charcoal, and evaporated to crystallisation. The potassic benzilate thus obtained is redissolved in water, and mixed with boiling dilute hydrochloric acid: on cooling, benzilic acid crystallises out.

It forms hard, shining, colourless needles, which are sparingly soluble in cold, more readily in hot water, easily in alcohol or ether. It has no smell, a bitter metallic taste, and a strong acid reaction. It melts at 120° C.; when heated more strongly, it turns red, and emits violet vapours which condense to a brown-red oily liquid, a residue of carbon being left. This oil is volatile, insoluble in water, soluble with a red colour in alcohol or ether: the solution is not decolorised by water, or by hydrochloric or sulphuric acid, but it is decolorised by potash, ammonia, or nitric acid. Benzilic acid burns with a very smoky flame. With strong sulphuric acid all benzilates give a fine crimson colour, which is not easily destroyed by heat disappears on adding water, but reappears on evaporation. It dissolves in warm nitric acid, and is precipitated unchanged by water. Pentachloride of phosphorus converts it into chlorobenzil.

Benzilates.—Their general formula is $C^{14}H^{11}MO^3$. The *lead-salt* is obtained by adding the aqueous acid to neutral acetate of lead. It is a white powder, slightly soluble in hot water: it is unalterable at 100° C., but when strongly heated melts to a red liquid, and emits violet vapours. The *potassium-salt* forms colourless, transparent, anhydrous crystals, readily soluble in water and alcohol, insoluble in ether. It melts at 200 °C., and solidifies on cooling: heated more strongly, it decomposes, yielding a colourless oily distillate, smelling like naphthaline, insoluble in water, soluble in alcohol; the residue contains carbon and potassic carbonate. The *silver-salt* is a white, crystalline powder, obtained by precipitating nitrate of silver by the potassium-salt. It is slightly soluble in hot water; at 100° C. it turns blue, without losing weight, and melts when further heated, emitting violet vapours and leaving metallic silver.

F. T. C.

BENZILIM. *Benzilimide.* $C^{28}H^{22}N^2O^2$ (Laurent [1845], Rev. scient. xix. 442).—One of the products of the action of ammonia on benzil. It is most easily obtained pure by dissolving imabenzil in boiling alcoholic potash, and adding water to the solution. It forms white, silky, very fine needles, sparingly soluble in alcohol or ether. It melts at 130° C. and solidifies slowly in cooling to an amorphous mass. It distils apparently undecomposed, but the distillate is readily soluble in ether, and crystallises from it in needles. It is not attacked by boiling potash or by hydrochloric acid: warm nitric acid attacks it, evolving red fumes, and yielding a yellow oil, which crystallises on cooling, and is insoluble in ammonia, but soluble and crystallisable from ether. It dissolves in warm sulphuric acid, and the addition of water separates benzilam. F. T. C.

BENZIMIC ACID. (Laurent, Compt. Chim. i. 37.)—The name given by Laurent to a peculiar acid which is formed in the preparation of amarine (*q. v.*) It is best prepared by saturating an alcoholic solution of bitter-almond oil with ammonia, letting it stand for 48 hours, and adding water, which takes up benzimate of ammonium. The addition of hydrochloric acid to the aqueous solution precipitates the acid, which is purified by dissolving it in alcohol containing ammonia, boiling the solution, and neutralising with hydrochloric acid. It forms white silky needles, insoluble in water slightly soluble in alcohol: it melts when heated, and cannot be distilled undecomposed. It has not been analysed. F. T. C.

BENZIMIDE. *Benzhydrocyanide. Hydride of Cyanobenzoyl,* $C^{23}H^{18}N^2O^2$. (Laurent (1836), Ann. Ch. Phys. [2] lix. 397: lxvi. 193; Rev. scient. x. 120. Zinin, Ann. Ch. Pharm. xxxiv. 188. Gregory *ibid.* liv. 372. Laurent and Gerhardt, Compt. chim. 1850, 116.)—Formed by the action of hydrocyanic acid on hydride of benzoyl:

$$3C^7H^6O + 2CNH = C^{23}H^{18}N^2O^2 + H^2O.$$

Hydride of benzoyl mixed with ½ its volume of nearly anhydrous prussic acid is shaken up with an equal volume of strong alcoholic potash diluted with 6 pts. alcohol, and the whole gently heated: after a time a white curdy precipitate separates, which is boiled with water, and purified by solution in alcohol. Benzimide also occurs, mixed with hydride of benzoyl and benzoin, in the resinous residue of the rectification of oil of bitter-almonds: it may be extracted by treating the residue with hot alcohol.

Benzimide forms a light loosely-coherent mass, white, with a greenish tinge, and leaves a stain when rubbed or pressed. It is insoluble in water, or in cold potash or hydrochloric acid; sparingly soluble in boiling alcohol or ether. When heated, it melts, and finally volatilises with decomposition, leaving a carbonaceous residue. It dissolves in strong sulphuric acid with a green colour, which soon changes to red, and is reprecipitated by water. Nitric acid dissolves it with decomposition: heated with nitric acid and alcohol, it evolves red fumes and yields ammonia and benzoate of ethyl. Boiled with hydrochloric acid, it yields hydride of benzoyl, sal-ammoniac, and probably also formic acid.

$$C^{23}H^{18}N^2O^2 + 5H^2O = 3C^7H^6O + 2CH^2O^2 + 2NH^3.$$

Heated with strong bases, it yields benzene; and with potassic hydrate moistened with alcohol, it forms ammonia and potassic benzoate. F. T. C.

BENZINE. Syn. with BENZENE (*q. v.*)

BENZOACETIC ANHYDRIDE. See ACETIC ANHYDRIDE.

BENZOANGELIC ANHYDRIDE. See BENZOIC ANHYDRIDE.

BENZOCARBOLIC ACID. BENZOATE OF PHENYL. See BENZOIC ACID.

BENZOCHLORHYDRIN, $C^{10}H^{11}ClO^3$ (Berthelot, Ann. Ch. Phys. [3] xli. 302).—One of Berthelot's artificial fats, containing the elements of benzoic and hydrochloric acids and glycerin, minus water:

$$C^7H^6O^2 + HCl + C^3H^8O^3 = C^{10}H^{11}ClO^3 + 2H^2O.$$

It is prepared by saturating with hydrochloric acid gas a mixture of glycerin and benzoic acid, which is kept for several hours at 100° C., and removing the excess of acid by sodic carbonate: the benzochlorhydrin then sinks to the bottom as an oily liquid. When pure, it is a neutral oil, solidifying at −40°. It is decomposed by potash, yielding potassic chloride and benzoate: and by hydrochloric acid and alcohol, yielding glycerine and benzoate of ethyl. The chlorine is not withdrawn from the compound even by long digestion at 100° with oxide of silver. F. T. C.

BENZOCINNAMIC ANHYDRIDE. See BENZOIC ANHYDRIDE.

BENZOCUMINIC ANHYDRIDE. See BENZOIC ANHYDRIDE.

BENZOCUMYLSULPHOPHENAMIDE. See BENZAMIDE.

BENZOEN. Syn. with Toluol. See BENZYL, HYDRIDE OF.

BENZOERETIC ACID. *Amorphous benzoic acid, Parabenzoic acid* (E. Kopp. Compt. chim. 1849, 154).—An amorphous powder, obtained by heating gum-benzoin with 6 or 8 pts. nitric acid, not strong enough to form nitrobenzoic acid. When quite pure, it is white; but it is commonly yellowish, owing to the presence of a small quantity of a yellow resin, which accompanies it into all its compounds. It is readily soluble in alcohol, ether, and boiling water. It has an aromatic, faintly sour and bitter taste. It melts at 113° C., boils at 256°, and by dry distillation yields pure crystalline benzoic acid, and, if not quite pure, a slight carbonaceous residue. When gently heated, or exposed to the sun, it becomes covered with small crystals of benzoic acid. Distilled with lime, it yields benzene. It forms salts which crystallise with difficulty, and are generally less soluble than the corresponding benzoates. Different specimens have yielded different results to analysis: but in some cases the composition is very near that of benzoic acid. F. T. C.

BENZOGLYCOLLIC ACID. $C^9H^8O^4 = (C^2H^2O)''.C^7H^5O.H.O^2$ (Strecker [1847], Ann. Ch. Pharm. lxviii. 54. Strecker and Socoloff, *ibid.* lxxx. 18. Gössman, *ibid.* xc. 181; xci. 359).—Formed by the action of nitrous anhydride on hippuric acid:

$$2C^9H^9NO^3 + N^2O^3 = 2C^9H^8O^4 + N^4 + H^2O.$$

It is prepared by rubbing hippuric acid to a thin paste with strong nitric acid, and passing a current of nitric oxide into the mixture: nitrogen is then evolved, and the hippuric acid gradually dissolved. After some time, the clear solution becomes opaque from the deposition of benzoglycollic acid: the current of gas is kept up until the liquid assumes a greenish colour, when a large quantity of water is added, and the whole allowed to cool. The acid then separates out in considerable quantities; it is collected on a filter, washed with cold water, suspended in water, neutralised with milk of lime, and the resulting calcium-salt is purified by recrystallisation and pressure between paper, and subsequently decomposed by hydrochloric acid (Socoloff and Strecker). It may also be prepared by slowly passing chlorine into a solution of hippuric acid in excess of moderately dilute potash: when the evolution of nitrogen ceases, the mixture is carefully neutralised by hydrochloric acid, concentrated by gentle evaporation, and mixed with a slight excess of hydrochloric acid, when it solidifies to a crystalline mass. This is purified by solution in ether, and distilling off the ether from the watery layer below it, when the acid separates as an oil in the midst of the water (Gössman). The acid obtained by either of these methods generally contains a large quantity of benzoic acid, which is removed by partially neutralising the acid with milk of lime and evaporating to dryness: benzoic acid, being the weaker acid of the two, remains uncombined, and is extracted from the residue by ether.

Benzoglycollic acid crystallises from alcohol in colourless prisms of 37° 40′ and 142° 20′, which often take the form of thin plates: when precipitated by acids from aqueous solutions of its salts, it separates as a white crystalline powder. It is scarcely soluble in cold, more so in hot water, readily in alcohol and ether: it melts in hot water before dissolving. It melts when heated and solidifies to a crystalline mass; heated more strongly, it gives off vapours containing benzoic acid, and leaves a slight residue of carbon. When boiled for some time with water, it is gradually decomposed into benzoic and glycollic acids:

$$C^9H^8O^4 + H^2O = C^7H^6O^2 + C^2H^4O^3.$$

This decomposition is accelerated by the presence of a mineral acid.

Benzoglycollates are mostly crystalline, soluble in water, some of them in alcohol also. They are neutral to litmus, and have a faint but peculiar taste. Their aqueous solutions may be boiled and even evaporated to dryness without decomposition. From most of their solutions strong acids separate benzoglycollic acid as a crystalline powder. The acid being monobasic, their general formula is $C^9H^7MO^4$.

The *Ammonium-salt* is obtained by saturating the acid with ammonia, or decomposing the calcium-salt with ammonic carbonate. It loses ammonia when evaporated.

The *Barium-salt*, $C^9H^7BaO^4$ + Aq, forms delicate silky needles, which lose their water at 100° C.

The *Calcium-salt*, $C^9H^7CaO^4$ + Aq, forms delicate silky needles, united in groups, which lose their water at 120° C. It dissolves in 42·3 pts. cold, and 7·54 pts. boiling water. It possesses in a remarkable degree the property of forming supersaturated solutions, so that a solution saturated at boiling heat frequently takes some days to deposit all its crystals in successive crops. When a strong solution of this salt is evaporated with chloride of calcium to a syrupy consistence, a double salt separates out on cooling in octahedrons, which are permanent in the air, but are decomposed by water or alcohol into benzoglycollate and chloride of calcium.

The *Copper-salt* crystallises on cooling in abundant blue rhombic tables, when a boiling saturated solution of the calcium-salt is mixed with nitrate of copper. It becomes green and opaque at 100° C, but retains its lustre; is scarcely soluble in cold, more so in hot, water.

The *Ferric salt*, $2Fe^2O^3.3C^{18}H^{14}O^7$ + 28Aq, or $3(\mathit{fe}O.2C^9H^7\mathit{fe}O^4)$ + Aq, is a voluminous flesh-coloured precipitate, insoluble in water, which becomes darker when dried. After drying in the air, it loses 27·36 per cent. (28 at.) water at 100° C.

There appear to be at least two basic *Lead-salts* besides the normal one. When a cold solution of benzoglycollate of calcium is mixed with normal acetate of lead, a flocculent precipitate is formed, which is a mixture of several salts. If this be dissolved in cold water, the solution, on spontaneous evaporation, yields, first, crystals of the salt *b*, and subsequently soft starry crystals of the normal salt $C^9H^7PbO^4$, which melt with partial decomposition at 100° C.

b. $4C^9H^7PbO^4.Pb^2O + 3Aq$, forms hemispherical groups of crystals, which melt at 100°, and lose $1\frac{1}{2}$ at. water.

c. $2C^9H^7PbO^4.5Pb^2O + 2Aq$.—When the cold solution of the calcium-salt is mixed with basic acetate of lead, and the precipitate digested in cold water and filtered, this salt crystallises after some days. It loses 1 at. water at 100° C.

The precipitate obtained by adding the calcium-salt to a boiling solution of normal acetate of lead, is a mixture of several basic salts.

The *Magnesium salt* forms long, very slender needles, readily soluble in water and alcohol.

The *Potassium-* and *Sodium-salts* are obtained like the ammonium-salt. The former crystallises with difficulty, being very soluble. The latter crystallizes more readily from a hot saturated solution in rhombic tables; it contains 3Aq, which it loses at 100° C.

The *Silver-salt*, $C^9H^7AgO^4$, is obtained as a curdy precipitate when the neutral ammonium salt is mixed with nitrate of silver; this precipitate is washed in cold, and dissolved in boiling, water, whence it separates in white microscopic crystals, which when moist quickly blacken in the light; when dry they are not changed at 100° C.

Zinc-salt, $C^9H^7ZnO^4 + 2Aq$. A boiling saturated solution of the calcium-salt mixed with chloride of zinc, yields on cooling long thin needles, which are dried by filter paper and recrystallised. They lose 2 at. water at 100° C. F. T. C.

BENZOHELICIN. $C^{20}H^{20}O^8$. (Piria, Ann. Ch. Phys. [3] xxxiv. 278; xliv. 366.) —The product of the action of the nitric acid on populin. It may be regarded as helicin, ($C^{13}H^{17}O^7$), in which 1 H is replaced by benzoyl, $C^{20}H^{20}O^8 = C^{13}H^{16}(C^7H^5O)O^7$. It is to populin (benzosalicin) as helicin is to salicin.

Obtained by dissolving populin in pure nitric acid of specific gravity 1·3, the solution becomes yellow, and benzohelicin soon crystallises out. On diluting the mother-liquor with water, more crystals separate out. It forms silky needles closely resembling helicin. When boiled with water and magnesia, it is converted into helicin and benzoic acid. Synaptase has no action upon it. Acids and alkalis convert it into benzoic acid, hydride of salicyl, and glucose:

$$C^{20}H^{20}O^8 + 2H^2O = C^7H^6O^2 + \underset{\substack{\text{Hydride}\\\text{salicyl.}}}{C^7H^6O^2} + \underset{\text{Glucose.}}{C^6H^{12}O^6}.$$

F. T. C.

BENZOIC ACID. *Flowers of Benzoin. Hydrate of Benzoyl. Benzoeblumen. Benzoesaüre. Acide benzoïque.* $C^7H^6O^2 = C^7H^5O.H.O.$ [or $C^{14}H^6O^4 = C^{14}H^5O.HO.$]

History and Sources.—First noticed by Blaise de Vigenère (*Traité du feu et du sel*, 1608). Its true composition was determined by Liebig and Wöhler (Ann. Ch. Pharm. iii. 249). It occurs ready formed in gum-benzoin, dragon's blood, storax, Peru and Tolu balsams, and in many other resins and balsams; also in castoreum (Wöhler, Ann. Ch. Pharm. lxvii. 360), in the spindle tree, *Euonymus europæus*, (Schweizer, J. pr. Chem. 411, 437), and in the putrefied urine of man and of graminivorous animals (Liebig, *ibid.* l. 168).

Formation.—It is formed in a great number of organic reactions. 1. By the oxidation of hydride of benzoyl, even by its exposure to moist air. 2. By the action of water on chloride, bromide, or iodide of benzoyl. 3. By heating benzylic alcohol with aqueous chromic acid. 4. By the action of nitric acid on hydride of cinnamyl, cinnamic acid, cinnamol, cumol, and cuminol. 5. By oxidising casein or gelatin with sulphuric acid and binoxide of manganese (Guckelberger, Ann. Ch. Pharm. lxiv. 80). 6. From hippuric acid, by putrefaction, or by boiling with acids or alkalis. 7. By the action of dilute alkalis on populin. 8. By the dry distillation of insolinic (Hofmann) and quinic acids (Wöhler, Ann. Ch. Pharm. li. 145).

Preparation.—Gum-benzoin is employed for the preparation of benzoic acid on the large scale; the process may be conducted either in the dry or wet way. The best method of preparing it in the dry way, or by sublimation, is that given by Mohr, Ann. Ch. Pharm. xxix. 177). The coarsely-powdered resin is placed at the bottom of a round shallow iron-pot, 8 inches in diameter and 2 inches deep; the mouth is closed by a diaphragm of coarse filter-paper, closely cemented to the sides of the vessel; and over this is tied a covering of thick paper, in size and shape like a hat. The vessel is then heated gently and slowly on a sand-bath (1 lb. of gum requires 3 or 4 hours). On removing the paper-cover when the whole is cool, it is found lined with a crystalline sublimate of benzoic acid. The diaphragm allows the vapours of benzoic acid to pass through it, purifies them in great measure from empyreumatic products, and prevents the sublimed acid from falling back into the vessel. About 4 per cent. acid is thus obtained: if the residue in the iron vessel be broken up and again heated, the yield may be increased to 12¼ per cent. The acid prepared by this method, which is on the whole the best for pharmaceutical purposes, is quite pure, with the exception of traces of a volatile oil, which gives it a smell like that of vanilla, and on which its medical properties depend, at least to some extent.—The extraction of the acid from gum-benzoin may be effected more completely in the wet way. Scheele's process (Opusc. ii. 23) is to mix 2 pts. resin with rather less than 1 pt. quick lime, which is first slaked, to digest the mixture for some hours with 20 pts. cold water, and to boil the whole for half an hour. The solution containing benzoate of calcium is filtered from the residue, which is then washed with hot water, evaporated to one-half, and mixed with excess of hydrochloric acid; the benzoic acid which crystallises out on cooling is purified by recrystallisation from hot water, or by sublimation. If sodic carbonate be employed instead of lime, a portion of the resin is apt to be dissolved, which colours the benzoic acid, and cannot be removed without difficulty. Wöhler (Ann. Ch. Pharm. xlix. 245) gives the following method:—Powdered gum-benzoin is dissolved by the aid of heat in an equal volume of alcohol of 90—95 per cent., the hot solution mixed with fuming hydrochloric acid till the residue begins to be precipitated, and the whole distilled as long as its consistency permits; it is then allowed to cool, and again distilled with water as long as any benzoic ether passes over. The joint distillates, containing benzoic ether, alcohol, and hydrochloric acid, are heated with caustic potash until the ether is entirely decomposed, and the resulting solution of potassic benzoate decomposed by hydrochloric acid. The acid thus obtained precisely resembles that prepared by Mohr's method.

Benzoic acid may also be prepared from hippuric acid by boiling it for half an hour with strong hydrochloric acid, and washing the product with cold water. Benzoic acid is sometimes met with in commerce, which is prepared from the urine of graminivorous animals. The urine is allowed to putrefy, then mixed with milk of lime and filtered; and the filtrate is evaporated and precipitated by hydrochloric acid. If the resulting benzoic acid be coloured, it is redissolved in thin milk of lime, the whole boiled with chloride of calcium, hydrochloric acid added, and the precipitate recrystallised from boiling water. The acid thus prepared is inferior to and cheaper than that obtained by sublimation. It always smells of urine, and never has the peculiar smell of the sublimed acid.

Properties.—Benzoic acid crystallises in colourless, transparent, pearly needles or laminæ, which, under the magnifying glass, appear to be six-sided prisms. It has no smell, and a faint but persistent sour and warm taste. It reddens litmus. It melts at 121·4° C. to a colourless liquid of specific gravity 1·0838 (water at 0° being taken as unity), and boils without decomposition at 249·2° (at 740 mm. pressure) (Kopp). It begins to sublime at a much lower temperature, and distils over abundantly with vapour of water. Its vapour-density is 4·27 (Mitscherlich); the vapours excite coughing. It dissolves in 200 pts. cold, and in 24—30 pts. boiling water, much more readily in alcohol and ether. Fats and volatile oils dissolve it abundantly. It dissolves in strong sulphuric acid without decomposition, and is reprecipitated by water. It is not attacked by boiling dilute nitric or chromic acid; and is thus distinguished from cinnamic acid, which, under these circumstances, yields hydride of benzoyl.

Decompositions. 1. *By heat.*—When vapour of benzoic acid is passed through a red-hot tube filled with fragments of pumice-stone, it is decomposed into benzene and carbonic anhydride. The same decomposition takes place at a lower temperature when 1 pt. acid is heated in a retort with 5 or 6 pts. coarsely powdered pumice. If too much heat be applied, naphthalin and some empyreumatic products are also formed, and a residue of carbon left (Barreswil and Boudault). If benzoic acid be heated with lime, only benzene passes over, the carbonic anhydride being retained by the lime. Heated in contact with air, benzoic acid burns with a bright smoky flame, and leaves no residue. 2. Dry *chlorine* acts upon benzoic acid in sunlight, forming a reddish, tough, gummy mass, whence potassic carbonate extracts chlorobenzoic acid (see below), and leaves a brown-red residue, which smells of benzoin, and contains chlorine (Herzog). *Bromine* acts on benzoic acid in similar a manner. When chlorine is passed into a hot aqueous solution of benzoic acid, or when benzoic acid is boiled with aqueous chloride of lime, or with potassic chlorate and hydrochloric acid, a mixture of mono-, di-, and tri-chlorobenzoic acids is obtained; but these acids have not been separated and examined (Stenhouse, Ann. Ch. Pharm. lv. 10). When a solution of benzoic acid in excess of potash is saturated with chlorine, chloroniceic acid, $C^6H^5ClO^2$, is produced (St. Evre). 3. When benzoic acid is heated with strong *nitric acid*, nitrobenzoic acid is formed: a mixture of sulphuric and fuming nitric acid converts it into dinitrobenzoic acid. 4. Fuming *sulphuric acid* converts it into sulphobenzoic acid. 5. Heated to 200° C. with a mixture of anhydrous acid sulphate of sodium, ($Na^2SO^4.SO^3$) and chloride of sodium, it yields chloride of benzoyl together with hydrochloric acid.

$$C^7H^6O^2 + SO^3 + 2NaCl = C^7H^5OCl + HCl + Na^2SO^4.$$

The neutral sulphate of sodium is associated with the sulphuric anhydride to prevent the latter from converting the benzoic acid into sulphobenzoic acid (Beketoff, Ann. Ch. Pharm. cix. 256). 6. *Perchloride of phosphorus* does not act upon benzoic acid till heat is applied, when hydrochloric acid is evolved, and chlorides of benzoyl and of phosphoryl formed. 7. In the animal organism, benzoic acid is converted into hippuric acid, which is found in the urine. (Wöhler, &c.)

Benzoates.—Benzoic acid decomposes carbonates, but an alcoholic solution of potassic benzoate is decomposed by carbonic anhydride, potassic carbonate being precipitated. It is a monobasic acid, but forms some acid and basic salts. The normal benzoates are mostly crystallisable, and soluble in water and alcohol. Their aqueous solutions are decomposed by almost all acids, benzoic acid being precipitated. Alkaline and alkaline-earthy benzoates yield, by dry distillation, benzene, benzone, solid hydrocarbons isomoric with naphthalin, and a metallic carbonate. A mixture of benzoate and formate of potassium yields, when heated, hydride of benzoyl (Piria). With chloride of phosphoryl, alkaline benzoates yield chloride of benzoyl and a phosphate; with chloride of benzoyl, an alkaline chloride and benzoic anhydride. With perchloride of phosphorus or chloride of sulphur, they yield either chloride of benzoyl or benzoic anhydride, according to the proportion of benzoate present.

Benzoate of Ammonium. *a. Normal.*—Obtained in crystals by cooling a solution of benzoic acid in strong warm ammonia; or by evaporating a more dilute solution with addition of ammonia from time to time. It deliquesces in the air, and is soluble in water and alcohol, but less so in the latter than the potassic salt. When heated in a retort, it loses water, and is converted into benzo-nitrile. Its solution loses ammonia on evaporation, yielding:

b. Acid salt.—Obtained in large irregular crystals by the spontaneous evaporation of the solution of *a*. Less soluble than *a* in water and alcohol.

Benzoate of Barium, $C^7H^5BaO^2$ + Aq.—Slender permanent needles (Trommsdorf), or large tables, which become opaque at 100° C. (Plantamour), and lose their water at 110° (Limpricht).

Benzoate of Cadmium, $C^7H^5CdO^2$ + Aq.—By evaporating a solution of carbonate of cadmium in aqueous benzoic acid, shining aggregated needles are obtained, soluble in hot water, sparingly in alcohol. (Schiff.)

Benzoate of Calcium, $C^7H^5CaO^2$ + Aq.—Crystallises in feathery needles or in granules, soluble in 29 pts. cold, and in less hot water.

Benzoate of Copper.—A hot solution of sulphate of copper gives with potassic benzoate an aggregate of bluish-green needles (Ettling), which are anhydrous (Mitscherlich). It dissolves in warm dilute acetic acid, and crystallises thence in small green needles. It is insoluble in alcohol. By dry distillation it yields benzene, benzoic acid, benzoate of phenyl, and an oil which boils at 260° C., and, when heated with sulphuric acid, is decomposed into hydrate of phenyl and a solid hydrocarbon, C^6H^4: the residue contains salicylate of copper.

Ferric Benzoate.—The normal salt crystallises in yellow needles from a solution of ferric hydrate in aqueous benzoic acid; it is soluble with decomposition in water and alcohol, a basic salt being left behind. A still more basic salt is obtained when a solution of ferric chloride, containing enough ammonia to give it a dark-red colour, is mixed with an alkaline benzoate: it is a flesh-coloured precipitate, insoluble in, and not decomposed by, cold water, and containing 17·5 per cent. iron. (Berzelius.)

Ferrous Benzoate crystallises in needles, which effloresce and turn yellow when exposed to the air, and are soluble in water and alcohol. Benzoate of ammonium does not precipitate ferrous salts.

Benzoate of Lead. $C^7H^5PbO^2 + \frac{1}{2}$ Aq.—A light crystalline powder, obtained by precipitating normal lead-salts with potassic benzoate. It melts a little above 100° C., and gives off its water (Berzelius). When digested with basic acetate of lead, it gradually becomes heavy and granular, being converted into a compound of basic benzoate and acetate of lead (Varrentrapp). A basic salt, $C^7H^5PbO^2 \cdot Pb^2O$, is obtained by digesting the normal salt with ammonia, or precipitating benzoate of ammonium with sub-acetate of lead.

Benzoate of Magnesium.—Feathery efflorescent crystals, readily soluble in water.

Manganous Benzoate. $C^7H^5MnO^2 + \frac{1}{2}$ Aq.—Transparent, colourless, permanent needles, soluble in 20 pts. cold, and in a much smaller quantity of boiling water; sparingly soluble in alcohol.

Mercuric Benzoate. $C^7H^5HgO^2 + \frac{1}{2}$ Aq.—A white precipitate, made up of slender needles, obtained by adding an alkaline benzoate to a solution of corrosive sublimate. It is insoluble in cold, tolerably soluble in hot, water; alcohol and ether decompose it, leaving a basic salt, which may also be obtained by boiling benzoic acid with water and excess of mercuric oxide. When treated with ammonia, mercuric benzoate is converted into *ammonio-mercuric benzoate*, a white powder, insoluble in water, almost insoluble in alcohol or ether; potash turns it yellow, and eliminates ammonia: it contains 69·92 per cent. mercuric oxide. (Harff.)

Mercurous Benzoate. $C^7H^5Hg^2O^2$.—A bulky crystalline precipitate, consisting of slender needles; insoluble in cold water; decomposed by boiling water or alcohol, with separation of metallic mercury. Becomes light-yellow when exposed to the light. Treated with ammonia, it is converted into a black powder, containing 80·9 per cent. mercurous oxide.

Benzoate of Potassium. a. Normal. $C^7H^5KO^2$ + Aq.—Crystallises with difficulty from an aqueous solution, more easily from hot alcohol, in feathery needles or pearly laminæ. It is very soluble in water, has a sharp burning taste, and at 100° C. loses its water. Heated with arsenious hydride, it yields benzene. (Darcet.)

b. Acid salt. $C^7H^5KO^2 + C^7H^6O^2$.—Formed in the preparation of acetic anhydride from chloride of benzoyl and acetate of potassium; the residue is washed with water, dried, and dissolved in boiling alcohol, when the acid benzoate crystallises in pearly laminæ. It is slightly soluble in cold water, or in boiling alcohol. (Gregory.)

Benzoate of Silver.—A white curdy precipitate, obtained by double decomposition: it dissolves in a large quantity of boiling water, and crystallises thence in long shining laminæ. When heated, it melts and swells up, and leaves very white metallic silver. It dissolves in 1·96 pts. alcohol, at 100° C. (Mitscherlich.)

Benzoate of Sodium. Efflorescent pointed crystals, soluble in water, sparingly in alcohol.

The *cobalt-*, *nickel-*, and *zinc-salts* are crystallisable and soluble in water and alcohol: the *aluminium-salt*, crystalline, tolerably soluble in water: the *lithium-salt*, uncrystallisable, very soluble: the *bismuth-*, *cerium-*, *tin-*, *yttrium-*, and *zirconium-salts*, are white precipitates, sparingly soluble in water.

BENZOIC ETHERS. *Benzoate of Methyl. Benzoeformester.* $C^8H^8O^2 = C^7H^5(CH^3)O^2$. (Dumas and Peligot [1835]; Ann. Ch. Phys. [2] lviii. 50; Malaguti, *ibid.* [2] lxx. 387.)—Formed, according to Scharling, in the dry distillation of tolu-balsam. For its preparation, 2 pts. benzoic acid, 1 pt. wood-spirit, and 2 pts. strong sulphuric acid, are distilled together, the residue redistilled two or three times with fresh wood-spirit, and the united distillates mixed with water. The impure benzoate of methyl which is thus precipitated, is washed, dried over chloride of calcium, and rectified over oxide of lead, that portion which comes over above 198° C. being collected apart. It may also be prepared by distilling sulphate of methyl with potassic benzoate. It is a colourless, oily liquid, with a pleasant balsamic smell, insoluble in water, soluble in alcohol and ether: boils at 198°·5 C. at 761 mm., or at 199°·2 at 746 mm. (Kopp). Specific gravity 1·10 at 17°, or 1·0876 at 16·3 (Kopp): vapour-density, by experiment, 4·717. Its vapour, passed through a red-hot tube filled with lime, yields, among other products, benzene. It absorbs chlorine without apparent alteration: when the saturated liquid is heated, hydrochloric acid and chloride of methyl pass over first, and then chloride of benzoyl in abundance; the coloured residue contains benzoic acid, benzoate, and (probably) chlorobenzoate of methyl.

Benzoate of Ethyl. Benzoevinester. $C^9H^{10}O^2 = C^7H^5(C^2H^5)O^2$. (Scheele, Opusc. ii. 141; Dumas and Boullay, Ann. Ch. Phys. [2] xxxviii. 20; Wöhler and Liebig, Ann. Ch. Pharm. iii. 274; Deville, Ann. Ch. Phys. [3] iii. 188.)—Benzoate of ethyl is not formed by the mere contact of benzoic acid and alcohol, however prolonged; but the reaction takes place gradually when the mixture is heated to 100° C. in a sealed tube, or when a small quantity of a strong acid is added to it. The statements of Deville and Cahours, that it is formed by the dry distillation of tolu-balsam and gum-benzoin, seem to require confirmation. It is prepared by distilling 4 pts. alcohol with 2 pts. benzoic acid, and 1 pt. fuming hydrochloric acid, till two-thirds have passed over, and pouring back the distillate into the retort two or three times: a little of the ether passes over, but the greater part remains in the residue, whence it is separated by addition of water. Or a solution of 3 pts. benzoic acid in 2 pts. boiling alcohol of 80 per cent. is heated for some time. Liebig and Wöhler prepare it by dissolving chloride of benzoyl in absolute alcohol: heat and hydrochloric acid are evolved, and the addition of water separates the ether. The ether prepared by any of these methods, contains some free benzoic acid, from which it is purified by agitation with sodic carbonate, washing with water, and rectification over oxide of lead.

Benzoate of ethyl is a colourless oil, with a pleasant aromatic smell, and a pungent taste; boils at 212·9° C., when the barometer stands at 745·5 mm. Specific gravity 1·0556 at 10°·5 C. (Kopp). Vapour-density by experiment, 5·406. It is slightly soluble in water, soluble in all proportions in alcohol and ether. It burns with a bright smoky flame. Chlorine does not act upon it below 60° or 70° C., when hydrochloric acid and chloride of ethyl pass over: on heating the mixture, a colourless distillate passes over at 190°, to which Malaguti (Ann. Ch. Phys. [2] lxx. 374), assigns the formula $C^{18}H^{16}Cl^{6}O^{3}$, regarding it as a compound of chloride of benzoyl with bichlorovinic ether: the black residue, when further heated, yields chloride of benzoyl. Nitric acid, or a mixture of nitric and sulphuric acids, converts it into nitrobenzoate of ethyl. It is not attacked by perchloride of phosphorus (Cahours). When distilled over fused chloride of zinc, it yields chloride of ethyl and benzoate of zinc, which latter is decomposed by further heat, forming benzoic acid and benzene. Ammonia acts upon it slowly, at the ordinary temperature; but, if the mixture be heated above 100° C. in a sealed tube, benzamide is readily formed. Aqueous potash converts it very slowly into alcohol and potassic benzoate: when heated with solid potash or potash-lime, hydrogen is evolved, and benzoate and acetate of potassium formed (Dumas and Stas). Sodium acts upon it between 60° and 70° C.: the liquid turns brown, without evolution of gas, yielding, among other products, the ether of a peculiar acid. (See HYPOBENZOYLOUS ACID.)

Benzoate of Ethylene. Benzoate of Glycol. $C^{16}H^{14}O^{4} = (C^{7}H^{5}O)^{2}.(C^{2}H^{4})''.O^{2}$. (M. Simpson and Wurtz, Ann. Ch. Phys. [3] lv. 400.)—Obtained by the action of dibromid of ethylene on benzoate of silver. It is soluble in ether, and crystallises from the solution in colourless, shining, right-rhombic prisms. Melts at 67° C., and distils without alteration at a temperature above the boiling point of mercury.

Benzoate of Amyl. $C^{12}H^{16}O^{2} = C^{7}H^{5}(C^{5}H^{11})O^{2}$ (Rieckher, (1847), Jahr. pr. Pharm. xiv. 15).—Obtained by distilling 1 pt. fusel-oil and 2 pts. sulphuric acid with excess of alkaline benzoate. It is a yellowish oil of peculiar smell: boils at 260·7° C. when the barometer stands at 745·6 mm. Specific gravity 0·9925 at 14°·4 (Kopp): readily decomposed by alcoholic potash.

Benzoate of Allyl. Benzoepropylenyl. $C^{10}H^{10}O^{2} = C^{7}H^{5}(C^{3}H^{5})O^{2}$ (Zinin, Ann. Ch. Pharm. xcvi. 362; Cahours and Hofmann, *ibid.* cii. 297; Berthelot and De Luca, Ann. Ch. Phys. [3] xlviii. 286).—Obtained by distilling equal quantities of iodide of allyl and benzoate of silver, washing the distillate with sodic carbonate, and rectifying over oxide of lead. Also by the action of chloride of benzoyl on allylic alcohol. A yellow aromatic oil, heavier than water: boils at 230°—240° C.: insoluble in water, soluble in alcohol or ether: decomposed by boiling with potash.

Benzoate of Benzyl. Benzoate of Tolyl. (Canizzaro.) $C^{14}H^{12}O^{2} = C^{7}H^{5}(C^{7}H^{7})O^{2}$. —When chloride of benzoyl and benzylic alcohol are distilled together in equal proportions, hydrochloric acid is evolved, benzoic acid and chloride of benzyl pass over, and finally benzoate of benzyl, in the form of a yellowish oil, which crystallises on cooling. It is purified by pressure between filter-paper, rectification over benzoic anhydride, washing with sodic carbonate, and another rectification. It forms colourless crystalline laminæ, which melt below 20° C., and boil at about 345°. After fusion, it recrystallises with great difficulty, often requiring the aid of a freezing mixture. It is isomeric with benzoin.

Benzoate of Glycyl. See BENZOICIN.

Benzoate of Phenyl. Benzophenid. Benzoeoxyd. Benzocarbolic acid. $C^{13}H^{10}O^{2} = C^{7}H^{5}(C^{6}H^{5})O^{2}$. (Ettling (1845), Ann. Ch. Pharm. liii. 87; Stenhouse, *ibid.* liii. 91; Laurent and Gerhardt, *ibid.* lxxv. 75; List and Limpricht, *ibid.* xc. 190.) —Obtained by the action of chloride of benzoyl on phenylic alcohol or phenylate of potassium: by the dry distillation of benzoate of copper (Ettling): by heating benzosalicylic anhydride (Gerhardt). List and Limpricht have shown the identity of the substances obtained by all these methods. It is best prepared by heating phenylic alcohol with chloride of benzoyl, as long as hydrochloric acid is evolved, washing the crystalline product with potash, exhausting it with ether-alcohol, and evaporating the solution to crystallisation. To obtain it from benzoate of copper, the dry salt is distilled over the open fire as long as vapours are evolved; the distillate again distilled with excess of sodic carbonate, as long as benzene passes over with aqueous vapour; the insoluble residue in the retort separated from the alkaline liquid, washed with water, and dissolved in hot alcohol; and the crystals which separate on cooling, purified by repeated crystallisation from hot alcohol. (List and Limpricht.)

Benzoate of phenyl forms hard, shining, colourless, rhombic prisms, often half an inch long. It melts at 66° C., and cools to a crystalline mass: at a higher temperature it volatilises undecomposed. It has a faint smell of geraniums, or, when heated, of lemons: is insoluble in water, soluble in alcohol and ether, especially on heating. It burns with a red, very smoky flame. Chlorine and bromine convert it into substitution-products (see below). Sulphuric acid dissolves it readily; the addition of water separates benzoic acid, while sulphophenylic acid remains in solution. Boiling hydrochloric acid does not attack it. It is not decomposed by boiling with aqueous potash, but, if the mixture be heated to 150°—170° C. in a sealed tube, potassic benzoate and phenylate are formed: the same decomposition is effected by fusion with solid potash, or by contact with alcoholic potash, even in the cold. It may be boiled with alcoholic ammonia without decomposition; if the mixture be heated to 150° C. in a sealed tube, phenylic alcohol and benzamide are formed, but no aniline. It is similarly decomposed when distilled in a stream of dry ammonia. Perchloride of phosphorus does not attack it. (List and Limpricht.)

Substitution-products of Benzoate of Phenyl.

1, 2, or 3 at. H in benzoate of phenyl may be replaced by Br, Cl, or NO^2. These substitution-products are obtained either by the direct action of chlorine, bromine, or nitrosulphuric acid, on benzoate of phenyl; or by the action of chloride of benzoyl on the substitution-products of hydrate of phenyl.

Benzoate of Bromophenyl, $C^{13}H^9BrO^2 = C^7H^5(C^6H^4Br)O^2$, and of *Dibromophenyl*, $C^{13}H^8Br^2O^2 = C^7H^5(C^6H^3Br^2)O^2$. *Bromo-* and *Dibromo-benzophenid.* (List and Limpricht, *loc. cit.*)—When dry benzoate of phenyl is treated with bromine as long as any hydrobromic acid is evolved, the excess of bromine distilled off, and the residue repeatedly crystallised from hot alcohol, large colourless needles are obtained, which melt below 100° C., sublime undecomposed, and are insoluble in water, but soluble in hot alcohol and ether. From the great variation in the analyses, this compound is certainly a mixture of at least two substitution-compounds: and it is probable that tribromobenzophenide is present also. The substance is dissolved and decomposed by cold alcoholic potash, into benzoic, bromophenylic, and dibromophenylic acids.

Benzoate of Chlorophenyl. Chlorobenzophenid. $C^{13}H^9ClO^2 = C^7H^5(C^6H^4Cl)O^2$. (Stenhouse, *loc. cit.*)—When dry chlorine is led for some days over fused benzoate of phenyl, a dark-yellow mixture is produced, consisting of an oily and a solid body, having a very pungent smell: this is pressed between filter-paper, and the solid residue repeatedly crystallised from ether. Large flat crystals are thus obtained, which melt at 84° C., and sublime in four-sided prisms: they have a faint smell, like that of sesquichloride of carbon. From analyses, this substance appears to be a mixture of chloro- with dichloro-benzophenide. The oily substance contains more chlorine, and probably consists in part of trichlorobenzophenide. Both compounds, when heated with alcoholic potash, yield chloride and benzoate of potassium, and on addition of hydrochloric acid, a dark, resinous body, smelling of creosote, which is probably impure chlorophenylic acid.

Benzoate of Dinitrophenyl. Dinitrobenzophenide. $C^{13}H^8N^2O^6 = C^7H^5(C^6H^3(NO^2)^2)O^2$. (Laurent and Gerhardt, *loc. cit.*)—Dinitrophenylic acid is heated with chloride of benzoyl, as long as hydrochloric acid is evolved; and the product is extracted with dilute ammonia, washed with cold alcohol, and crystallised from boiling alcohol. Yellow rhombic laminæ, insoluble in water, slightly soluble in hot alcohol, more readily in warm ether, partly soluble in potash.

Benzoate of Trinitrophenyl. Trinitrobenzophenide. $C^{13}H^7N^3O^8 = C^7H^5(C^6H^2(NO^2)^3)O^2$.—Prepared like the preceding compound, trinitrophenylic (picric) acid being substituted for dinitrophenylic acid. Shining yellow rhombic laminæ, less soluble in all menstrua than the dinitro-compound. When heated, it melts and solidifies to a crystalline mass: heated more strongly, it explodes. Dissolves in boiling potash, forming a dark-red solution, whence acids precipitate crystalline flakes.

Substitution-products of Benzoic Acid.

BROMOBENZOIC ACID. $C^7H^5BrO^2$. (Péligot [1836], Ann. Ch. Pharm. xxviii. 246; Herzog, N. Br. Arch. xxiii. 16; Müller, Compt. rend. xxx. 325.)—Benzoic acid is treated with bromine in the sunshine, the excess of bromine distilled off, the residue dissolved in sodic carbonate (when an oil containing bromine remains undissolved), and the solution precipitated by nitric acid (Herzog). Péligot makes bromine-vapour act upon benzoate of silver, by placing the salt, together with a tube containing bromine, in a closed vessel, and leaving it for twenty-four hours: from the product the bromobenzoic acid is dissolved out by ether. The solution, on evaporation, yields a brown oil, which crystallises on cooling: this is dissolved in potash, treated with animal charcoal, and reprecipitated by nitric acid. It forms a colourless crystalline mass, which melts at 100° C., and sublimes at 250°, leaving a residue of carbon. It burns with a smoky green-edged flame: is sparingly soluble in water, readily in alcohol and ether.

Bromobenzoates are generally soluble and crystallisable: the *lead-*, *copper-*, and *mercurous-salts* are less soluble. The *silver-salt*, $C^7H^4AgBrO^2$, is soluble in warm water.

CHLOROBENZOIC ACID. *Chloromichmylic acid.* $C^7H^5ClO^2$. (Herzog, 1840, N. Br. Arch. xxiii. 15; Scharling, Ann. Ch. Pharm. xli. 49; xlii. 268; Stenhouse, *ibid.* lv. 1; Field, *ibid.* lxv. 55; Limpricht and v. Uslar, *ibid.* cii. 259; Chiozza, Ann. Ch. Phys. [3] xxxvi. 102).—When dry benzoic acid is acted on by chlorine, a moist viscid reddish mass is formed, which appears to contain a mixture of mono-, bi-, and trichlorobenzoic acids; these acids (which Stenhouse also obtained by treating benzoic acid with chloride of lime and hydrochloric acid), cannot be separated from each other. Limpricht and Uslar obtained pure chlorobenzoic acid from chloride of chlorobenzoyl. According to them, the acid obtained by Chiozza, by the action of perchloride of phosphorus on salicylic acid, is not identical, but isomeric, with chlorobenzoic acid: we shall describe it separately as *parachlorobenzoic acid.* There is no doubt that the chloromichmylic acid obtained by Scharling by distilling urine with nitric acid, is identical with chlorobenzoic acid.

Limpricht and Uslar boil chloride of chlorobenzoyl (obtained by the action of perchloride of phosphorus on chlorosulphobenzoic acid) with potash, and saturate the solution with hydrochloric acid: the precipitated chlorobenzoic acid is purified by recombination with a base and reprecipitation by an acid. It forms colourless, concentrically-grouped prisms, which melt at about 140° C., but sublime at a lower temperature in small needles. It dissolves sparingly in cold water, readily in hot water, alcohol, or ether. Fuming nitric acid converts it into nitrochlorobenzoic acid. The *chlorobenzoates* are generally soluble. The solution of the *ammonium-salt* gives off ammonia abundantly when evaporated, so that the residue is nearly pure chlorobenzoic acid. The acid which Field obtained by boiling benzoic acid with potassic chlorate and hydrochloric acid, melts with difficulty, and blackens when heated. The *barium-* and *calcium-salts* crystallise with 1½ aq., which they lose at 100° C. The *lead-salt* is a white precipitate, which melts and turns yellow at 110°. The *potassium-* and *sodium-salts* are uncrystallisable. The *silver-salt*, $C^7H^4AgClO^2$, is a white precipitate, consisting of microscopic needles. *Chlorobenzoic ether* (chlorobenzoate of ethyl), $C^9H^9ClO^2 = C^7H^4(C^2H^5)ClO^2$, is obtained by treating the acid with alcohol and sulphuric acid, or chloride of chlorobenzoyl with alcohol, and precipitating the product with water. It is a liquid smelling like benzoate of ethyl, and boiling at 245° C. It dissolves in nitrosulphuric acid, and water precipitates from the solution an oil which gradually solidifies into crystals, probably of *nitrochlorobenzoic ether.*

Parachlorobenzoic Acid, $C^7H^5ClO^2$ (Chiozza, *loc. cit.*)—Salicylic acid is distilled with perchloride of phosphorus, and the distillate rectified, when a heavy, strongly refracting oil passes over between 200° and 250° C., which is converted gradually by cold, immediately by hot water, into hydrochloric and parachlorobenzoic acids: the oil is probably the chloride corresponding to the acid. Parachlorobenzoic acid forms colourless shining crystals, like those of salicylic acid, from which it is distinguished by giving no violet colour with ferric salts. It melts at 130° C., and sublimes undecomposed: dissolves readily in hot water, and the saturated solution solidifies on cooling into a mass of needles. Some of its salts differ from the corresponding chlorobenzoates in the amount of water of crystallisation which they contain: thus the *barium-salt* is anhydrous, and the *calcium-salt* contains 1 aq. The *silver-salt* may be obtained in rather large crystals.

NITROBENZOIC ACID, $C^7H^5NO^4 = C^7H^4(NO^2)O^2$. (Plantamour [1839], Ann. Ch. Pharm. xxx. 349; Mulder, *ibid.* xxxiv. 297; Abel, *ibid.* lxiii. 313; Bertagnini, *ibid.* lxxix. 259; Blumenau, *ibid.* lxxxvii. 127; Gerland, *ibid.* xci. 185). Mulder's method of heating benzoic acid with fuming nitric acid, is a long process. Gerland recommends agitating 1 pt. benzoic acid and 2 pts. nitre with strong sulphuric acid, and heating the whole till it softens: the resulting nitrobenzoic acid is purified by crystallisation from boiling water. The acid is also formed by the decomposition of several organic compounds: by the oxidation of hydride of nitrobenzoyl by chromic acid (Bertagnini): by boiling cinnamic acid and other cinnamyl-compounds (Plantamour, Mulder), cumene (Abel), or dragon's blood (Blumenau), with nitric acid: by heating nitrohippuric acid with hydrochloric acid (Bertagnini). Nitrobenzoic acid forms colourless laminæ, generally grouped together. It melts at 127° C., but sublimes at 110°, and if pure, leaves no residue: the vapours excite coughing. When boiled it blackens and decomposes. It dissolves in 400 pts. water, at 10°, and in 10 pts. at 100°, forming strongly acid solutions; it melts in water below 100°, to a heavy oil: is readily soluble in alcohol and ether. Strong nitric or hydrochloric acid dissolves it without decomposition: but it is decomposed by prolonged boiling with nitric acid. It dissolves in cold sulphuric acid: on heating the solution, some nitrobenzoic acid sublimes, and near the boiling point of sulphuric acid the mixture becomes red, a peculiar compound being formed (Mulder). It is not altered by sublimation in dry chlorine. Perchloride of phosphorus attacks it when heated, yielding chlorides of nitrobenzoyl and of phosphoryl. With sulphide of ammonium it forms benzamic acid (*q. v.*) In the animal system it is converted into nitrohippuric acid, which appears in the urine.

Nitrobenzoates are generally crystallisable and soluble in water and alcohol: they explode when heated, and give off nitrobenzol. Nitrobenzoic acid is a strong acid, and decomposes the salts of many other acids. The normal *ammonium-salt* loses ammonia when heated, and yields an acid salt, which also crystallises when the solution of the normal salt is evaporated: the normal salt on prolonged fusion, yields nitrobenzamide (Field). The *barium-salt*. $C^7H^4BaNO^4$ + 2aq., forms fine crystals which lose their water at 100° C. The *calcium-salt* contains 1 aq., which it loses at 130°—180° C. The *copper-salt* is a blue powder, which separates on cooling from a hot mixture of the acid with cupric acetate: at 130° C. it loses water and some acid. The *ferric salt* is anhydrous: it is obtained as a bulky flesh-coloured powder, when a boiling solution of the acid is precipitated by ferric chloride. The normal *lead-salt* is obtained in crystals when a boiling solution of the acid is added to basic acetate of lead, until a permanent precipitate is formed: it is decomposed by washing with water, and yields basic salts.

The *manganese-salt* contains 2 aq., one of which it loses below 100°, the other at 133° C. The *potassium-* and *sodium-salts* crystallise with difficulty: when heated, they are decomposed, emitting sparks. The *silver-salt*, $C^7H^4AgNO^4$, is obtained in pearly laminæ, by crystallising from hot water the precipitate which nitrobenzoate of ammonium gives with nitrate of silver: at 120° C. it turns grey, and loses acid, at 250° it explodes in closed vessels, forming nitrobenzenel. The *zinc-salt* contains 2½ aq., which it loses at 140°: it crystallises from the filtrate which runs off from the gelatinous precipitate formed by nitrobenzoate of ammonium with sulphate of zinc: this precipitate is a basic salt.

Nitrobenzoic Ethers. Nitrobenzoate of Methyl, $C^8H^7NO^4 = C^7H^4(CH^3)(NO^2)O$ (Chancel, Compt. Chim. 1849, 179; Bertagnini, Ann. Ch. Pharm. lxxix. 269.) — Prepared in a similar manner to nitrobenzoate of ethyl, which it resembles in all its reactions. It forms small, white, nearly opaque right rhombic prisms, which melt at 70° and boil at 129° C.: are insoluble in water, slightly soluble in alcohol and ether, somewhat more in wood-spirit: have a faint aromatic smell, and a cooling taste.

Nitrobenzoate of Ethyl. $C^9H^9NO^4 = C^7H^4(C^2H^5)(NO^2)O^2$. (E. Kopp, Compt. rend. xxxiv. 615; Chancel, *loc. cit.*; Bertagnini, *loc. cit.*; List and Limpricht, Ann. Ch. Pharm. xc. 206.)—A boiling alcoholic solution of nitrobenzoic acid is saturated with hydrochloric acid: after some time water is added, and the precipitated ether is agitated with hot sodic carbonate, washed with cold water, dried between filter-paper, and crystallised from ether-alcohol. Bertagnini prepares it by crystallising a solution of chloride of nitrobenzoyl in alcohol; and List and Limpricht, by dropping benzoate of ethyl into a mixture of 1 pt. nitric and 2 pts. sulphuric acid. It forms right rhombic prisms, which melt at 42°, and boil at 298° C.: smells like strawberries, and has a fresh taste; is insoluble in water, readily soluble in alcohol and ether. Boiling potash decomposes it into alcohol and nitrobenzoic acid: with ammonia it forms nitrobenzamide and alcohol: with sulphide of ammonium, benzamate of ethyl.

Nitrobenzoate of Dibromophenyl. (*Nitrobibromobenzophenide.*) $C^{13}H^7BrNO^4 = C^7H^4(C^6H^3Br^2)(NO^2)O^2$ (List and Limpricht, *loc. cit.*)—Separates as a resin when benzoate of dibromophenyl is added to nitrosulphuric acid; the addition of water scarcely precipitates anything more. It crystallises from hot alcohol in nodules, composed of small needles: from a concentrated solution, it separates as an oil. It melts between 90° and 100° C.: is insoluble in water, sparingly soluble in hot alcohol. Alcoholic potash decomposes it into nitrobenzoic and dibromophenylic acids.

Nitrobenzoate of Dinitrophenyl. $C^{13}H^7N^3O^8 = C^7H^4[C^6H^3(NO^2)^2](NO^2)O^2$ (List and Limpricht, *loc. cit.*)—Powdered benzoate of phenyl is added to cold nitrosulphuric acid, whereupon it dissolves, and yellow crystals separate out, which are increased by the addition of water; these are washed, first with cold water, then with alcohol. It forms a white crystalline powder, which turns yellow when heated, and melts at 150° C.: on cooling, it solidifies to a yellow glass, which gradually becomes opaque. It is insoluble in cold water or alcohol, sparingly soluble in hot alcohol or in ether. Heated on platinum-foil, it burns with yellow smoky flame: heated in a tube, it explodes feebly. It is decomposed by alcoholic potash. Sulphide of ammonium dissolves it with deep-red colour: by evaporation on a water-bath, a dark-violet resinous mass is obtained partly soluble in acids.

Dinitrobenzoic Acid. $C^7H^4N^2O^6 = C^7H^4(NO^2)^2O^2$ (Cahours, Ann. Ch. Phys. [3] xxv. 30).—When fused benzoic acid is gradually added to a warm mixture of nitric and sulphuric acids, it dissolves with slight evolution of gas: the whole is then boiled (for 1 hour, Cahours;—for 6 hours, Voit), and as soon as it begins to be turbid, it is cooled and water added, which precipitates yellow flakes, which are washed with water, dried, and crystallised from boiling alcohol. Dinitrobenzoic acid is thus obtained in short shining prisms, which melt at a gentle heat, and sublime in delicate needles. It is slightly soluble in cold, more in boiling, water; readily in alcohol or ether, especially on heating. It dissolves in hot nitric acid, and crystallises on cooling. Cold sulphuric acid dissolves it unaltered, but decomposes it when heated strongly. Sulphide of ammonium and other reducing agents convert it into diamidobenzoic acid. The alkaline *dinitrobenzoates* are soluble and crystallisable: the *lead-* and *silver-salts* are slightly soluble. *Dinitrobenzoic ether* (dinitrobenzoate of ethyl), $C^9H^8N^2O^6 = C^7H^3(C^2H^5)(NO^2)^2O^2$, is obtained by saturating absolute alcohol with the acid, or heating the acid with alcohol and sulphuric acid: it forms oily drops, which solidify on cooling, and are washed with dilute ammonia, and crystallised from hot alcohol. Long delicate needles, with a slight yellow tinge: decomposed by strong potash, especially on heating, into alcohol and potassic dinitrobenzoate. Digestion with alcoholic ammonia converts it into dinitrobenzamide: sulphuretted hydrogen converts it into diamidobenzoic acid. (Voit.)

Nitrochlorobenzoic Acid. $C^7H^4NClO^4 = C^7H^4(NO^2)ClO^2$ (Limpricht and v. Uslar, Ann. Ch. Pharm. cii. 261).—When chlorobenzoic acid is dissolved in fuming nitric acid, there is no immediate precipitate, but the solution continues for several days to deposit colourless tables of nitrochlorobenzoic acid. These melt at 118° C.; are soluble in alcohol and ether; melt in warm water, dissolve on boiling, and do not separate out on cooling. The *barium-* and *silver-salts* only are known: the latter, $C^7H^3AgClNO^4 + \frac{1}{2}$ Aq (?), forms small shining laminæ, tolerably soluble in water. For *nitrochlorobenzoic ether*, see above, *chlorobenzoic ether*. F. T. C.

BENZOIC ALCOHOL. Syn. with BENZYLIC ALCOHOL (*q. v.*)

BENZOIC ANHYDRIDE. *Benzoate of Benzoyl.* $C^{14}H^{10}O^3 = (C^7H^5O)^2.O$ (Gerhardt (1852), Ann. Ch. Phys. [3] xxxvii. 299; Wunder, J. pr. Chem. lxi. 498; Heintz, Pogg. Ann. xcii. 458).—Formed by the action of chloride of benzoyl on alkaline oxalates or benzoates: also of oxychloride or perchloride of phosphorus, or chloride of sulphur on alkaline benzoates, the first stage of the reaction being the formation of chloride of benzoyl: also by the dry distillation of acetobenzoic and similar anhydrides:

$$\begin{aligned}
C^7H^5KO^2 + C^7H^5OCl &= C^{14}H^{10}O^3 + KCl.\\
C^2O^4K^2 + 2C^7H^5OCl &= C^{14}H^{10}O^3 + 2KCl + CO + CO^2.\\
2C^7H^5KO^2 + PCl^5 &= C^{14}H^{10}O^3 + 2KCl + POCl^3\\
8C^7H^5KO^2 + 3SCl^2 &= 4C^{14}H^{10}O^3 + 6KCl + SO^4K^2 + S^2.
\end{aligned}$$

Equal parts of dry benzoate of sodium and chloride of benzoyl are heated to 130° C. on a sand-bath, whereby a clear liquid is produced, from which chloride of sodium separates out: the cooled mass is washed with cold water containing sodic carbonate, and crystallised from ether or warm alcohol. The previous preparation of chloride of benzoyl is avoided by employing perchloride or oxychloride of phosphorus (5 pts. oxychloride to 1 pt. benzoate). Oxalate of potassium is heated with an equal weight of chloride of benzoyl, with constant agitation, till the smell of chloride of benzoyl has disappeared; and the cooled mass is suspended in cold water, washed with water containing ammonia, and crystallised from alcohol (Gerhardt). In preparing large quantities, it is better to purify the product by distillation than by crystallisation from alcohol.

Benzoic anhydride forms oblique rhombic prisms, sometimes smelling of bitter-almond oil or benzoic ether: it melts at 42° C., and distils undecomposed at about 310°. It is insoluble in cold water, soluble in alcohol and ether: the solution when fresh has no acid reaction. It melts in boiling water, and remains fluid for a long time, even when agitated, and is slowly converted into benzoic acid, which dissolves. Caustic alkalis convert it much more rapidly into benzoic acid. Aqueous ammonia does not attack it in the cold, but dissolves it on heating, forming benzamide and benzoate of ammonium: the same reaction takes place when it is heated in dry ammonia:

$$C^{14}H^{10}O^3 + 2NH^3 = C^7H^7NO + C^7H^5(NH^4)O^2.$$

Aniline acts similarly, forming phenylbenzamide. (Gerhardt.)

One atom of benzoyl in benzoic anhydride is capable of being replaced by other acid radicles, forming a series of anhydrides containing benzoyl. They are obtained by the action of chloride of benzoyl on the alkaline salts of other monobasic acids, or, conversely, by treating alkaline benzoates with the chlorides of monobasic acid radicles. They are generally decomposed by heat into two simple anhydrides: by water, and more rapidly by alkalis, into two acids.

Benzoacetic Anhydride. See Acetic Anhydride.

Benzoangelic Anhydride. $C^{12}H^{12}O^3 = C^5H^7O.C^7H^5O.O$ (Chiozza, Ann. Ch. Phys. [3] xxxix. 210).—Produced by gently heating chloride of benzoyl with angelate of potassium. It is a limpid oil, heavier than water, somewhat less fluid than angelic anhydride, and quite neutral to test-paper. It smells like angelic anhydride, but emits much more acrid vapours when heated. In a mixture of ice and salt, it thickens slightly, without crystallising.

Benzocinnamic Anhydride. *Benzoate of Cinnamyl.* $C^{16}H^{12}O^3 = C^7H^5O.C^9H^7O.O$ (Gerhardt, *loc. cit.*)—Obtained by heating 7 pts. chloride of benzoyl with 10 pts. dry cinnamate of sodium, and purifying the product as in the case of benzoic anhydride. It is a thick oil, colourless and odourless, which gradually becomes acid when exposed to moist air. Specific gravity 1·184 at 23° C. Is decomposed by distillation, yielding a yellow oil, smelling of cinnamol, which gradually deposits crystals of benzoic anhydride, and an acid substance soluble in sodic carbonate.

Benzocuminic Anhydride. *Benzoate of Cumyl.* $C^{17}H^{16}O^3 = C^7H^5O.C^{10}H^{11}O.O$ (Gerhardt, *loc. cit.*)—Obtained like the preceding, cuminate being substituted for cinnamate of potassium. Resembles the preceding in appearance and behaviour in moist air. Specific gravity 1·115 at 23° C. Is decomposed by distillation: when heated in a closed vessel, it appears to volatilise without decomposition. Aqueous ammonia converts it into cuminamide, and benzamide, or benzoate of ammonium.

Benzomyristic Anhydride. *Benzoate of Myristyl.* $C^{21}H^{32}O^3 = C^7H^5O.C^{14}H^{27}O.O$ (Chiozza and Malerba, 1855).—Obtained by heating chloride of benzoyl with myristate of potassium. Crystallises from boiling ether, in which it is slightly soluble, in shining laminæ: melts at 38°, and solidifies at 36° C.

Benzoœnanthylic Anhydride. *Benzoate of Œnanthyl.* $C^{14}H^{18}O^3 = C^7H^5O.C^7H^{13}O.O$ (Chiozza and Malerba, Ann. Ch. Pharm. xci. 102).—Obtained by the action of chloride of benzoyl on œnanthylate of potassium. Colourless oil, of specific gravity 1·043 at 11° C.; smells like œnanthylic anhydride: exposed to the air, it yields crystals of benzoic acid.

Benzopelargonic Anhydride. *Benzoate of Pelargonyl.* $C^{16}H^{22}O^3 = C^7H^5O.C^9H^{17}O.O$ (Chiozza, Ann. Ch. Phys. [3] xxxix. 310).—Prepared like the foregoing compounds. A heavy oil, resembling pelargonic anhydride. A little below 0° C. it solidifies to the consistency of butter: is decomposed by heat into benzoic and pelargonic anhydrides.

Benzostearic Anhydride. *Benzoate of Stearyl.* $C^{25}H^{40}O^3 = C^7H^5O.C^{18}H^{35}O.O$ (Chiozza and Malerba, *loc. cit.*)—Prepared by heating chloride of benzoyl and potassic stearate in an oil-bath. Shining scales, which melt at 70° C.

Benzovaleric Anhydride. *Benzoate of Valeryl.* $C^{12}H^{14}O^3 = C^7H^5O.C^5H^9O.O.$ (Chiozza, Ann. Ch. Pharm. lxxxiv. 106).—Chloride of benzoyl acts violently on valerate of potassium: the product is a heavy, neutral, strongly refracting oil, smelling like valeric anhydride. At about 260° C. it is decomposed into benzoic and valeric anhydrides.

Substitution-products of Benzoic Anhydride.

Benzonitrobenzoic Anhydride. *Benzoate of Nitrobenzoyl.* $C^{14}H^9NO^5 = C^7H^5O.C^7H^4(NO^2)O.O.$—3 pts. chloride of benzoyl are heated with 7 pts. dry nitrobenzoate of sodium, and the product is purified as in the case of benzoic anhydride. Crystalline: more stable than the following compound. (Gerhardt, *loc. cit.*)

Nitrobenzoic Anhydride. *Nitrobenzoate of Nitrobenzoyl.* $C^{14}H^8N^2O^7 = [C^7H^4(NO^2)O]^2.O.$ — 8 pts. nitrobenzoate of sodium are heated to 150° C. with 1 pt. oxychloride of phosphorus, till the smell of chloride of nitrobenzoyl has disappeared. On treating the product with cold water, a white mass is obtained, almost insoluble in alcohol and ether, less fusible than nitrobenzoic acid, into which it is quickly converted by washing with water. (Gerhardt, *loc. cit.*) F. T. C.

BENZOIC ETHERS. See p. 552.

BENZOICIN. (Berthelot, Ann. Ch. Phys. [3] xli. 290.)—The name given by Berthelot to the artificial fats obtained by the action of benzoic acid on glycerin. Glycerin being a triatomic alcohol, $C^3H^5.H^3.O^3$, contains 3 at. H replaceable by other radicles; and Berthelot has succeeded in obtaining the compounds in which 1 and 3 H respectively are replaced by benzoyl.

Monobenzoicin. *Benzoate of Glycyl.* $C^{10}H^{12}O^4 = C^3H^5.C^7H^5O.H^2.O^3$. — Obtained by heating benzoic acid with glycerin in a sealed tube, for forty-four hours, to 120°—150° C. if the acid be in excess, to 200° C. if the glycerin be in excess; at a higher temperature a shorter time suffices. The product is purified by washing with potassic carbonate. It is a colourless, neutral, very viscid oil, with a bitter aromatic taste, and a slight balsamic smell; specific gravity 1·228 at 16°·5 C. At 40° it is a transparent nearly solid mass, that can be drawn out into threads; it boils at 320°, but decomposes at the same time, yielding acrolein and benzoic acid. It is insoluble in water, scarcely soluble in bisulphide of carbon, readily in alcohol, ether and benzene. It oxidises very slightly in the air. Heated with potash it forms potassic benzoate; with ammonia, benzamide. Alcohol and hydrochloric acid convert it in the cold into glycerin and benzoate of ethyl; the same decomposition is effected when its alcoholic solution is heated to 100° C. for forty-eight hours.

Tribenzoicin. *Tribenzoate of Glycyl.* $C^{24}H^{20}O^6 = C^3H^5.(C^7H^5O)^3.O^3$. — Obtained by heating monobenzoicin for four hours to 250° C., with 10 or 15 pts. benzoic acid; the product is washed with sodic carbonate, and repeatedly crystallised from ether. Large white needles, unctuous to the touch, and fusing pretty readily. Alcohol and hydrochloric acid decompose it like monobenzoicin. F. T. C.

BENZOIN. *Bitter-almond-oil-camphor.* $C^{14}H^{12}O^2$. (Liebig and Wöhler, Ann. Ch. Pharm. iii. 276; Robiquet and Boutron-Charlard, Ann. Ch. Phys. [2] xliv. 352; Laurent, *ibid.* lix. 402; lxvi. 193; Zinin, Ann. Ch. Pharm. xxxiv. 186.) —First described by Stange, 1823 (Repert. Pharm. xiv. 329); first correctly examined by Liebig and Wöhler in 1832. It is frequently contained in crude bitter-almond oil, and is obtained as a by-product when the oil is purified by lime and ferrous chloride; the residue is treated with dilute hydrochloric acid, and dissolved in alcohol. Pure bitter-almond oil (hydride of benzoyl) is converted into benzoin by cyanide of potassium. To prepare benzoin from crude bitter-almond oil, the oil is mixed with its own volume of a saturated alcoholic solution of potash; after a few minutes, the whole solidifies to a mass of crystals, which are purified by recrystallisation from alcohol. As the amount of benzoin in different specimens of the crude oil varies considerably, according to their age and to the amount of prussic acid which they contain, it is always advisable to test a small portion first with alcoholic potash; if it does not speedily solidify, the crude oil had better be first freed from prussic acid, and then treated by the ensuing method. Pure oil of bitter-almonds is readily converted into benzoin by the addition of a dilute alcoholic solution of cyanide of potassium, or of alcoholic potash to which a few drops of hydrocyanic acid have been added: this reaction is difficult to account for.

Benzoin is isomeric with benzoate of benzyl, and polymeric with hydride of benzoyl. It forms shining, transparent, colourless prisms, without smell or taste; melts at 120° C., and crystallises on cooling; if further heated, it distils undecomposed. It is insoluble in cold, slightly soluble in hot water, whence it crystallises on cooling; more soluble in hot than in cold alcohol. It burns readily in the air, with a bright smoky flame. Its vapour passed through a red-hot tube is reconverted into hydride of benzoyl. When heated in *chlorine*, it yields benzil and hydrochloric acid. *Bromine* attacks it, evolving hydrobromic acid, and forming (probably) benzil. Strong *nitric acid* converts it into benzil. *Sulphuric acid* dissolves it, forming a violet solution, which blackens when heated. Boiling *potash* does not attack it; fused with solid potash, it evolves hydrogen and yields benzoic acid: $C^{14}H^{12}O^2 + 2KHO = 2C^7H^5KO^2 + H^4$; boiled with alcoholic potash, it is coloured violet, and yields benzilic acid, with evolution of hydrogen: $C^{14}H^{12}O^2 + KHO = C^{14}H^{11}KO^3 + H^2$. With *ammonia*, it yields, among other products, benzoinam and benzoinamide. *Perchloride of phosphorus* attacks it violently, yielding chloride of phosphoryl, and other products difficult to obtain pure. (Cahours.)

Benzoin combines with chlorides of acid radicles, yielding compounds representing benzoin in which 1 H is replaced by an acid radicle. Zinin (Ann. Ch. Pharm. civ. 116) has obtained the following: —

Acetyl-benzoin. $C^{16}H^{14}O^3 = C^{14}H^{11}(C^2H^3O)O^2$.—4 pts. of benzoin dissolve in 3 pts. chloride of acetyl at 40° – 50° C., with evolution of hydrochloric acid; when the solution is complete, the whole is heated to 100° as long as vapours are evolved: on cooling, the product slowly solidifies into crystals, which are recrystallised from alcohol or ether. It crystallises from the ethereal solution in large rhombic prisms and six-sided tables; from the alcoholic solution in thin shining crystals. It is insoluble in water, melts below 100°, and does not always crystallise on cooling. Sulphuric or hydrochloric acid, or aqueous potash does not act upon it; with alcoholic potash it yields acetate and benzoate of potassium. Strong nitric acid converts it into a mixture of two nitro-products in the form of a viscid colourless mass, insoluble in water, soluble in alcohol and ether; the solution deposits crystals.

Benzoyl-benzoin. $C^{21}H^{16}O^3 = C^{14}H^{11}(C^7H^5O)O^2$.—Chloride of benzoyl does not act upon benzoin in the cold, but at about 70° C. the benzoin dissolves and hydrochloric acid is evolved; the whole is then heated to nearly the boiling point of chloride of benzoyl (196° C.), when a yellowish oily liquid is obtained, which solidifies into crystals on cooling. This product is purified by being poured while liquid into cold 75 per cent. alcohol, when benzoyl-benzoin separates as a crystalline powder, which is washed on a filter with cold alcohol. It is insoluble in water, sparingly soluble in cold alcohol, soluble in 6 pts. boiling 80 per cent. alcohol, whence it crystallises in thin colourless needles; readily soluble in ether, and crystallises by spontaneous evaporation in large shining rhombic prisms; soluble in chloride of benzoyl, and may be heated with it to 150° C. without alteration. Melts at 125° C., and crystallises very slowly on cooling. Chlorine does not attack it, neither does hydrochloric or dilute sulphuric acid; strong sulphuric acid decomposes it. Aqueous potash does not attack it; alcoholic potash dissolves it with a violet colour, and, on boiling, converts it into benzoate and benzilate of potassium.

Nitrobenzoyl-benzoin. $C^{21}H^{15}NO^5 = C^{14}H^{11}(C^7H^4(NO^2)O)O^2$.—Strong nitric acid (specific gravity 1·51) dissolves benzoyl-benzoin, which, if too little acid be employed, crystallises out again unaltered; but if at least 1½ pt. acid be taken, and the yellowish solution poured into cold water, a resinous substance separates, which is a mixture of two nitro-products. Ether dissolves one of these, and abandons it on evaporation as a thick oil; the other, which is nitrobenzoyl-benzoin, remains undissolved as a crystalline powder, which is recrystallised from boiling alcohol. White shining scales, composed of rhombic tables, aggregated into scalariform groups, insoluble in water. Melts at 137° C., and solidifies at 110° to an amorphous mass, which very slowly becomes crystalline. Strong nitric acid dissolves it unaltered and in large quantities, especially if gently heated; on boiling the solution a new body is formed, soluble in ether, which separates as a powder on cooling. F. T. C.

BENZOINAM. $C^{28}H^{24}N^2O$. (Laurent, Compt. Chim. [1845] 37).—Formed by the action of alcoholic ammonia on benzoin:

$$2C^{14}H^{12}O^2 + 2NH^3 = C^{28}H^{24}N^2O + 3H^2O.$$

Obtained, together with benzoinamide and other products, when a mixture of alcoholic ammonia and benzoin is left for some months in a closed vessel. Forms white microscopic inodorous needles, insoluble in water; slightly soluble in hot ether or rock-oil, whence it crystallises on cooling in very bulky needles, readily soluble in hot alcohol containing hydrochloric acid, whence it is partially precipitated by water, entirely by ammonia. Melts when heated, and partly solidifies on cooling. Potash does not attack it; strong sulphuric acid dissolves it with red colour, and water precipitates orange flakes. F. T. C.

BENZOINAMIDE. $C^{42}H^{36}N^4$. (Laurent [1837], Ann. Ch. Phys. [2] lxvi. 189.)—Formed by the action of aqueous ammonia on benzoin:

$$3C^{14}H^{12}O^2 + 4NH^3 = C^{42}H^{36}N^4 + 6H^2O.$$

Obtained as a white powder when benzoin and aqueous ammonia are left for eight weeks in a closed vessel; it is boiled in alcohol to remove excess of benzoin, and crystallised from boiling ether. A white, tasteless, odourless powder, consisting of fine microscopic needles; insoluble in water, very sparingly soluble in alcohol or ether; melts when heated, and solidifies to a fibrous mass; distils without decomposition.

F. T. C.

BENZOIN-GUM. The commercial name of a resin which flows from the bark of *Styrax benzoin*, a tree growing in Sumatra, Borneo, Java, and Siam. It comes into the market in different forms. The Siamese gum occurs in irregular flat fragments, about an inch long, which are reddish-yellow on the outside, white and shining in the inside. The common or Calcutta-gum forms larger irregular lumps, brittle, of a dirty reddish-grey or brown colour, with many light coloured spots, and often contains fragments of wood and bark. The Siamese almond-gum appears to be a mixture of both these kinds. The commercial gum has a pleasant smell, especially when heated, and a sweetish, sharp, balsamic taste. It melts when heated, evolves vapours of benzoic acid, and burns with a smoky flame. Specific gravity 1·063—1·092. Alcohol dissolves it completely, excepting impurities; ether partially; boiling water dissolves out benzoic acid.

According to Unverdorben (Pogg. Ann. viii. 397), Stolze (Berl. Jahrb. Pharm. xxvi. 75), Van der Vliet (Ann. Ch. Pharm. xxxiv. 177), and E. Kopp (Compt. rend. xix. 1269), gum-benzoin is a mixture of three resins, which may be distinguished as α, β, and γ, together with benzoic acid, and a small quantity of a volatile oil. The whole of the benzoic acid cannot be driven off by heat. According to Kolbe and Lautemann (Ann. Ch. Pharm. cxv. 113), some varieties of gum-benzoin, especially the almond gum of Sumatra, contain not benzoic acid, but an acid isomeric with toluylic acid, $C^8H^8O^2$, which melts to a clear liquid under hot water, crystallises in forms quite different from that of benzoic acid, and yields hydride of benzoyl when treated with oxidising agents.

Unverdorben separates the resins in the following manner:—The powdered gum is extracted with boiling sodic carbonate, which dissolves out all the benzoic acid and the resin γ; the alkaline solution is precipitated by hydrochloric acid, and the precipitate treated with boiling water, which dissolves the acid only, leaving the resin γ insoluble. The portion insoluble in sodic carbonate is washed, dried, and digested with ether, which dissolves the resin α, and leaves the resin β undissolved. According to Kopp, the ethereal solution of α gradually deposits a small quantity of a fourth resin, δ, of a reddish-brown colour. Analyses of two specimens of gum gave the following results (Kopp):

	I.	II.
Benzoic acid	14·0	14·5
Resin α	52·0	48·0
Resin β	25·0	28·0
Resin γ	3·0	3·5
Resin δ	0·8	0·5
Impurities	5·2	5·5

Kopp further states that the white spots in the gum are composed only of resin α, and contain 8—12 per cent. benzoic acid; while the brown portions consist of resins β and γ, and contain as much as 15 per cent. acid (18 per cent. according to Unverdorben).

The resin α is readily soluble in ether and alcohol, insoluble in naphtha; soluble in potash, and not reprecipitated by excess; insoluble in ammonia. Salts of the earthy or heavy metals give, in its alkaline solution, precipitates which are insoluble in ether. According to Van der Vliet it is a mixture of resins β and γ, for it is decomposed into these two resins by prolonged ebullition with sodic carbonate. Resin β is a brownish mass, soluble in alcohol, insoluble in ether and volatile oils; soluble in potash, and reprecipitated by excess; insoluble in ammonia. Resin γ is dark-brown, soluble in alcohol, slightly in ether and volatile oils, insoluble in naphtha. Potassic carbonate slowly dissolves it, and the solution is precipitated by sal-ammoniac. Its alcoholic solution precipitates acetate of lead, but not acetate of copper. Resins α and β, when precipitated by acids from their alkaline solutions, are converted into γ by exposure to the air.

The following are the results of the analysis of these resins, and the (unreliable) formulæ, which Van der Vliet has deduced therefrom:

		V. d. V.		Mulder.	
Resin α	Carbon	72·9	71·8	73·1	$C^{35}H^{42}O^7 = \beta + \gamma$
	Hydrogen	7·2	7·1	7·3	
Resin β	Carbon	71·1	71·0	71·7	$C^{20}H^{21}O^{4\frac{1}{2}}$
	Hydrogen	6·2	6·3	6·9	
Resin γ	Carbon	73·2	73·2	73·2	$C^{15}H^{21}O^{2\frac{1}{2}}$
	Hydrogen	8·6	8·4	8·6	

By the dry distillation of the resins of gum-benzoin, completely freed from benzoic acid, Kopp obtained a solid substance, which he regards as the odorous principle of the gum, and a rose-red distillate, which gradually becomes darker, and contains crystals of benzoic acid; the fluid portion appears to be hydrate of phenyl. By the same process, Cahours obtained an oil, which Deville (Ann. Ch. Phys. [3] iii. 192) regards as benzoate of ethyl. When they are distilled to dryness, with excess of nitric acid, nitrous fumes are abundantly evolved, and a distillate is obtained, containing hydride of benzoyl, benzoic acid, and hydrocyanic acid; boiling water extracts picric acid from the residue, and leaves a yellow powder, *benzoeretic acid* (*q. v.*) Sulphuric acid dissolves the resins to a common solution, whence the addition of water separates them almost completely as a violet precipitate; the acid liquid, decanted and neutralised with lime yields a soluble calcium-salt. F. T. C.

BENZOLACTIC ACID. *Benzomilchsaure.* $C^{10}H^{10}O^4 = C^3H^4O.C^7H^5O.H.O^2$ (Socoloff and Strecker, Ann. Ch. Pharm. lxxx. 46. Strecker *ibid.* xci. 359).—This acid is analogous to benzoglycollic acid, representing lactic acid in which 1 at. of of basic hydrogen is replaced by benzoyl, just as benzoglycollic acid represents glycollic acid in which 1 at. of basic hydrogen is similarly replaced.

It is prepared by heating 10 pts. of syrupy lactic acid with 14 pts. of benzoic acid in an oil-bath to 150° C., finally raising the temperature to 200°, and keeping it there for some hours. Water distils over, and some benzoic acid sublimes. The residue in the retort solidifies on cooling to a crytsalline mass of benzoic and benzolactic acids. These are separated by partial saturation with sodic carbonate, which takes up the benzolactic acid first; the solution is filtered from the benzoic acid, and freed from the small quantity of benzoic acid which it contains by agitation with ether; on the addition of hydrochloric acid, benzolactic acid separates in crystals, which are purified by recrystallisation from boiling water, or from ether-alcohol.

It forms colourless tabular or spear-shaped crystals, unctuous to the touch: melts at 112° C., and solidifies very slowly on cooling to a crystalline mass; sublimes undecomposed when heated considerably above 120°. It dissolves in 400 pts. cold, and in much less boiling water: when boiled with not enough water to dissolve it, the excess of acid melts and the solution becomes milky on cooling, and clarifies very slowly, with separation of crystals. It dissolves readily in alcohol or ether, the latter removing it entirely from its aqueous solution; after drying in the air, it does not lose any water when heated to melting. By prolonged boiling in water, it is decomposed with benzoic and lactic acids: the decomposition is accelerated by the addition of a dilute acid.

The *benzolactates* are mostly crystalline, soluble in water, and closely resemble the benzoates, from which, however, they are distinguished by their neutral solution not being precipitated by normal acetate of lead. The *barium-salt*, $C^{10}H^9BaO^4 + 3\,aq.$, crystallises in thin, shining, six-sided laminæ, which lose their water at 100° C. The *silver-salt* $C^{10}H^9AgO^4$, is a flocculent precipitate, soluble in boiling water, whence it crystallises in fine needles. The *sodium-salt* crystallises in colourless needles from boiling alcohol. F. T. C.

BENZOLIC ALCOHOL. See BENZYLENE.

BENZOLINE. Syn. with AMARINE (*q.v.*)

BENZOLONE. $C^{21}H^{15}O^2$ (?) (Rochleder, Ann. Ch. Pharm. xli. 94).—Formed together with benzostilbin, when hydrobenzamide is heated with solid potash. The mixture must be heated till it blackens; the product is powdered, extracted with water, washed with cold hydrated alcohol, and the residue dissolved in strong sulphuric acid. The blood-red solution thus formed becomes greenish-yellow on addition of dilute alcohol, and deposits small crystals of benzolone: on addition of water, it separates in the uncrystalline state. It is insoluble in water or alcohol; melts at 248° C., and sublimes almost without decomposition, when more strongly heated. Strong nitric acid dissolves it with a reddish-yellow colour, and it is reprecipitated by water; fuming nitric acid decomposes it, forming a yellowish resin with evolution of nitrous fumes. It is not attacked by aqueous potash. Rochleder's analyses give a mean composition of C 83·5, H 5·2. F. T. C.

BENZOMERCURAMIDE. See BENZAMIDE.

BENZOMYRISTIC ANHYDRIDE. See BENZOIC ANHYDRIDE.

BENZONE. *Benzophenone. Phenyl-benzoyl.* $C^{13}H^{10}O = C^6H^5.C^7H^5O$ (Péligot, Ann. Ch. Phys. [2] lvi. 59. Chancel, Compt. rend. xviii. 83.; Ann. Ch. Pharm. lxxx. 25).—The acetone of benzoic acid; it is formed by the dry distillation of benzoate of calcium:

$$2C^7H^5CaO^2 = C^{13}H^{10}O + CO^3Ca^2.$$

Dry benzoate of calcium is mixed with $\frac{1}{10}$ of its weight of quick lime, and distilled in an iron mercury bottle, fitted with a bent gun-barrel. The red liquid which passes over (which Péligot called benzone), contains,—besides benzone,—benzene, hydride of benzoyl, and two solid hydrocarbons isomeric with naphthalin. On distilling it in a tubulated retort, benzene first passes over; and the temperature rises rapidly: the portion which comes over at 315°—325° C. is collected apart, and consists of nearly pure benzone, which solidifies on cooling, and may be obtained quite pure by recrystallisation from ether-alcohol. 1 kilogr. benzoate of calcium yields about 250 grms. benzone.

Benzone forms colourless, transparent crystals, often of considerable size, belonging to the trimetric system. It melts at 46° C. to a thick oil which does not solidify unless it be agitated; boils at 315° and distils undecomposed: its vapour is very inflammable, and burns with a bright flame. It has a pleasant smell, somewhat like that of benzoic ether. It is very soluble in ether, less so in alcohol, not at all in water; strong nitric or sulphuric acid dissolves it abundantly, and water reprecipitates it unchanged. When heated with soda-lime to about 260° C. it is decomposed, yielding sodic benzoate and benzene, but not a trace of hydrogen:

$$C^6H^5.C^7H^5O + NaHO = C^6H^5.H + C^7H^5O.Na.O.$$

Dinitrobenzone. Dintrobenzophenone. $C^{13}H^8N^2O^5 = C^{13}H^8(NO^2)^2O$.—Warm fuming nitric acid converts benzone into a thick oil, which solidifies very slowly; ether dissolves it and deposits it speedily in the form of a yellowish crystalline powder, which is dinitrobenzone. Reducing agents convert it into diphenyl-carbamide (flavine):

$$C^{13}H^{8}N^{2}O^{5} + 6H^{2}S = \underset{\text{flavine.}}{C^{13}H^{12}N^{2}O} + 4H^{2}O + S^{6}.$$

Of the two hydrocarbons, isomeric with naphthalin, mentioned above, one crystallises in large needles, fusible at 92° C., the other, much less soluble in alcohol and ether, forms small nodules fusible at 65°. The former is readily obtained by dissolving in strong sulphuric acid the liquid obtained by the dry distillation of calcic benzoate; it immediately solidifies on the surface, and is removed, washed, dried by filter paper, and crystallised from hot alcohol. The latter is best prepared by the dry distillation of potassic benzoate with potash-lime: it then passes over alone, in solution in benzol, which is distilled off in a water-bath, and the residue crystallised from alcohol. It is also formed together with benzol, when ammonic benzoate is passed over heated baryta. F. T. C.

BENZONITRILE. *Cyanide of Phenyl.* $C^{7}H^{5}N = C^{6}H^{5}.CN$ (Fehling (1844), Ann. Ch. Pharm. xlix. 91. Limpricht and v. Uslar, *ibid.* lxxxviii. 133).—Benzonitrile is obtained by various methods:—1. By the dry distillation of benzoate of ammonium, or by heating benzamide, either alone or with caustic lime, or baryta, phosphoric anhydride, or perchloride of phosphorus: the reaction in all these cases consists in the abstraction of the elements of water:

$$\underset{\text{Benz. amm.}}{C^{7}H^{5}O.NH^{4}.O} - 2H^{2}O = C^{7}H^{5}N.$$

$$\underset{\text{Benzamide.}}{N.C^{7}H^{5}O.H^{2}} - H^{2}O = C^{7}H^{5}N.$$

2. By heating hippuric acid, either alone (Limpricht), or with chloride of zinc (Gössmann). 3. By the action of chloride of benzoyl or benzoic anhydride on benzamide, or by heating benzamide with potassium (see BENZAMIDE). 4. By the action of chloride of benzoyl on oxamide (Chiozza):

$$C^{7}H^{5}O.Cl + N^{2}.C^{2}O^{2}.H^{4} = C^{7}H^{5}N + CNH + HCl + CO^{2} + H^{2}O.$$

or on sulphocyanate or cyanate of potassium (Schiff, Ann. Ch. Pharm. xcix. 117, ci. 93):

$$2C^{7}H^{5}O.Cl + 2CNSK = 2C^{7}H^{5}N + 2KCl + CO^{2} + CS^{2}.$$

5. By heating benzoic anhydride with cyanate or sulphocyanate of potassium (Schiff):

$$C^{14}H^{10}O^{3} + 2CNOK = 2C^{7}H^{5}N + CO^{3}K^{2} + CO^{2}.$$

6. By the action of mercuric oxide on thiobenzamide (*q. v.* under BENZAMIDE).

Preparation.—1. When dry benzoate of ammonium is heated in a retort, ammonia escapes, benzoic acid sublimes, and water passes over with a few oily drops of benzonitrile; as most of the benzonitrile remains in the fused residue in the retort, this is covered with water (to which a little ammonia is added), again distilled to dryness, and the operation repeated as long as any oil passes over with the water: 12 oz. benzoic acid yield in 5 days, 6 oz. impure benzonitrile. This product is washed with dilute hydrochloric acid, then with water, dried over chloride of calcium, and rectified (Fehling). According to Laurent and Chancel (Compt. chim. 1849, 117), benzonitrile is more easily prepared by passing the vapour of ammonic benzoate over heated baryta.—2. One pt. dry hippuric acid is mixed in a warm mortar with an equal bulk of quartz-sand and 2 pts. chloride of zinc dried as completely as possible, and the mixture is heated in a dry retort to 300°—350°C.: benzontrile then distils over, carbonic anhydride escapes, and a little carbon is deposited; 100 grms. hippuric acid (the utmost precautions being taken to exclude moisture) yielded 33—40 grms. benzonitrile; calculation requires 57 grm. (Gössmann, Ann. Ch. Pharm. c. 72).—3. According to Buckton and Hofmann, benzonitrile is best prepared by distilling benzamide with phosphoric anhydride.

Benzonitrile is a clear, colourless, strongly refracting oil, smelling like bitter-almond oil, and having a burning taste; specific gravity 1·0230 at 0°, 1·0084 at 16·8° C. Kopp). At higher temperatures it is less dense than water, for it sinks in cold water, but rises to the surface when heated. It boils at 190·6° C. with the barometer at 733·4 mm. (Kopp), and distils undecomposed: its vapour density is 3·7 (expt.); its coefficient of refraction is 1·503 (Reusch). It dissolves in 100 pts. boiling water, and separates out again on cooling; it mixes with alcohol and ether in all proportions. Sulphur dissolves in it with the aid of heat, and crystallises out on cooling.

Benzonitrile burns with a bright smoky flame. Cold *aqueous potash* does not attack it, but on boiling, ammonia is evolved and potassic benzoate formed; a similar decomposition is effected by dilute acids. Strong *sulphuric acid* dissolves it, and on heating, sulphobenzoic and disulphobenzolic acids, and acid sulphate of ammonium are formed, and carbonic anhydride is evolved: (Buckton and Hofmann):

$$2C^7H^5N + 5SO^4H^2 + H^2O = C^7H^6SO^5 + C^6H^6S^2O^6 + 2(NH^4.H.SO^4.) + CO^2.$$

With fuming *nitric acid* it forms a substitution-product (see below); when heated with potassium in a sealed tube, it assumes a carmine colour, and at 240° C. yields a sublimate of fine needles; water extracts cyanide of potassium from the product, and the residue yields on distillation, a green oil smelling of creosote, in which crystals again form (Bingley, Chem. Gaz. 1854, 329). With *sulphide of ammonium*, it forms *thiobenzamide* (*q. v.* under BENZAMIDE).

Substitution-products of Benzonitrile.

Chlorobenzonitrile or *Cyanide of Chlorophenyl*, C^7H^4ClN, has not been obtained by the action of chlorine on benzonitrile; but it is the principal product when sulphobenzamide or sulphobenzamic acid is distilled with perchloride of phosphorus. The distillate is mixed with potash, and rectified, when chlorobenzonitrile passes over with aqueous vapour, and collects in the receiver, forming crystals which are obtained in large colourless prisms by recrystallisation from alcohol or ether. It smells like bitter-almond oil, is insoluble in water, but readily soluble in alcohol or ether; melts below 40°, and solidifies at 36° C., volatilises slightly at the ordinary temperature, more rapidly at a gentle heat. Prolonged boiling with dilute nitric acid converts it into chlorobenzoic acid; heated to 100° with ammonia in a sealed tube, it yields chlorobenzamide. (Limpricht.)

Nitrobenzonitrile or *Cyanide of Nitrophenyl.* $C^7H^4N^2O^2 = C^6H^4(NO^2)N$.—Precipitated as a white solid body when benzonitrile is heated gently with fuming nitric acid and water added to the solution; it is tolerably soluble in hot water, and separates on cooling in small white silky needles, soluble in acids, and reprecipitated by water. When heated, it evolves irritating vapours, and leaves a residue of carbon. When boiled with acids or alkalis, it yields ammonia and a nitrobenzoate. It cannot be obtained by the dry distillation of nitrobenzoate of ammonium (Gerland). F. T. C.

BENZOPROPYLENYL. Syn. with BENZOATE OF ALLYL. See BENZOIC ACID.

BENZOSALICIN. Syn. with POPULIN (*q. v.*)

BENZOSALICYLAMIC ACID. *Benzosalicylamide.* $C^{14}H^{11}NO^3 = N.H.C^7H^5O.C^7H^4O.H.O.$ (Gerhardt and Chiozza, Compt. rend. xxxvii. 86; Limpricht, Ann. Ch. Pharm. xciv. 249.)—When equivalent quantities of salicylamic acid and chloride of benzoyl are heated together to 120—145° C., as long as hydrochloric acid escapes, the product remains liquid a long time after cooling, but crystallises on adding a few drops of alcohol or ether; it is washed with ether, and dissolved in boiling alcohol, whence it crystallises in slender needles united in flocks. It is sparingly soluble in alcohol, even on boiling. When heated, it gives off water, and is converted into benzosalicylimide. It is readily soluble in ammonia, and is reprecipitated unchanged on evaporating the solution, or on addition of an acid. It dissolves in the fixed alkalis, forming deep yellow solutions, but is generally decomposed into benzoate and salicylate. It is attacked by chloride of benzoyl, yielding a crystalline product, which appears to be converted into benzosalicylamic acid by the addition of water or alcohol. After fusion, it is no longer completely soluble in hot ammonia; the yellow residue is soluble in alcohol, forming a yellow solution which deposits on evaporation small crystals, apparently of an ammonium-salt: the solution is decolorised by hydrochloric acid.

Benzosalicylamates.—The ammoniacal solution of the acid forms a light-yellow precipitate with normal acetate of lead, and a light-blue with sulphate of copper. With nitrate of silver, it forms the *silver-salt*, $C^{14}H^{10}AgNO^3$, a yellow precipitate, which becomes heated on contact with chloride of benzoyl, forming a viscous product, which dissolves in alcohol, leaving a residue of chloride of silver.

If salicylic acid be regarded as monobasic, this compound becomes *benzosalicylamide*, $N.C^7H^5O.C^7H^4O.^2H$. F. T. C.

BENZOSALICYLAMIDE. See BENZOSALICYLAMIC ACID.

BENZOSALICYLIC ACID. $C^{14}H^{10}O^4 = C^7H^4O.C^7H^5O.H.O^2$. (Gerhardt (1852), Ann. Ch. Phys. [3] xxxvii. 322.)—Formed by the action of chloride of benzoyl on salicylate of potassium, as a viscous mass difficult to purify, soluble in ether, decomposed by boiling water into benzoic and salicylic acids. By dry distillation, it yields benzoate of phenyl, and other products soluble in potash.

This compound is analogous to benzoglycollic and benzolactic acids. If salicylic acid be regarded as monobasic, it becomes benzosalicylic anhydride, $C^7H^5O.C^7H^5O^2.O$. F. T. C.

BENZOSALICYLIMIDE. See BENZAMIDE.

BENZOSTEARIC ANHYDRIDE. See BENZOIC ANHYDRIDE.

BENZOSTILBIN. $C^{14}H^{10}O$ (?) (Rochleder, Ann. Ch. Pharm. xli. 93).—The yellow powder obtained by fusing hydrobenzamide with solid potash consists of a mixture of three substances, a peculiar yellow oil, benzostilbin, and benzolone: the proportions of these three compounds vary with the duration of the fusion, benzolone not being formed at all unless the mixture has been heated till it blackens. The two former are separated from the third by alcohol, in which benzolone is insoluble. The alcoholic solution is mixed with a little hydrochloric acid, when it becomes red, but is decolorised by standing, and deposits benzostilbin in small crystals; the same result is produced more rapidly by passing chlorine into the solution. The crystals may be obtained larger by the slow evaporation of their solution in ether. When quite free from the yellow oil, they are but slightly soluble in alcohol. They melt at 244·5° C., and sublime when further heated, being in great measure decomposed. They dissolve with a red colour in sulphuric acid, and may be boiled without decomposition in aqueous potash of 1·2 specific gravity. Rochleder's analysis gives 86·5—86·6 C, 5·2—5·3 H. F. T. C.

BENZOSUCCININ. $C^{14}H^{12}O^6$. — The name given by Van Bemmelen (J. pr. Chem. lxix. 84) to a glyceride or artificial fat obtained by heating glycerin to 200° C. with benzoic and succinic acids. It is a soft dark-brown mass, which is decomposed by long boiling with water or alcohol, more rapidly in presence of an alkali, into benzoate and succinate. It represents glycerine in which 1 at. H is replaced by benzoyl and 2 at. by succinyl, $C^3H^5(C^7H^5O)(C^4H^4O^2)O^3$. F. T. C.

BENZOSYLANILIDE. See BENZYLENE-PHENYLAMINE.

BENZOTARTARIC ACID. $C^{11}H^{10}O^7 = (C^4HO^4)''.C^7H^5O.H.O^2$. (Dessaignes, J. de Pharm. [3] xxxii. 47.)—Obtained by heating a mixture of equivalent quantities benzoic and tartaric acids to 150° C. The acids melt at first without mixing, but at last form a homogeneous brown mass. When this is dissolved in boiling water, some benzoic acid crystallises out; the mother-liquor is partially neutralised by sodic carbonate, decolorised by animal charcoal, and acidulated with hydrochloric acid. After some time, nodular masses separate out, which are formed of microscopic crystals, and are not altered in form by recrystallisation. The acid is more soluble in cold water than benzoic acid, but less soluble in alcohol; its solution has no smell. No sublimate is formed when it is heated to the melting-point of benzoic acid; when it is further heated, benzoic acid sublimes, and the brown residue smells of heated tartaric acid. A cold saturated solution of the acid does not precipitate lime-water, ferric chloride, or nitrate of silver; it slightly precipitates a concentrated solution of normal acetate of lead. When neutralised with ammonia, it gives a pale yellow precipitate with ferric chloride, but does not precipitate chloride of calcium. When its solution is one-fourth neutralised with ammonia, it gives with nitrate of silver, a precipitate, which at first is redissolved: it contains 46·35 per cent. silver, corresponding to the formula $C^{11}H^8Ag^2O^7$. From this the acid would appear to be dibasic, in which case it is not analogous to benzoglycollic and benzolactic acids. F. T. C.

BENZOVALERIC ANHYDRIDE. See BENZOIC ANHYDRIDE.

BENZOYL. C^7H^5O.—The hypothetical radicle which, according to Liebig and

Wöhler's original suggestion, is usually considered as existing in benzoic acid and many of its kindred compounds,—benzoic acid, $C^7H^6O^2$, being regarded as hydrate of benzoyl, $C^7H^5O.H.O$, bitter-almond oil, C^7H^6O, as hydride of benzoyl, &c. This view explains the reactions of the majority of benzoyl-compounds in a far more satisfactory manner than that of Berzelius, who, in accordance with his opinion that oxygen never entered into the composition of an organic radicle, considered C^7H^5 as the radicle of this group of compounds. The readiness with which many benzoyl-compounds pass into phenyl-compounds renders it probable that benzoyl should be regarded as a compound of phenyl, C^6H^5, with carbonyl, CO; just as acetyl may be regarded as a compound of methyl and carbonyl. One or more atoms of hydrogen in benzoyl is capable of being replaced by a monatomic radicle (Cl, Br, NO^2, &c.) forming what may be called secondary or substitution-radicles (chlorobenzoyl, C^7H^4ClO, nitrobenzoyl, $C^7H^4(NO^2)O$, &c.), which may be supposed to exist in chloro- or nitro-benzoic acid, &c. Benzoyl has not yet been isolated. Benzil, which has the same composition, does not exhibit any analogy with other organic radicles. F. T. C.

BENZOYL, BROMIDE OF. *Brombenzaldid.* $C^7H^5O.Br$. (Liebig and Wöhler, Ann. Ch. Pharm. iii. 266.)—When hydride of benzoyl is mixed with bromine, heat is evolved, and hydrobromic acid given off: the mixture is then heated, to free it completely from hydrobromic acid and excess of bromine. Thus obtained, bromide of benzoyl is a soft, brown, broadly laminar, crystalline mass, semifluid at the ordinary temperature, and melting at a very gentle heat to a brownish-yellow liquid. It has a faint aromatic odour, somewhat like that of chloride of benzoyl, and is readily soluble, without decomposition, in alcohol and ether. When heated with water, it melts, and remains at the bottom, as a brownish oil, which is decomposed into benzoic and hydrobromic acids only by prolonged boiling. It fumes slightly in the air, strongly when heated, and burns with a bright sooty flame. F. T. C.

BENZOYL, CHLORIDE OF. *Chlorbenzaldid.* $C^7H^5O.Cl$. (Liebig and Wöhler (1832), Ann. Ch. Pharm. iii. 262; Cahours, Ann. Ch. Phys. [3] xxii. 334; Gerhardt, *ibid.* xxxvii. 291).—Formed: 1. by the action of chlorine on hydride of benzoyl (L. and W.)—2. By heating perchloride of phosphorus with benzoic acid (Cahours).—3. By the action of oxychloride of phosphorus on benzoates (Gerhardt). Also in small quantities, by the action of chlorine on mandelic acid, or on benzoate of methyl or ethyl (Malaguti, Ann. Ch. Phys. [2] lxx. 374), and on cinnamein (Fremy, *ibid.* 180).—4. By heating benzoic acid to 200° C. with a mixture of chloride of sodium and anhydrous acid sulphate of sodium or potassium.

Preparation.—1. Dry chlorine is passed into hydride of benzoyl, the liquid being gradually heated to boiling, till no more hydrochloric acid is evolved: the product is freed by heat from dissolved chlorine.—2. A better and easier method is to warm equivalent proportions of benzoic acid (122 pts.) and perchloride of phosphorus (209 pts.) in a tubulated retort; a violent reaction takes place, hydrochloric acid is evolved, and a mixture of chlorides of benzoyl and phosphoryl distils over, heat being gradually applied. The mixed chlorides are separated by fractional distillation: at 110° C., chloride of phosphoryl passes over; from 110° to 196°, a mixture of the two chlorides; and from 196° to 200°, nearly pure chloride of benzoyl, which is readily freed from traces of oxychloride by washing with water, and dried over chloride of calcium.—3. Sodic benzoate is treated in a similar manner with oxychloride of phosphorus: the reaction is violent even in the cold, and if the oxychloride be slightly in excess, chloride of benzoyl and sodic phosphate are the only products:

$$3C^7H^5NaO^2 + POCl^3 = 3C^7H^5O.Cl + PO^4Na^3,$$

otherwise benzoic anhydride is also formed. The distillate below 196° obtained in (2) may advantageously be employed for this purpose.

Chloride of benzoyl is a clear colourless liquid, with a peculiar smell, which resembles that of horse-radish and makes the eyes water. Specific gravity 1·196 (L. and W.); 1·25 at 15° C. (Cahours): boils at 196°: vapour-density (expt.) 4·987 (Cahours); 4·901 (calc.). It is insoluble in water, but is decomposed slowly by cold, and quickly by hot water, into benzoic and hydrochloric acid: the same decomposition is slowly effected when it is exposed to moist air. It is decomposed by alcohol, with evolution of heat, into benzoic ether and hydrochloric acid: it does not act upon pure ether. It is soluble in all proportions in bisulphide of carbon, without decomposition, and with the aid of heat dissolves sulphur and phosphorus, which crystallise out on cooling.

It burns with a bright, green-edged, very smoky flame. When boiled with *aqueous alkalis*, it is immediately decomposed into benzoate and chloride, but it may be distilled without alteration over anhydrous lime or baryta. With dry *ammonia* or *ammonic carbonate*, it forms benzamide and chloride of ammonium; it is similarly decomposed by phenylamine and other alkaloids, yielding phenylbenzamide, &c. It is decomposed by certain metallic *bromides*, *iodides*, *sulphides*, and *cyanides*, yielding bromide, iodide, sulphide, or cyanide of benzoyl. With *sulphocyanate of potassium*, it evolves heat, and yields carbonic anhydride and sulphide, and benzonitrile (Schiff, Ann. Ch. Pharm. xcix. 117): probably owing to the decomposition of sulphocyanate of benzoyl:

$$2(CNS.C^7H^5O) = 2C^7H^5N + CO^2 + CS^2 \text{ (Limpricht).}$$

It is not attacked by *potassium*. When heated with *hydride of copper*, it yields hydride of benzoyl and subchloride of copper (Chiozza). With *chloride of aluminium*, it forms a crystalline compound, but not with the chlorides of copper, magnesium, or zinc: it is decomposed by *perchloride of tin* (Casselmann). With the alkaline salts of many organic monobasic acids, it yields an alkaline chloride and an anhydride, *e. g.* with *sodic benzoate*, benzoic anhydride; with *sodic pelargonate*, benzopelargonic anhydride, &c. (Gerhardt). Heated with *formate of sodium*, it yields carbonic oxide, chloride of sodium, and benzoic acid:

$$CHNaO^2 + C^7H^5OCl = CO + NaCl + C^7H^6O^2 \text{ (Gerhardt).}$$

Heated with *potassic oxalate*, it yields benzoic anhydride, potassic chloride, and carbonic oxide and anhydride (Gerhardt) with *oxamide*, benzonitrile and other products (see BENZONITRIL), with most *amides*, a secondary or tertiary amide containing benzoyl.

When finely powdered *aldehyde-ammonia* is gradually added to chloride of benzoyl, sal-ammoniac and benzoic acid are formed, together with a substance which crystallises from hot alcohol in needles having the composition $C^{16}H^{16}N^2O^2$, isomeric (perhaps identical) with hipparaffin. It is insoluble in water, readily soluble in hot alcohol or ether; is fusible, and sublimes partly undecomposed; is slowly decomposed by boiling potash or sulphuric acid into benzoic acid and a brown resin; is not attacked by boiling with water and peroxide of lead, till sulphuric acid is added, when aldehyde is evolved and benzamide formed; is similarly decomposed by nitrous acid. (Limpricht, Ann. Ch. Pharm. xcix. 119.)

Pentachloride of phosphorus dissolves in hot chloride of benzoyl, and is deposited on cooling (Gerhardt). According to Schischkoff and Rosing (Compt. rend. xlvi. 867), when equivalent quantities of the two substances are heated together in a sealed tube to 200° C. for some days, a compound, $C^7H^5Cl^3$, is formed, which they call *perchloride of benzoyl*. The contents of the tube are heated in a retort to about 110° C., washed first with strong potash, and then with water, and dissolved in alcohol; the addition of water precipitates the compound as a yellowish neutral oil, heavier than water, soluble in alcohol or ether. It blackens at 130°—140°, and cannot be distilled without decomposition. It is decomposed when heated with water in a sealed tube, but not by mere contact with water or aqueous or solid potash: it is also decomposed by fuming nitric acid, evolving nitrous fumes; with acetate of silver in the cold it yields chloride of silver.

By the action of chlorine on benzoate of ethyl (*q. v.*) a compound is obtained, having the composition $C^{18}H^{16}Cl^6O^3$, which may be regarded as a compound of chloride of benzoyl with tetrachlorovinic ether, $C^{18}H^{16}Cl^6O^3 = 2C^7H^5OCl.C^4H^6Cl^4O$. It is a colourless liquid, boiling at 188°—190° C., of specific gravity 1·346 at 10·8°, smells like chloride of benzoyl, fumes in moist air, and is slowly decomposed by water into hydrochloric, benzoic, and acetic acids. (Malaguti, Ann. Ch. Phys. [2] lxx. 374.)

Chloride of benzoyl appears to form a compound with hydride of benzoyl. (See BENZOYL, HYDRIDE OF.)

Substitution-products of Chloride of Benzoyl.

Chloride of Chlorobenzoyl. $C^7H^4Cl^2O = C^7H^4ClO.Cl$. (Limpricht and v. Uslar, Ann. Ch. Pharm. cii. 262).—Obtained: 1. By the action of perchloride of phosphorus on chlorobenzoic acid.—2. By the decomposition of chlorosulphobenzoic acid:

$$C^7H^4Cl^2SO^3 = C^7H^4Cl^2O + SO^2.$$

1 at. sulphobenzoic acid is heated with 2 at. perchloride of phosphorus, as long as anything distils over; by repeated rectification of the distillate, a yellowish liquid is obtained, which boils at 285° C., and consists of impure chloride of chlorobenzoyl, which cannot be purified by distillation. As obtained by (1) it is a clear, colourless, strongly-refracting liquid, which boils at 225° C.: is slowly decomposed by boiling water into chlorobenzoic and hydrochloric acids, and quickly by strong aqueous ammonia, into chlorobenzamide and chloride of ammonium.

By the distillation of salicylic acid with perchloride of phosphorus Chiozza (Ann.

Ch. Phys. [3] xxxvi. 102) obtained a compound isomeric with the foregoing, which may be called *chloride of parachlorobenzoyl:*

$$C^7H^6O^3 + 2PCl^5 = C^7H^4Cl^2O + 2POCl^3 + 2HCl.$$

The distillate, which is probably not quite pure, is a heavy strongly-refracting liquid, with a suffocating smell, and decomposed slowly by cold, immediately by hot water, into parachlorobenzoic and hydrochloric acids: when gently heated with salicylous acid, it yields hydrochloric acid and salicylide of benzoyl. This reaction has not yet been explained.

Chloride of Nitrobenzoyl. $C^7H^4ClNO^3 = C^7H^4(NO^2)O.Cl.$ (Cahours (1848), Ann. Ch. Phys. [3] xxiii. 339; Bertagnini, *ibid.* [3] xxxiii. 465.)—Formed by the action of chlorine in the sunshine on hydride of nitrobenzoyl. Also by heating nitrobenzoic acid with perchloride of phosphorus; a mixture of the chlorides of phosphoryl and nitrobenzoyl distils over, which is rectified, and the portion which passes over last, is washed with water, dried over chloride of calcium, and again distilled. It is a yellow liquid, heavier than, and insoluble in, water, something like chloride of benzoyl, and boiling at 265°—268° C. It is gradually decomposed in moist air into nitrobenzoic and hydrochloric acids. It is similarly decomposed by strong boiling potash. With ammonia, it forms nitrobenzamide; with phenylamine, phenylnitrobenzamide. With alcohol or wood-spirit, it forms nitrobenzoate of ethyl or methyl: it is not decomposed by ether. F. T. C.

BENZOYL, CYANIDE OF. $C^8H^5NO = C^7H^5O.CN.$ (Liebig and Wöhler (1832), Ann. Ch. Pharm. iii. 267; H. Strecker, *ibid.* xc. 62.)—When chloride of benzoyl is distilled with cyanide of mercury, a yellow oil passes over, which may be obtained colourless by rectification (L. and W.); after a time, it solidifies to a crystalline mass, which, after washing with water as long as any mercury-salt is washed out, and drying with filter-paper and over sulphuric acid, leaves pure cyanide of benzoyl. It is a colourless crystalline body, which melts at 31° C., and crystallises by slow cooling in tables an inch long; it has a pungent odour, exciting tears; boils at 206°—208° C.; is heavier than water; is inflammable, and burns with a very smoky flame. It is very slowly decomposed by water in the cold, and not rapidly, even on heating: is decomposed by aqueous potash; also by ammonia, into benzamide and cyanide of ammonium; and by zinc and hydrochloric acid, into hydride of benzoyl and benzoin. F. T. C.

BENZOYL, HYDRIDE OF. *Benzaldine. Bitter-Almond Oil. Oxide of Picramyl. Oxide of Stilbene.* $C^7H^6O = C^7H^5O.H.$ (Liebig and Wöhler (1832), Ann. Ch. Pharm. xxii. 1.)—The principal constituent of crude bitter-almond oil, the volatile oil which is obtained by distilling bitter-almonds with water (see BITTER-ALMOND OIL). It is also formed by the decomposition of many organic substances. 1. By the oxidation of amygdalin, amygdalic acid, benzylic alcohol (Cannizzaro, Ann. Ch. Pharm. lxxxviii. 180), cinnamon-oil, cinnamic acid (Mulder, Dumas, and Péligot), and gum-benzoin, by nitric acid; of stilbene and styracene by aqueous chromic acid (Laurent); of mandelic acid, styrone, and (with several other products) of casein, albumin, fibrin, and gelatine, by sulphuric acid and binoxide of manganese.—2. By the action of hydride of copper on chloride of benzoyl (Chiozza, Compt. rend. xxxvi. 631).—3. By the rapid dry distillation of a mixture of benzoate and formate of calcium:

$$C^7H^5CaO^2 + CHCaO^2 = C^7H^6O + CO^3Ca^2$$

a brown oily liquid passes over, whence hydride of benzoyl is separated by acid sulphite of ammonium (Piria, Ann. Ch. Pharm. c. 104).—4. By the action of nascent hydrogen on cyanide of benzoyl. Cyanide of benzoyl is heated gently with hydrochloric acid and excess of zinc; the cyanide turns yellow, and the zinc becomes covered with an unctuous mass, containing hydride of benzoyl, hydrocyanic acid, and benzoin. This, when heated with potash, yields reddish-yellow oily drops, which, when distilled, yield pure hydride of benzoyl (Kolbe, Ann. Ch. Pharm. xcviii. 344).—5. By the action of oxalate of silver on chloride of benzylene,

$$C^7H^6Cl^2 + C^2Ag^2O^4 = C^7H^6O + CO^2 + CO + 2AgCl.$$

The mixture must be very cautiously heated under rock-oil, otherwise a violent reaction takes place, attended with complete destruction of the organic compound. (Golowkinsky, Ann. Ch. Pharm. cxi. 252.)

Crude bitter-almond oil contains, besides hydride of benzoyl, hydrocyanic and benzoic acids, benzoin, and benzimide. By submitting the oil to fractional distillation, hydrocyanic acid first passes over, and then tolerably pure hydride of benzoyl; the other compounds remain in the residue. Pure hydride of benzoyl may also be obtained from the crude oil by several chemical means: 1. By agitating the oil with powdered mercuric oxide and water (v. Ittner), or with milk of lime and protochloride of iron (W. and L.), and distilling.—2. By agitating the oil with three to four times its volume of acid sulphite of sodium of 27° B., or 1·231 specific gravity; drying by pressure, or on a porous tile, the crystalline mass which forms after some hours; washing it with cold alcohol; dissolving it in the smallest possible quantity of water, and decomposing it by a strong solution of sodic carbonate. The oil which separates is decanted and distilled over chloride of calcium (Bertagnini, Ann. Ch. Pharm. lxxxv. 186). According to Müller and Limpricht (Ann. Ch. Pharm. cxi. 136), it is necessary, in order to obtain a pure product by this method, either to recrystallise the crystalline compound before distilling it with carbonate of sodium, or to rectify the liquid which passes over; the portion which distils up to 184° C. is then free from hydrocyanic acid.

Pure hydride of benzoyl is a colourless, limpid, strongly-refracting liquid, with a smell resembling that of oil of bitter-almonds, and a burning aromatic taste. Its specific gravity is 1·0499 at 14·6 or 1·063 at 0° C. (Kopp); boils at 179·1° with the barometer at 751·3 mm.; vapour-density (calc.) 3·66. It is soluble in 30 pts. water, and in all proportions in alcohol and ether; when free from prussic acid, it is not poisonous; in the animal organism it is converted into hippuric acid (Wöhler and Frierichs, Ann. Ch. Pharm. lxvi. 336). It dissolves in sulphurous acid more easily than in water, and separates out on evaporating the solution. It is generally regarded as the aldehyde of the benzoic group, since it exhibits many of the reactions of an aldehyde, combining with acid sulphites of alkali-metals, and oxidising in moist air to benzoic acid; but it does not reduce silver-solutions.

It burns with a bright very smoky flame. It may be passed through a tube heated to dull redness without decomposition; but if the tube be filled with fragments of pumice-stone, it is decomposed into benzoyl and carbonic oxide (Barreswil and Boudault, J. Pharm. [3] v. 267). Heated to 100° C. in a sealed tube with ferric hydrate (previously dried at 100°) it is oxidised, and yields a considerable quantity of ferrous benzoate, part of the non-combined ferric oxide being also reduced to ferrous oxide (Gräger, Ann. Ch. Pharm. cxi. 124). Dry *chlorine* converts it into chloride of benzoyl and hydrochloric acid; this decomposition is seldom complete, especially if the gas be moist, a compound of chloride and hydride of benzoyl being formed (see below). *Bromine* converts it into bromide of benzoyl and hydrobromic acid. *Iodine* does not attack it. Cold strong *nitric acid* dissolves it undecomposed, and on heating, slowly oxidises it into benzoic acid: fuming nitric acid, or nitrosulphuric acid, converts it into hydride of nitrobenzoyl (see below). Strong *sulphuric acid* dissolves it, forming a red solution, which blackens and gives off sulphurous anhydride when heated. With *sulphuric anhydride* it forms a sulpho-conjugated acid, sulphomandelic acid (Mitscherlich, Lehrb. 4te Aufl. i. 163). With *perchloride of phosphorus*, it yields the chlorides of benzylene and phosphoryl (Cahours, Compt. rend. xxv. 725). Heated with *chloride of acetyl* in equivalent proportions for several hours to 120°—130° C. in a sealed tube, it yields hydrochloric and cinnamic acids (Bertagnini, Ann. Ch. Pharm. c. 125):

$$C^7H^6O + C^2H^3O.Cl = C^9H^8O^2 + HCl.$$

With *sulphydric acid* or *sulphide of ammonium*, it yields peculiar products containing sulphur, and varying according to the amount of alkali present, and the medium in which the hydride of benzoyl is dissolved. In an alcoholic solution, it yields hydride of thiobenzoyl (see below); in an ethereal solution, *thiobenzaldine*. With *ammonia* and *sulphide of carbon* it yields *sulphocyanobenzylene*. It dissolves *potassium*, becoming thick and dark, but without evolution of hydrogen (Löwig). When heated with solid *potash*, it evolves hydrogen, and is converted into benzoate; with alcoholic potash, into benzoate and benzylic alcohol. *Cyanide of potassium* converts it into benzoin. With *ammonia* it forms various products (Laurent); with *aqueous* ammonia hydrobenzamide and azobenzoilide; with *alcoholic* ammonia amarine, benzimic-acid, and sometimes, dibenzoylimide (Robson). With *aniline*, it yields benzylene-phenylamine; with *urea*, benzoyluride.

Combinations. Benzoate of Hydride of Benzoyl. See BITTER-ALMOND OIL. *Hydride of Benzoyl with Chloride of Benzoyl.* $C^{14}H^{11}ClO^2 = C^7H^6O.C^7H^5OCl$ (Laurent and Gerhardt, Compt. chim. 1850, p. 123.)—Formed abundantly when hydride of benzoyl is imperfectly saturated with chlorine, or even when it is treated with excess of chlorine. The saturated solution, when left to itself in a stoppered bottle, gradually solidifies into a crystalline mass, which is washed with cold alcohol, and dried. It forms colourless shining laminæ, resembling benzoic acid; melts very readily, and remains liquid a long time when at rest; heated above its melting point it gives off chloride of benzoyl. When dry, it is inodorous, but if moist it gives off fumes of hydrochloric acid, and smells of hydride of benzoyl. Hot water decomposes it into benzoic and hydrochloric acids, and hydride of benzoyl. It is insoluble in cold alcohol; warm alcohol decomposes it. It is decomposed by strong sulphuric acid.

Hydrocyanate of Hydride of Benzoyl. $C^8H^7NO = C^7H^6O.CNH$ (**Voelckel** (1844), Pogg. Ann. lxii. 444).—When crude bitter-almond oil or bitter-almond water is mixed with hydrochloric acid, and evaporated below 100° C., till it is considerably concentrated, this compound separates as a yellowish oil, which is washed with water, and dried over sulphuric acid in vacuo. It is inodorous; boils at 170° C. Specific gravity 1·24. Slightly soluble in water, forming a bitter or neutral solution, readily in alcohol or ether. It begins to decompose at 100° C., and when boiled is entirely resolved into hydride of benzoyl and hydrocyanic acid; it is similarly decomposed by aqueous potash. When evaporated with strong hydrochloric acid, it takes up water and forms mandelic acid and ammonia:

$$C^8H^7NO + 2H^2O = C^8H^8O^3 + NH^3.$$

Gerhardt (Traité, iii. 193) mentions a compound obtained by distilling in a brine-bath, a mixture of 2 pts. hydride of benzoyl, 1 pt. cyanide of mercury, and 1 pt. hydrochloric acid; it is an oil which smells like hydride of benzoyl, has a specific gravity of 1·10; is somewhat soluble in water, more in alcohol, readily in ether; does not solidify at 12° C.; boils at 312°, yielding a distillate which crystallises on cooling.

Hydride of Benzoyl with Chloride of Calcium.—When dry pulverised chloride of calcium is added to anhydrous bitter-almond oil, heat is evolved, and a solid compound is formed, which separates from the liquid in easily decomposible crystals, apparently containing 2·5 to 3·3 at. CaCl to 1 at. hydride of benzoyl. (**Ekmann**, Ann. Ch. Pharm. cxii. 151.)

Hydride of Benzoyl with Acid Sulphites of Alkali-metals. (**Bertagnini**, Ann. Ch. Pharm. lxxxv. 183.)

a. With Acid Sulphite of Ammonium.—Hydride of benzoyl dissolves in all proportions in acid sulphite of ammonium; but the resulting compound cannot be obtained in the crystalline state. The solution dissolves an excess of hydride of benzoyl, which separates out on addition of water. Ammonia renders it turbid, and gradually precipitates a body having the properties of hydrobenzamide. When the dry compound is heated with excess of slaked lime, it yields amarine and lophine. (**Gössmann.**)

b. With Acid Sulphite of Potassium.—When hydride of benzoyl is shaken up with a solution of this salt of 28°—30° Baumé (specific gravity 1·24—1·26), a crystalline magma is speedily formed, which must be dried with filter-paper, and dissolved in dilute boiling alcohol (if boiled too long decomposition takes place); the solution on cooling deposits the compound in shining rectangular laminæ. It is very soluble in water, less so in presence of alkaline sulphites, not at all in a saturated solution of these salts; sparingly soluble in cold, readily in boiling, alcohol. It is permanent in the air. Its aqueous solution is decomposed by boiling, either alone or with dilute acids, and by alkaline carbonates, with separation of hydride of benzoyl.

c. With Acid Sulphite of Sodium. $C^7H^6O.SO^3NaH. \frac{1}{2}Aq.$—Formed like (*b*). Small white aggregated prisms, tasting of hydride of benzoyl and sulphurous acid, readily soluble in water, sparingly in hot alcohol, insoluble in cold alcohol. It may be kept in stoppered bottles, and decomposes but slowly when exposed to the air. When carefully heated in the air, it is decomposed without blackening, into sulphurous anhydride and hydride of benzoyl, sulphite of sodium remaining; in a stream of hydrogen, this decomposition takes place below 100° C. Its aqueous solution is decomposed by boiling, either alone or with acids or alkalis, like that of (*b*), also by iodine or chlorine, sodic sulphate being formed. Nitric acid decomposes the dry salt in a similar manner. Its aqueous solution gives, with barium-salts, a white precipitate, soluble in hydrochloric acid; it also precipitates lead- and silver-salts: the precipitates appear to contain a portion of the oil.

Substitution-products of Hydride of Benzoyl.

Hydride of Nitrobenzoyl. Nitrobenzaldide. $C^7H^5NO^3 = C^7H^4(NO)^2O.H$ (**Bertagnini**, Ann. Ch. Pharm. lxxix. 259; lxxxvi. 190.)—When hydride of benzoyl is gradually added to fuming nitric acid, or to 15—20 vols. of a mixture of 1 vol. nitric and 2 vols. sulphuric acid, heat is evolved, and the addition of water precipitates hydride of nitrobenzoyl in yellowish oily drops, which crystallise in a few days. The vessel must be kept cool during the operation, otherwise nitrobenzoic acid will be formed. The crystals are contaminated by a yellow fetid oil, whence they are purified by pressure between filter-paper, and recrystallisation from boiling dilute alcohol.

It forms white shining needles, inodorous when pure, with a taste like that of hydride of benzoyl. It is slightly soluble in cold, readily in hot water or alcohol, less so in ether; dissolves undecomposed in nitric, hydrochloric, or sulphuric acids, and crystallises out as the last solution absorbs moisture from the air. It melts easily to a colourless liquid, which solidifies at 46° C.; when further heated, it gives off vapours, which smell pleasantly when dilute, but are very pungent when concentrated. It may be volatilised in small quantities without decomposition; partly even when boiled with water, completely when heated in an oil-bath in a stream of gas.

Hydride of nitrobenzoyl burns with a smoky flame. It does not absorb oxygen from the air, but is readily converted into nitrobenzoic acid by oxidising agents, *e. g.* aqueous chromic acid, or a mixture of nitric and sulphuric acids. *Chlorine* in sunshine converts it into *chlorine of nitrobenzoyl* (see BENZOYL, CHLORIDE OF). *Bromine* dissolves readily in fused hydride of nitrobenzoyl, but does not decompose it till heated over 100° C., when a brown resinous mass is formed. Strong *hydrocyanic acid* readily dissolves it, the solution, if evaporated at once, deposits it unaltered, but after standing for a few hours, yields on evaporation, a viscid liquid, permanent in the air, soluble in hot water, and separating out on cooling, which, when boiled with hydrochloric acid, yields chloride of ammonium, and another body soluble in water. *Cyanide of potassium* decomposes it at once, forming compounds which have not been examined. With *sulphydric acid*, its alcoholic solution forms *hydride of thionitrobenzylene* (see below). When its solution in alcoholic ammonia is treated with sulphuretted hydrogen, a semifluid mass is deposited, which consists of a sulphur-compound mixed with free sulphur; the former is dissolved out by ether, and obtained by evaporation as a viscid reddish liquid, insoluble in water or dilute acids, soluble in warm alcohol; it is decomposed by heat, evolving sulphuretted hydrogen, and when boiled with nitric acid, forms sulphuric acid and a yellow resin. Heated with *sulphite of ammonium* it yields an acid product, readily soluble in water or alcohol. *Alcoholic potash* converts it into nitrobenzoate in the cold; *aqueous potash* requires the aid of heat. *Ammonia*, whether dry, aqueous, or alcoholic, converts it into trinitrohydrobenzamide. When it is gently heated with *urea*, water is given off, and the whole solidifies on cooling into an opaque mass (nitrobenzoylureid?) slightly soluble in alcohol, readily in alcohol containing hydrochloric acid, being thereby decomposed into urea and hydride of nitrobenzoyl.

Hydride of nitrobenzoyl combines with acid sulphites of alkali-metals, forming compounds of which the following have been examined:

a. With Acid Sulphite of Ammonium. $C^7H^5NO^3.SO^3NH^5 + \frac{1}{2}\,Aq.$—Hydride of nitrobenzoyl is dissolved in a solution of acid sulphite of ammonium of 29° Bm. at a gentle heat, when this compound crystallises out on cooling. It forms small, transparent, colourless prisms, which grate between the teeth, and have a bitter and sulphurous taste; are soluble in water or boiling alcohol, and crystallise readily from the latter solution only. It is permanent in the air, though it gradually acquires a violet tinge. Its aqueous solution is decomposed by boiling, either alone or with acids or alkalis. With barium- lead- or silver-salts, its aqueous solution gives a precipitate of metallic sulphite mixed with hydride of nitrobenzoyl; with dichloride of platinum, it gives chloroplatinate of ammonium.

b. With Acid Sulphite of Sodium. $C^7H^5NO^3.SO^3NaH + 5Aq.$—Obtained in the same manner manner as (*a*), in yellow scales, which are rendered nearly colourless by recrystallisation from a little hot water. It is readily soluble in hot, less so in cold water: effloresces in the air: loses its water at 70°—80° C.; above 90° it is decomposed giving off hydrogen, sulphurous anhydride, and hydride of nitrobenzoyl, sulphite of sodium remaining behind. Its aqueous solution is decomposed by boiling, especially on addition of acids or alkalis.

Hydride of Thiobenzoyl. Hydride of Sulphobenzoyl. Sulphide of Stilbene. Sulphopicramyl. $C^7H^6S = C^7H^5S.H$ (Laurent, Ann. Ch. Phys. [3] i. 292. Rochleder, Ann. Ch. Pharm. xxxvii. 346. Cahours, Compt. rend. xxv. 357.)—When 1 vol. of bitter-almond oil (crude or pure), is dissolved in 8—10 vols. alcohol, and 1 vol. sulphide of ammonium gradually added, this compound speedily separates as a mealy powder, which is easily purified by washing with alcohol. It is also obtained when an alcoholic solution of hydrobrobenzamide is supersaturated with sulphuretted hydrogen, and the liquid left at rest. It is a white powder consisting of microscopic granules; is inodorous, but imparts to the fingers a smell of onions; is insoluble in water or alcohol. With ether it forms a transparent liquid, which resolidifies on adding a few drops of alcohol. It becomes soft at 90°—95° C. After fusion it solidifies to a transparent non-crystalline mass. By dry distillation, it evolves sulphuretted hydrogen and bisulphide of carbon, and yields a sublimate of stilbene and thionessal:

$$8C^7H^6S = 2CS^2 + 3H^2S + \underset{\text{Stilbene.}}{2C^{14}H^{12}} + \underset{\text{Thionessal.}}{C^{26}H^{18}S.}$$

It burns with an offensive smell and bright smoky flame. With *bromine*, it evolves hydrobromic acid, and forms an oily body. Heated with *nitric acid*, it yields sulphuric acid and hydride or hydrate of benzoyl; with *sulphuric acid*, it dissolves, forming a carmine solution, which water decolorises, precipitating yellow flakes; boiled with *hydrochloric acid*, it evolves a little sulphuretted hydrogen. It is slowly decomposed by *alcoholic potash;* water separates an oil from the solution, and acids evolve sulphuretted hydrogen from the alkaline liquid. It is isomeric with sulphide of benzylene.

Hydride of Thionitrobenzoyl. Sulphide of Nitrobenzylene. $C^7H^5NO^2S = C^7H^4(NO^2)S.H$ (Bertagnini, Ann. Ch. Pharm. lxxix. 269).—When an alcoholic solution of hydride of nitrobenzoyl is saturated with sulphuretted hydrogen, this compound separates as a grey light mealy powder, which is inodorous, but imparts a disagreeable smell to the fingers. It becomes electric when rubbed. It does not dissolve in the usual solvents, but melts in boiling *water*, aggregates together in boiling *alcohol*, and becomes soft and transparent with *ether* in the cold. It dissolves in strong *sulphuric acid*, and is reprecipitated unaltered by water. Strong nitric acid decomposes it in the cold, dilute *nitric acid* on heating, forming sulphuric acid and hydride of nitrobenzoyl. *Alcoholic potash* dissolves it in the cold, and water precipitates a brown substance from the solution. *Ammonia*, whether dry or aqueous, attacks it, evolving sulphuretted hydrogen, and forming (probably) trinitrohydrobenzamide.

Oxyiodide of Benzaldide. $C^{21}H^{18}I^4O$ (Geuther and Cartmell, Ann. Ch. Pharm. cxii. 1).—This compound, which may be regarded as a triple molecule of hydride of benzoyl ($C^{21}H^{18}O^3$), having 2 at. O replaced by 4 at. I, is produced by the action of hydriodic acid gas on hydride of benzoyl. Two layers of liquid are thereby formed, the upper consisting of aqueous hydriodic acid; the lower, which is oily, of the oxyiodide: the latter may be purified by repeated treatment with water and acid sulphite of sodium. It is then obtained as a solid mass, which melts at 28° C. and crystallises at 25° in colourless rhombic plates; smells like cress; dissolves readily in alcohol and ether, and is insoluble in water. It may be distilled with water without decomposition; is not decomposed by acid sulphites of alkali-metals, but is resolved by alcoholic potash into iodide of potassium, a small quantity of benzoic acid, and an oily body soluble in alcohol, but different from bitter-almond oil. By ammonia, it appears to be gradually converted into hydride of benzoyl. Boiled with nitrate of silver, it forms iodide of silver, and emits an odour of bitter-almond oil. F. T. C.

BENZOYL, IODIDE OF. $C^7H^5O.I.$ (Liebig and Wöhler, Ann. Ch. Pharm. iii. 266.)—Obtained readily by heating iodide of potassium with chloride of benzoyl; a brown liquid distils over, which solidifies to a crystalline mass, coloured brown by free iodine. When pure, it is colourless, lamino-crystalline and readily fusible, always with partial decomposition; in solubility and general reactions it resembles bromide of benzoyl. F. T. C.

BENZOYL, PERCHLORIDE OF. See BENZOYL, CHLORIDE OF.

BENZOYL, SULPHIDE OF. $(C^7H^5O)^2S$ (Liebig and Wohler, *loc. cit.*)—When chloride of benzoyl is distilled with finely-powdered sulphide of lead, a yellow oil passes over, which solidifies to a soft yellow crystalline mass. It has an unpleasant sulphurous smell; is not decomposed by boiling with water or alcohol, and but slowly with aqueous potash; burns with a bright smoky flame, giving off sulphurous anhydride. F. T. C.

BENZOYL SULPHOCYANIDE OF. See SULPHOCYANOBENZYLENE.

BENZOYLAZOTIDE. $C^{15}N^2H^{12}$ (Laurent (1837), Ann. Ch. Phys. [2] lxvi. 187. Laurent and Gerhardt, Compt. chim. (1850), 115. Robson, Chem. Soc. Qu. J. iv. 225).—A product of the action of ammonia on bitter-almond oil. It is the residue insoluble in alcohol, obtained in the preparation of *azobenzoyl*, *benzhydramide*, and *dibenzoylimide* (*q. v.*) It is a white powder, without taste or smell, consisting of microscopic prisms. It is insoluble in water; requires 300—400 pts. boiling alcohol for its solution, and at least as much ether. Fuses when heated, and solidifies to a vitreous mass, in which a few oblique prisms separate. When boiled with alcohol and hydrochloric acid, it is slowly decomposed, evolving hydrocyanic acid. By dry distillation, it yields an oil, then a sublimate of lophine and amarone, and finally a carbonaceous residue.

Gerhardt (Traité, iii. 194) describes this body and benzhydramide under the name of *hydrides of cyanazobenzoyl*.

Quadrat (Ann. Ch. Pharm. lxxi. 18), by heating sulphocyanobenzylene, obtained a resinous mass, which, when exhausted with alcohol, left a crystalline residue, insoluble in water, almost so in alcohol, to which he assigns the formula $C^{15}H^{10}N^2$. The crystals are permanent at 100° C. and are not decomposed by nitric acid. F. T. C.

BENZOYL-BENZOIN. See BENZOIN.

BENZOYL-UREA. Syn. with BENZOCARBAMIDE. See CARBAMIDE.

BENZOYLUREID. $C^{25}H^{28}N^{8}O^{4}$ (Laurent and Gerhardt, Compt. chim. [1850], p. 119).—Formed by the action of urea on hydride of benzoyl:

$$4CH^{4}N^{2}O + 3C^{7}H^{6}O = C^{25}H^{28}N^{8}O^{4} + 3H^{2}O.$$

When 5 pts. powdered urea are heated to somewhat below 100° C. with 2 pts. hydride of benzoyl, the mixture becomes liquid, and shortly solidifies to a compact mass. When cold, this is powdered, freed from excess of hydride of benzoyl by ether, and of urea by boiling with water; the residue, which is dried at 120°, is benzoylureid. It is a white amorphous powder, without smell or taste, insoluble in water or ether, soluble in alcohol, whence it separates on evaporation in amorphous crusts. It turns yellow at 170° C. gives off hydride of benzoyl a few degrees higher, and when further heated, yields hydride of benzoyl and ammoniacal water, leaving a yellow residue, which finally volatilises completely, and is sparingly soluble in alcohol. When boiled with dilute acids, it is decomposed into hydride of benzoyl and urea. It is not decomposed by boiling ammonia; slowly by strong boiling potash, evolving ammonia and hydride of benzoyl, and leaving potassic benzoate in solution. Hydride of nitrobenzoyl yields with urea a similar compound. (Bertagnini.) F. T. C.

BENZUREID. Syn. with Benzoyl-urea. See Carbamide.

BENZYL. *Tolyl. Toluenyl.* $C^{7}H^{7}$.—A hypothetical radicle, isomeric with cresyl, contained in benzylic alcohol, toluene, and other compounds. F. T. C.

BENZYL, CHLORIDE OF. *Chloride of Tolyl* or *Toluenyl. Chlorotoluol.* $C^{7}H^{7}Cl$ (Cannizzaro, Ann. Ch. Pharm. lxvxviii. 129; xcvii. 246. Deville, Ann. Ch. Phys. [3] iii. 178).—Obtained by saturating benzylic alcohol with hydrochloric acid gas whereupon heat is evolved, and the liquid divides itself into two layers, the lower of which is aqueous hydrochloric acid, the upper chloride of benzyl. Or by passing chlorine into hydride of benzyl in the dark, expelling excess of chlorine by a stream of carbonic anhydride, and rectifying the product. It forms a colourless liquid, of specific gravity 1·117 at 0° C; boils at 170° (Deville); 175°—176° (Cannizzaro); insoluble in water, soluble in alcohol or ether. It is not attacked by aqueous potash; alcoholic potash decomposes it on boiling into benzylethylic ether and chloride of potassium. When boiled with an alcoholic solution of acetate of potassium, it is converted into acetate of benzyl; of cyanide of potassium, into cyanide of benzyl. When heated in a sealed tube with alcoholic ammonia, it yields tribenzylamine. F. T. C.

BENZYL, CYANIDE OF. *Cyanide of Tolyl* or *Toluenyl.* $C^{8}H^{7}N = C^{7}H^{7}.CN$ (Cannizzaro, Ann. Ch. Phys. [3] xlv. 468).—Obtained by boiling chloride of benzyl with a strong alcoholic solution of cyanide of potassium, till no more chloride of potassium separates out, and distilling the filtrate to remove the alcohol. The residual liquid separates into two layers, the upper containing cyanide of benzyl, which may be obtained from it by rectification. It is a colourless liquid, which, by boiling with strong potash, is converted into toluic acid, $C^{8}H^{8}O^{2}$. F. T. C.

BENZYL, HYDRATE OF. Syn. with Benzylic Alcohol (*q. v.*)

BENZYL, HYDRIDE OF. *Hydride of Tolyl* or *Toluenyl. Toluene* or *Toluol. Benzoene. Dracyl.* $C^{7}H^{8} = C^{7}H^{7}.H$.—Discovered by Pelletier and Walter (1837) in the oily products obtained in the manufacture of illuminating gas from resin; first examined by Deville.

Formed: 1. By the action of potash on benzylic alcohol (Cannizzaro, Ann. Ch. Pharm. xc. 252; xcvi. 246):

$$3C^{7}H^{8}O + KHO = C^{7}H^{5}KO^{2} + 2C^{7}H^{8} + 2H^{2}O.$$

2. By heating toluic acid with excess of lime (Noad, *ibid.* lxiii. 305):

$$C^{8}H^{8}O^{2} = C^{7}H^{8} + CO^{2}.$$

3. By the dry distillation of tolu-balsam (Deville, Ann. Ch. Phys. [3] iii. 152, 168; Muspratt and Hofmann, Ann. Ch. Pharm. liv. 9); of dragon's blood (Glénard and Boudault, Ann. Ch. Phys. [3] iv. 274); of the resin of *Pinus maritima* (Pelletier and Walter, *ibid.* [2] lxvii. 269); of Burmese naphtha (De la Rue and Müller, Proc. Roy. Soc. viii. 221); of resin-oil (Couerbe, Ann. Ch. Phys. [2] lxix. 184); of wood (Völckel, Ann. Ch. Pharm. lxxxvi. 334), and of coal. In distilling coal-tar, the portion which passes over at 100°—115° C. consists of toluene (Mansfield, Chem. Soc. Qu. J. i. 266).—4. The yellow oil which separates from crude wood-spirit on addition of water contains hydride of benzyl. (Cahours, Compt. rend. xxx. 319.)

Preparation.—1. When benzylic alcohol is distilled with four or five times its volume of strong alcoholic potash in an apparatus which allows the less volatile products to run back again, alcohol first passes over, then water, and finally, when the residue has become solid, a mixture of hydride and hydrate of benzyl. This mixture is distilled by itself, the portion which passes over at 116° C. collected apart and shaken up with sulphuric acid, the decanted liquid washed with potassic carbonate, and twice rectified over phosphoric anhydride.—2. When tolu-balsam, freed by distillation with water from toluene, cinnamein, and a portion of the benzoic acid is subjected to dry distillation, there passes over,—besides carbonic oxide and anhydride,—water, abundance of benzoic, and a little cinnamic acid, a heavy oil consisting of a mixture of benzoate of ethyl (benzoate of methyl, according to Muspratt and Scharling), and hydride of benzyl. This oil is distilled, and the portion which passes over at 13°—140° C. repeatedly rectified over strong aqueous potash, and dried over chloride of calcium. E. Kopp (Compt. chim. 1849, p. 149) purifies the balsam by boiling with sodic carbonate, boils the residue with strong aqueous soda, distils the brown solution, decants the oil which passes over from the water which accompanies it, and rectifies it repeatedly.—3. To prepare hydride of benzyl from coal-tar, the oil which comes over at 100°—120° C. is mixed with half its weight of sulphuric acid and rectified, when a product of constant boiling-point is obtained. (Wilson, Chem. Soc. Qu. J. iii. 154.)

Hydride of benzyl is a colourless, very mobile, strongly refracting liquid, with a smell like benzene, and a burning taste; specific gravity 0·87 at 18° C. (Deville). The boiling-point is variously stated at from 103°·7 (Church), to 114° (Gerhardt), vapour-density 3·27 (Deville); does not solidify at −20°. It is insoluble in water, slightly soluble in alcohol, more so in ether or in fixed or volatile oils. It dissolves most resins, also iodine, forming an amber-red solution, and, when heated, sulphur, which crystallises out on cooling.

It is not decomposed when passed through a red-hot tube filled with potash-lime. It burns with a smoky flame. With *chlorine*, it evolves heat, and yields several substitution-compounds (see below). With fuming *nitric acid*, it yields substitution-compounds (see below). It dissolves in fuming *sulphuric acid*, forming sulphibenzylic (sulphotoluic) acid, and sulphibenzyl (sulphotoluol). It is not attacked either by *potassium* or by *potash*. When digested with *sodium*, in a closed vessel for fourteen days, it yields two substances, boiling respectively at 97° C. and 112°. (Church, Phil. Mag. [4] ix. 256.)

Substitution-products of Hydride of Benzyl.

Deville (Ann. Ch. Phys. [3] iii. 178) enumerates several compounds obtained by the action of chlorine on hydride of benzyl. When the reaction takes place in the dark, *chloride of benzyl* (chlorotoluol) is the product (see BENZYL, CHLORIDE OF). When chlorine is passed through hydride of benzil in bright daylight, as long as hydrochloric acid is evolved, and excess of chlorine removed by carbonic anhydride, *hydrochlorate of trichlorotoluol*, $C^7H^4Cl^6 = C^7H^5Cl^3.HCl$, is formed; when distilled it decomposes and evolves hydrochloric acid. When the action of the gas is still further prolonged, a thickish liquid is formed, together with some crystals. If the liquid be separated, further treated with chlorine with aid of heat, and purified by carbonic anhydride, the product is *dihydrochlorate of pentachlorotoluol*, $C^7H^5Cl^7 = C^7H^3Cl^5.2HCl$; when distilled it evolves hydrochloric acid; it is soluble in ether. The crystals are *trihydrochlorate of pentachlorotoluol*, $C^7H^6Cl^8 = C^7H^3Cl^5.3HCl$, they are purified by recrystallisation from ether, in which they are soluble, especially with aid of heat; they are colourless when pure. When the liquid and crystals together are distilled in a stream of chlorine, the distillate being repeatedly poured back again, the whole is gradually converted into a silky substance, abundance of hydrochloric acid being evolved; this substance, which is *hexchlorotoluol* (hydride of hexchlorobenzyl), $C^7H^2Cl^6$, is purified by pressure between filter-paper and recrystallisation from ether; it is volatile without decomposition.

Hydride of Nitrobenzyl. *Nitrotoluol.* $C^7H^7NO^2 = C^7H^6NO^2.H$. (Deville, *loc. cit.;* Glénard and Boudault, Compt. rend. xix. 505; Hofmann and Muspratt, Ann. Ch. Pharm. liii. 220, 224.)—Hydride of benzyl is added to cold fuming nitric acid as long as it dissolves immediately; on adding water to the red solution, hydride of nitrobenzyl separates as a red liquid, which may be decolorised by washing with water and repeated distillation. It is a nearly colourless liquid, smelling of bitter almonds, with a very sweet and afterwards pungent taste; specific gravity 1·18 at 16°·5 C.; vapour-density 4·95; boils at 225°—230° C. Readily soluble in alcohol or ether. It is partially decomposed by distillation, completely when passed at a high temperature through a red-hot tube filled with pieces of glass. It burns with a smoky flame, emitting the odour of gum-benzoin; when passed over red-hot baryta, it is resolved into phenylamine and carbonic anhydride. With fuming sulphuric acid it forms nitrosulphotoluic acid (Church). Aqueous potash dissolves it, forming a red solution, whence hydrochloric acid precipitates a brown powder; with alcoholic potash it forms a black liquid, whence a reddish oil containing phenylamine is obtained by distillation. Boiled with alcoholic sulphite of ammonium, it forms thiotoluate of ammonium. With sulphide of ammonium, it yields benzylamine.

Hydride of Dinitrobenzyl. *Dinitrotoluol.* $C^7H^6N^2O^4 = C^7H^5(NO^2).^2H$. (Deville, *loc. cit.*; Cahours, Compt. rend. xxiv. 555.)—Obtained by boiling hydride of benzyl with fuming nitric acid, or treating it with nitrosulphuric acid. It crystallises from alcohol in lustrous, hard, brittle, prismatic needles, which melt at 71° C. and solidify to a radiated mass. It boils at 300°, becoming coloured, and leaving a residue: when strongly heated, it yields a sublimate. It is sparingly soluble in water. It is not attacked by fuming nitric acid. Its solution in potash deposits a brown powder on addition of hydrochloric acid. Sulphide of ammonium converts it into nitrobenzylamine. F. T. C.

BENZYL, IODIDE OF. C^7H^7I. (Cannizzaro, 1854.)—When a solution of benzylic alcohol in bisulphide of carbon is mixed with a solution of phosphorus in bisulphide of carbon, iodine gradually added, and excess of bisulphide distilled off, a liquid is obtained, which irritates the eyes, and is probably iodide of benzyl.

F. T. C.

BENZYLAMINE. *Toluidine.* $C^7H^9N = N.C^7H^7.H^2$. (Muspratt and Hofmann (1845), Ann. Ch. Pharm. liv. 1; Noad, *ibid.* lxiii. 305; Hofmann, *ibid.* lxvi. 144; Wilson, Chem. Soc. Qu. J. iii. 154; Chautard, J. Pharm. [3] xxiv. 166.)—Formed by the reduction of hydride of nitrobenzyl by sulphydric acid (Muspratt and Hofmann): or by the action of potash on the yellow resin obtained by treating oil of turpentine by nitric acid. (Chautard.)

Preparation.—1. A solution of hydride of nitrobenzyl in alcohol saturated with ammonia, is treated with sulphuretted hydrogen till it smells strongly of the gas, even after long standing: sulphur then crystallises out. The reaction is accelerated by the application of heat, but the decomposition is never complete. The product is mixed with water and hydrochloric acid, and shaken up with ether to remove undecomposed hydride; it is then evaporated to $\frac{1}{3}$, and distilled with potash, when water, ammonia, and benzylamine pass over, the last as a heavy oil, which soon crystallises. The whole distillate is saturated with oxalic acid, evaporated to dryness on the water-bath, and exhausted with boiling absolute alcohol, which dissolves only the oxalate of benzylamine, which crystallises on cooling. The crystals are washed, dissolved in boiling water, and the solution decomposed by strong potash, when benzylamine separates in oily drops, which collect and crystallise into a radiated mass on cooling: it is purified by washing and one rectification, or by crystallisation from ether.—2. The resin obtained by treating oil of turpentine with nitric acid, is gradually mixed with aqueous potash; the mixture assumes a dark-brown colour, and becomes hot, and when the reaction has ceased, it is distilled as long as alkaline vapours pass over. The distillate is supersaturated with hydrochloric acid, evaporated to dryness over the water-bath, and exhausted with absolute alcohol, which dissolves hydrochlorate of benzylamine, and leaves sal-ammoniac undissolved.

Benzylamine crystallises from dilute alcohol in large colourless laminæ, which are sparingly soluble in cold, more readily in boiling, water: readily in alcohol, ether, wood-spirit, acetone, fixed and volatile oils, and bisulphide of carbon. It smells like phenylamine, and has a burning taste. It evaporates at ordinary temperatures, melts at 40° C. to a colourless, strongly-refracting oil, and boils at 198°. It is heavier than water; slightly blues red litmus, but does not redden turmeric; colours fir-wood deep yellow, but does not give the purple colour of phenylamine with chloride of lime, but only a faint reddish tint. With nitric acid benzylamine gives a deep-red, phenylamine a deep-blue, colour.

Bromine acts on benzylamine violently: when the product is heated, shining needles sublime, insoluble in water, soluble in alcohol and ether,—probably *tribromobenzylamine.* It is decomposed by boiling with strong *nitric acid,* with evolution of nitrous fumes; water added to the solution precipitates yellow flakes, which dissolve in alkalis, and are reprecipitated by acids. With aqueous *chromic acid,* it gives a red-brown precipitate. When its vapour is passed over fused *potassium,* vivid combustion takes place, and potassic cyanide is formed. *Cyanogen* passed into its alcoholic solution, yields cyanobenzylamine (see below).—With *chloride of cyanogen* it forms melobenzylamine (metoluidine) (see below.) With *bromide* or *iodide of ethyl,* it yields benzylethylamine (see below).

Combinations. 1. With Acids.—Benzylamine combines with acids, forming crystalline salts, which are mostly inodorous and colourless, but quickly become rose-coloured when exposed to the air: they are decomposed by alkalis or alkaline carbonates, benzylamine being separated as a crystalline curd. The *chloraurate,* $AuCl^4C^7H^{10}N$, separates as a thick precipitate, which soon aggregates to a crystalline mass, when the hydrochlorate is mixed with trichloride of gold: it melts in water at 50° — 60°C., dissolves when further heated, and crystallises on cooling in fine yellow needles. The *chloroplatinate,* $PtCl^3C^7H^{10}N$, separates as an orange-yellow crystalline pulp, when the hydrochlorate is mixed with bichloride of platinum: it is washed with ether-alcohol and dried in a water-bath. The *chloropalladate* is similar in appearance. The *hydrochlorate*, $C^7H^{10}NCl$, is deposited in white crystalline scales, becoming yellow on exposure to the air, when a solution of benzylamine in hydrochloric acid is evaporated and cooled: it is readily soluble in water or alcohol, sparingly in ether, forming acid solutions: when gently heated, it sublimes like sal-ammoniac. The *nitrate*, *phosphate*, and *sulphite* are crystallisable. The *acid oxalate*, $C^2O^4.C^7H^{10}N.H + \frac{1}{2}Aq$, is obtained by mixing an alcoholic solution of benzylamine with excess of oxalic acid, in delicate silky needles, soluble in boiling water or alcohol, insoluble in ether. The *sulphate*, $SO^4(C^7H^{10}N)^2$, is obtained when a few drops of sulphuric acid are added to an ethereal solution of benzylamine, as a white crystalline precipitate, which may be washed with ether: it is readily soluble in water, sparingly in alcohol. With *cupric sulphate* or *chloride*, benzylamine gives a greenish crystalline precipitate; with *nitrate of silver*, a white precipitate, which soon blackens; it precipitates ferric hydrate from ferric chloride.

2. With CYANOGEN; *Cyanobenzylamine; Cyanotoluidine.* $C^8H^8N^2 = C^7H^8N.CN$. (Hofmann, *loc. cit.* Chem. Soc. Qu. J. i. 170.)—When cyanogen is passed through an alcoholic solution of benzylamine, the red-brown solution deposits, after some hours, a crystalline mass, whence hydrochloric acid extracts cyanobenzylamine, which is precipitated by potash from the hydrochloric acid solution. It is homologous with cyanophenylamine, which it closely resembles, only being less soluble in alcohol or ether.

Melobenzylamine. Metoluidine. $C^{15}H^{17}N^3 = C^7H^9N.C^7H^8CyN$. (Wilson, *loc. cit.*)—When the vapour of chloride of cyanogen is passed over fused benzylamine, heat is evolved, and a resinous mass obtained, consisting of hydrochlorate of metoluidine; this is dissolved in water acidulated with hydrochloric acid, filtered, and mixed with potash; and the white precipitate thus produced, is boiled with potash, washed, and recrystallised from alcohol. Crystalline laminæ, sparingly soluble in cold, somewhat more in boiling water; crystallises best from a mixture of water and alcohol; readily soluble in hydrochloric acid: the solution gives with dichloride of platinum, a dark-yellow precipitate of *chloroplatinate*, which is insoluble in water or alcohol and may be dried at 100° C. It is homologous with melaniline (melophenylamine).

Secondary and Tertiary Amines containing Benzyl.

Benzylethylamine. Ethyltoluidine. $C^9H^{13}N = N.C^7H^7.C^2H^5.H$. (Morley and Abel, Chem. Soc. Qu. J. vii. 68.)—Benzylamine is heated with iodide of ethyl in a sealed tube for two or three days in a water-bath; the product freed from excess of iodide by heat; the resulting oil, which is hydriodate of benzylethylamine, distilled with strong potash, and the distillate rectified over solid potash. It is a colourless oil with a peculiar smell: specific gravity 0·9391 at 15°·5 C.; boils at 217° The *chloroplatinate* is a pale-yellow crystalline compound, soluble in water or alcohol, less so in ether: at 100° it becomes dark, and is decomposed. The *oxalate* and *sulphate* are crystalline.

Benzyldiethylamine. Diethyltoluidine. $C^{11}H^{17}N = N.C^7H^7.(C^2H^5)^2$.—Prepared in the same manner as the foregoing compound, benzylethylamine being substituted for benzylamine. A colourless, odorous oil: specific gravity 0·9242 at 15·5 C., boils at 229°. The *chloroplatinate* is a resinous non-crystalline mass. The *hydriodate* forms oily drops which crystallise when touched with a glass-rod; is very soluble in water, decomposes when exposed to the air, or in contact with alcohol.

Benzyltriethylium. $C^{13}H^{22}N = N.C^7H^7.(C^2H^5)^3$.—Known only in combination with acids. When benzyldiethylamine is heated with iodide of ethyl to 100° C. in a sealed tube till crystals are formed and excess of iodide of ethyl is removed by distillation, *iodide of benzyltriethylium* remains as a heavy oil. This is decomposed by heating with oxide of silver, yielding a solution of *hydrate of benzyltriethylium* $N.C^7H^7(C^2H^5)^3.H.O$, which is strongly alkaline, has a bitter taste, and precipitates most metallic salts. The *chloroplatinate* is insoluble in cold, soluble in hot water, whence it crystallises in fine needles; it loses platinum on recrystallisation.

Nitrobenzylamine. Nitrotoluidine. $C^7H^8N^2O^2 = N.C^7H^6NO^2.H^2$. (Cahours. Compt. rend. xxx. 320.)—Formed by the action of sulphide of ammonium on hydride of dinitrobenzene; it crystallises in yellow needles, forms definite compounds with nitric, hydrochloric, sulphuric, and phosphoric acids: yields alkalamides with the chlorides of benzene and cumyl.

Tribenzylamine. $C^{21}H^{21}N = N.(C^7H^7)^3$. (Cannizzaro, Cimento, iii. 397.)—When chloride of benzyl is heated with alcoholic ammonia to 100° C. in a sealed tube, ammonia passed into the cooled product, the resulting precipitate exhausted with ether, and the ethereal solution evaporated, this compound is obtained in shining laminæ, which melt at 91·3° C. to a colourless liquid, and at 360° volatilise with partial decomposition. It is sparingly soluble in cold water or alcohol, more so in boiling alcohol, still more in ether, forming alkaline solutions. The *hydrochlorate* crystallises in needles from hot water. The *chloroplatinate* forms orange-needles. F. T. C.

BENZYLENE. C^7H^6.—A hypothetical diatomic radicle, of which, according to Wicke (Ann. Ch. Pharm. cii. 356.) Cahours' chlorobenzol is the chloride. It has not been isolated; neither has its hydrate (benzylenic or benzolic alcohol,) $C^7H^6.H^2.O^2$, nor its oxide (benzylenic ether) C^7H^6O been obtained; the reason assigned by Wicke being that the former readily decomposes, yielding water and the latter compound, which in turn is readily converted into its isomer, hydride of benzoyl. Several compound ethers have, however, been obtained, representing the alcohol in which the 2 atoms of basic hydrogen are replaced by positive or negative organic radicles (see BENZYLENIC ETHERS). Hydrobenzamide $C^{21}H^{18}N^2$, should probably be regarded as a tertiary diamine containing this radicle. $N^2(C^7H^6)^3$. F. T. C.

BENZYLENE, CHLORIDE OF. *Chlorobenzol.* $C^7H^6Cl^2$. (Cahours (1848), Ann. Ch. Phys. [3] xxiii. 129. Wicke, Ann. Ch. Pharm. cii. 356.)—When hydride of benzoyl is brought into contact with a slight excess of pentachloride of phosphorus, a lively action takes place; and if, when this is over, a gentle heat be applied, oxychloride of phosphorus distils over at about 110° C., and chloride of benzylene at about 206°. The latter is washed with water, dried over chloride of calcium, and rectified. It is a colourless liquid, smelling faintly in the cold, but strongly when heated; insoluble in water, soluble in alcohol or ether: specific gravity 1·245 at 16°: vapour-density (expt.) 5·595; boils at 206°—208°. It is not oxidised by exposure to the air, or to oxygen. When heated in a water-bath with alcoholic *potash*, more slowly with aqueous potash to 100°, in a sealed tube, it yields chloride of potassium and hydride of benzoyl. *Ammonia*, whether dry, aqueous, or alcoholic, does not act upon it in the cold: when heated in a sealed tube to 100° with an ammonia-solution, it yields chloride of ammonium, and bitter-almond oil. It is not attacked by dry *cyanide of potassium* at 100°. Heated with alcoholic *sulphocyanate of potassium* to 100° in a sealed tube, it yields chloride of potassium, and an oil smelling like oil of mustard. Alcoholic *nitrate of silver* deprives it of all its chlorine, hydride of benzoyl being formed. Alcoholic *hydrosulphate of potassium* converts it into sulphide of benzylene.

Gerhardt (Traité, iii. 167) regards this compound as hydride of benzoyl in which oxygen is replaced by chlorine: Wicke, however, shows conclusively that it possesses none of the properties of an aldehyde. F. T. C.

BENZYLENE, SULPHIDE OF. *Sulphobenzol*, C^7H^6S. (Cahours, *loc. cit.*)—Formed by the action of alcoholic sulphydrate of potassium on chloride of benzylene, and recrystallised from boiling alcohol, in which it is readily soluble. White pearly scales, insoluble in water, which melt at 64° C. and crystallise on cooling: when further heated, it is partly volatilised, and partly decomposed. It is oxidised even by dilute nitric acid, with formation of sulphuric acid, and a substance soluble in alkalis, which crystallises in shining yellow scales. F. T. C.

BENZYLENE-PHENYLAMINE. *Benzosylanilide. Stilbylaniline.* $C^{13}H^{11}N = N.C^7H^6.C^6H^5$. (Laurent and Gerhardt, Compt. chim. 1850, 117.)—When perfectly dry hydride of benzoyl is mixed with about its own volume of perfectly dry phenylamine, water separates out, and a crystalline mass forms after a time (sometimes not until water is added): this is pressed between filter-paper, and recrystallised from hot alcohol, or purified by rectification. It forms beautiful shining laminæ, without taste or smell, insoluble in water, soluble in alcohol or ether. It is easily fusible, and boils at a very high temperature without decomposition. *Bromine* acts with violence on its alcoholic solution, forming after a time crystals of tribromophenylamine. With cold fuming *nitric acid*, it forms a dark-green solution, whence water precipitates hydride of benzoyl, nitrate of phenylamine remaining in solution: *sulphuric acid* decomposes it in a similar manner, forming a yellow solution. It becomes liquid by contact with *acetic* or *hydrochloric acid*: the latter dissolves it on boiling, without decomposition. It is scarcely attacked by boiling potash. F. T. C.

BENZYLENIC ETHERS. Salts or ethers of Benzylene. (Wicke, *loc. cit.*)

a. *Ethers containing a Positive Radicle.*

METHYLBENZYLENIC ETHER. *Methylate of Benzylene.* $C^9H^{12}O^2 = C^7H^6.(CH^3)^2O^2$.—A mixture of 1 at. chloride of benzylene with a solution of 2 at. sodium in absolute methylic alcohol, is heated for some hours, when chloride of sodium separates in abundance; the methylic alcohol is distilled off, and the residue mixed with water, when the ether rises to the surface, and is removed with a pipette, dried and rectified. It is a transparent, colourless liquid, heavier than water, with a pleasant smell like that of geraniums; insoluble in water, soluble in wood-spirit, alcohol, or ether. It boils at 208° C., leaving a brown residue arising from decomposition.

Ethylbenzylenic Ether. *Ethylate of Benzylene.* $C^{11}H^{16}O^2 = C^7H^6(C^2H^5)^2.O^2$.—Prepared precisely like the foregoing compound, ethylic being substituted for methylic alcohol. It boils at 222° C.: in other respects it resembles the methyl-compound.

Amylbenzylenic Ether. *Amylate of Benzylene.* $C^{17}H^{28}O^2 = C^7H^6.(C^5H^{11})^2.O^2$.—Prepared like the preceding compounds: but the ether must be separated by fractional distillation, not by addition of water. It is a slightly yellowish oil, smelling like fusel-oil, and lighter than water: it boils, not without considerable decomposition, about 292° C.

b. *Ethers containing Acid Radicles:*

The only one of these which has been obtained perfectly pure, and in the crystalline form, is

Acetobenzylenic Ether. *Acetate of Benzylene.* $C^{11}H^{12}O^4 = C^7H^6.(C^2H^3O)^2.O^2$—1 at. chloride of benzylene is triturated with rather more than 2 at. dry acetate of silver, and the mixture heated very gently in a flask; the reaction is so violent that it is well not to use more than 10 grm. silver-salt at a time. The product, when cool, is repeatedly extracted with ether; the extracts are distilled in the water-bath; and the yellowish oily residue is washed with weak soda-solution and with water, then redissolved in ether, and left to evaporate. A viscid oil is thus obtained, in which crystals gradually form, until at last it solidifies completely. It forms small white shining crystals, belonging to the monoclinic system, insoluble in water, soluble in alcohol or ether, whence it separates on evaporation as an oil, which often does not crystallise till agitated. It melts at 36° C., and crystallises on cooling: begins to boil at 190°, the temperature gradually rising to 240°, and yields a distillate consisting of acetic anhydride and hydride of benzoyl. Heated with aqueous potash or dilute sulphuric acid, to 100° in a sealed tube, it is converted into acetic acid and hydride of benzoyl: with aqueous ammonia under the same circumstances, it yields acetamide and hydrobenzamide.

Benzobenzylenic Ether. *Benzoate of Benzylene.* $C^{21}H^{16}O^4 = C^7H^6.(C^7H^5O)^2.O^2$.—Chloride of benzylene acts violently on benzoate of silver, with evolution of heat: the ethereal extract of the product yields on evaporation a viscid, brown, non-crystallisable mass. With alcoholic potash it forms immediately a solid mass of potassic benzoate, mixed with hydride of benzoyl.

Succinobenzylenic Ether. *Succinate of Benzylene.* $C^{11}H^{10}O^4 = C^7H^6.C^4H^4O^2,O^2$.—Prepared like the foregoing compounds: its ethereal solution is decomposed by evaporation or by washing with dilute soda, into succinic acid and hydride of benzoyl.

Sulphobenzylenic Ether. *Sulphate of Benzylene.* $C^7H^6SO^4 = C^7H^6SO^2.O^2$.—Prepared in the same manner. It is a red-brown, non-crystallisable oil.

Valerobenzylenic Ether. *Valerate of Benzylene.* $C^{17}H^{24}O^4 = C^7H^6.(C^5H^9O).\,^2O$.—Obtained like the acetate. On evaporating its ethereal solution, it remains as a thick, yellow, non-crystallisable oil, which is decomposed by distillation into valerianic acid and hydride of benzoyl.

Chloride of benzylene acts so violently on oxalate of silver, that no definite product can be obtained.

F. T. C.

BENZYLETHYLAMINE. BENZYLDIETHYLAMINE. BENZYLTRIETHYLIUM. (See Benzylamine.)

BENZYLIC ALCOHOL. *Hydrate of Benzyl. Benzoic Alcohol. Toluylic Alcohol.* $C^7H^8O = C^7H^7.H.O$. (Cannizzaro [1853], Ann. Ch. Pharm. lxxxviii. 129; xc. 252; xcii. 113; xcvi. 246; Scharling, *ibid.* xcvii. 168.)—Formed: 1. By the action of alcoholic potash on hydride of benzoyl:

$$2C^7H^6O + KHO = C^7H^8O + C^7H^5KO^2.$$

When a mixture of pure hydride of benzoyl with its own volume of absolute alcohol is mixed with 3—4 vols. alcoholic potash, of specific gravity 1·02, heat is evolved, and the whole solidifies to a crystalline magma. The potassic benzoate is dissolved out with hot water, the alcohol distilled off, the residue mixed with water till it begins to be turbid, and then shaken up with ether. The brown oily residue obtained by evaporating the ethereal solution, is dried over fused potash, and repeatedly rectified.—2. When acetate of benzyl, obtained by boiling chloride of benzyl with alcoholic acetate of potassium, is boiled with strong alcoholic potash, and the alcohol distilled off, the residual liquid separates into two layers, the upper of which contains benzylic alcohol, which is separated by fractional distillation.—3. Scharling has shown that the substance known as *peruvin*, obtained by the action of potash on cinnamein, is benzylic alcohol.

It is a colourless, strongly-refracting oil, with a faint pleasant smell: specific gravity 1·051 at 14°·4 C., 1·063 at 0° (Kopp): vapour-density (expt.) 3·85: boils at 206°·5, under pressure of 751·4 mm. (Kopp.) It is insoluble in water: soluble in all proportions in alcohol, ether, acetic acid, or bisulphide of carbon.

When its vapour is passed through a red-hot tube filled with spongy platinum, benzene with other compounds is formed. It is converted into hydride of benzoyl by *oxygen*, in presence of platinum-black, or by *nitric acid:* aqueous *chromic acid* converts it into benzoic acid. With strong *sulphuric acid*, *phosphoric anhydride*, or *chloride of zinc*, it yields a brown resin, insoluble in water, alcohol, or ether (probably stilbene). Fused *boric anhydride* converts it at 100°—120° C. into benzylic ether, at a higher temperature into stilbene (or benzylene?): with *fluoride of boron*, it yields the same product. Distilled with strong alcoholic potash, it yields hydride of benzyl (*q. v.*)

F. T. C.

BENZYLIC ETHER. $C^{14}H^{14}O = (C^7H^7)^2.O$. (Cannizzaro, Ann. Ch. Pharm. xcii. 115.)—Fused and pulverised boric anhydride is mixed into a paste with benzylic alcohol; the mixture is heated for some hours to 120°—125° C.; and the resulting hard brown mass is treated with water and a solution of alkaline carbonate, when a greenish-brown oil rises to the surface. When this is distilled, benzylic alcohol passes over below 300°, and benzylic ether at 300°—315°: the residue contains stilbene. Benzylic ether is a colourless, slightly fluorescent oil, boiling at 300°—315°. When heated above its boiling-point, it becomes yellow and is decomposed, yielding resinous stilbene, hydride of benzoyl, and a light oil, which is probably hydride of benzyl. With phosphoric anhydride or sulphuric acid, it yields the same product as benzylic alcohol.

Ethyl-benzylic Ether. $C^9H^{12}O = C^7H^7.C^2H^5.O$. (Cannizzaro, Cimento, iii. 397.)—Chloride of benzyl is distilled upwards with alcoholic potash, and the resulting liquid is decanted from the chloride of potassium, and mixed with water, when it separates into two layers: the upper of these is distilled, and the portion which comes over at 185° C. dried over chloride of calcium and rectified. Colourless, mobile liquid, with a pleasant smell; lighter than, and insoluble in, water: boils at 185°.

For the compound benzylic ethers containing acid radicles, see ACETIC and BENZOIC ACIDS.

F. T. C.

BERAUNITE. A hydrated sesquiphosphate of iron occurring at St. Benigna in the circle of Beraun in Bohemia, together with cacoxene and Dufrenite. It forms radiated or laminar masses, with perfect cleavage in one direction; imperfect at right angles to the first. Specific gravity 2·878. Hardness 2·0 to 2·5. Rather brittle.

BERBERINE. $C^{21}H^{19}NO^5$ (?)* An organic base discovered in 1837, by Buchner (Ann. Ch. Pharm. xxiv. 228), in the root of the barberry (*Berberis vulgaris*), and since found in other species of Berberis growing in Mexico and in India. It has also been obtained by Bödeker (Ann. Ch. Pharm. lxvi. 384; lxix. 40), from colombo-root (*Cocculus palmatus*); by Perrins (Ann. Ch. Pharm. lxxxiii. 276), from the colombo-root of Ceylon (*Menispermum fenestratum*); and by Stenhouse (Pharm. J. Trans. xiv. 455), in a yellow bark used as a dye by the natives of Abeoconta in West Africa.

Preparation. a. *From Barberry-root.*—The root is exhausted with boiling water; the extract concentrated by evaporation, and treated with warm alcohol of 82 per cent.; the solution filtered; the greater part of the alcohol distilled off; and the residue left to itself in a cool place. Yellow crystals of berberine are then deposited, and may be purified by recrystallisation from boiling water or alcohol. The root contains about 1·3 per cent. of berberine. (Buchner.)

b. From Colombo-root. — The dried alcoholic extract of the root is treated with hot water; the filtered solution neutralised with hydrochloric acid; and the liquid again filtered, treated with excess of hydrochloric acid, and left at rest for some days. It then deposits a crystalline sediment of hydrochlorate of berberine, which is dissolved in a small quantity of alcohol and reprecipitated by ether (Bödeker). For further purification, the hydrochlorate is converted into a sulphate; this salt is recrystallised and dried at 100° C.; the aqueous solution decomposed by baryta-water; the excess of baryta removed by passing a stream of carbonic acid through the liquid, then filtering, evaporating nearly to dryness, and digesting the residue in alcohol. The alcoholic solution is then precipitated by ether, and the precipitated berberine recrystallised from water. The same mode of purification may be adopted with berberine obtained from barberry-root. (Fleitmann, Ann. Ch. Pharm. xxiv. 228.)

Properties.—Small silky needles or concentrically grouped prisms of a light yellow colour. Odourless, but has a strong and persistently bitter taste. Sparingly soluble in water and alcohol when cold; easily at the boiling heat; insoluble in ether. Oils, both fatty and volatile, dissolve it in small quantity.

The crystals heated to 100° C. give off 19·26 per cent. (5 at.) water of crystallisation, and the residue contains 66·7 to 67·4 carbon, and 5·6 to 5·7 hydrogen, agreeing

---

* Or rather $C^{20}H^{17}NO^4$ (Perrins, Chem. Soc. J. xv. 339). See APPENDIX.

nearly with the formula $C^{21}H^{19}NO^5.\frac{1}{2}H^2O$, or $C^{42}H^{19}NO^{10}.HO$ (Fleitmann). The remaining water cannot be expelled without further decomposition. According to Fleitmann, the anhydrous salts of berberine contain the group $C^{42}H^{18}NO^9$ associated with acids: *e.g.* the hydrochlorate = $C^{42}H^{18}NO^9.HCl$; berberine dried at 100° is $C^{42}H^{18}NO^9.2HO$, and the crystals contain $C^{42}H^{18}NO^9.2HO + 10\,aq$. These formulæ are, however, by no means probable, and further examination is required to determine the rational constitution of the base. The formula $C^{21}H^{19}NO^5$ or $C^{42}H^{19}NO^{10}$ is that suggested by Gerhardt (Traité, iv. 205).

Berberine melts at 120° C. to a resinous mass, without loss of weight. Between 160° and 200° C. it gives off yellow odorous vapours, which condense into a solid body insoluble in water, but very soluble in alcohol, and leaves an abundant residue of charcoal. Ammonia colours berberine yellow-brown, and dissolves it in nearly the same proportions as water. Berberine boiled with caustic potash-ley melts, and is converted into a resinous substance, sparingly soluble in water, easily in alcohol. According to Bödeker, berberine distilled with milk of lime or hydrate of lead, yields chinoline.

The *salts of berberine* are, for the most part, sparingly soluble in water; many of them may be prepared by treating the hydrochlorate with a salt of potassium. *Hydrochlorate of berberine*, $C^{21}H^{19}NO^5.HCl + 2H^2O$, crystallises in slender yellow needles, which give off their water of crystallisation (8·65 per cent.) at 100° C. With sulphide of ammonium containing excess of sulphur, it forms a fœtid brown-red precipitate containing sulphur. A hot alcoholic solution of the hydrochlorate mixed with a concentrated alcoholic solution of glycocine, yields on cooling, a mass of slender orange-coloured needles, sparingly soluble in water, which appear to contain $C^{21}H^{19}NO^5.HCl.C^2H^5NO^2$(?) The *chloroplatinate of berberine*, $C^{21}H^{19}NO^5.HCl.PtCl^2$ (?) is a yellow precipitate nearly insoluble in water. The *chlorate*, $C^{21}H^{19}NO^5.HClO^3$ (?) is a bulky yellow precipitate obtained by mixing the hydrochlorate with chlorate of potassium. It is moderately soluble in pure water, sparingly soluble in saline liquids. The acid *chromate*, $C^{21}H^{19}NO^5.Cr^2H^2O^4$ (?) is a bulky yellow precipitate, sparingly soluble in water, obtained by mixing the hydrochlorate with acid chromate of potassium. It is very soluble in hydrochloric and sulphuric acids. When strongly heated, it decomposes suddenly, yielding a large quantity of the yellow substance produced in the dry distillation of berberine. *Nitrate of berberine* forms yellow crystals sparingly soluble in cold water. The *acid sulphate*, $C^{21}H^{19}NO^5.SO^4H^2$(?) is deposited after a while in small yellow crystals on adding sulphuric acid to a dilute solution of the hydrochlorate.

BERENGELITE. *Berengela resin.*—A bituminous mineral found in the province of St. Juan de Berengela in Peru, about one hundred miles from Arica, where it occurs in amorphous masses of considerable extent, forming a sort of pitch-lake, like that of Trinidad (p. 426). It has a conchoïdal fracture, a dark brown colour, inclining to green, and waxy lustre; yields a yellow powder; has a resinous unpleasant odour and a rather bitter taste. Melts below 100° C., and after cooling remains soft and unctuous at ordinary temperatures. It dissolves readily in cold alcohol and in ether. It is used for caulking ships. According to Johnston's analysis (Phil. Mag. [3] xiv. 87), its formula is $C^{20}H^{30}O^4$.

BERESITE is a fine-grained granite containing pyrites, occurring at Beresowsk in the Ural, in the rocks in which the gold veins are found.

BERGAMOT, OIL OF. A volatile oil obtained by pressing the rind of a variety of orange, *Citrus bergamia*, cultivated in the south of Europe. The oil thus obtained is light-yellow or sometimes greenish or brownish-yellow; mobile, with a very agreeable odour and aromatic somewhat bitter taste. Specific gravity 0·869. It generally exhibits an acid reaction, arising from the presence of a small quantity of acetic acid. It solidifies a little below 0° C., and at ordinary temperatures deposits, after a while, a solid camphor or stearoptene.

Bergamot-oil is a mixture of two essential oils, the more volatile of which is isomeric with oil of turpentine and oil of lemon, $C^{10}H^{16}$; but it is difficult to separate this oil by simple distillation.

The less volatile portion which, when rectified, boils at 183° C. and has a density of 0·856, contains oxygen, and according to Ohme (Ann. Ch. Pharm. xxxi. 316), has the composition of a hydrate of oil of lemon, $3C^{10}H^{16}.2H^2O$. According to Soubeiran and Capitaine (J. Pharm. xxvi. 68, 509), this portion of the oil is not of constant composition, but yields by fractional distillation, oils continually increasing in amount of oxygen, from 3·37 to 16·14 per cent. (perhaps the oil was oxidised during the distillation). They find also that the first portions turn the plane of polarisation of a luminous ray to the right, but that the subsequent portions exhibit less and less of this power, and finally none.

Ohme's rectified bergamot-oil is not altered by caustic potash. Its vapour passed over red-hot lime yields a large quantity of benzene. It absorbs hydrochloric acid gas abundantly, forming a liquid compound, which, after being shaken up and distilled with water, has the specific gravity 0·896; boils at 183° C., and contains $C^{60}H^{100}Cl^2O$, or $6C^{10}H^{16}.2HCl.H^2O$.

Bergamot-oil placed in contact with phosphoric anhydride becomes heated, and afterwards yields by distillation an oil smelling like oil of turpentine, and having exactly the composition $C^{10}H^{16}$. The residue of the distillation contains a conjugated acid, *phosphobergamic acid*, which forms soluble salts with calcium and lead.

BERGAMOT-CAMPHOR, *Bergaptene*, *Stearoptene of bergamot-oil*, is a solid substance deposited by crude oil of bergamot after long keeping. It crystallises in needles, melts at 206° C., and volatilises without decomposition. It is odourless and dissolves in boiling water, alcohol, and ether. Strong sulphuric acid colours it red. Heated with nitric acid, it yields oxalic acid. It gives by analysis about 66·2 per cent. carbon and 3·8 hydrogen, numbers answering to the formula $C^3H^6O^2$, but the rational formula is not yet determined. (Mulder, Ann. Ch. Pharm. **xxxi.** 70; Ohme, *loc. cit.*)

BERTHIERIN. The name given by Beudant to a ferruginous mineral occurring in small grains, resembling iron-spar or brown iron ore; but whether it is a definite species or a mixture is not decidedly known. According to Berthier, it contains 12·4 per cent. silica, 74·7 protoxide of iron, 7·8 alumina, and 5·1 water. The same name is also applied to a mineral from Hayanges near Metz, of greyish-green or liver-brown colour, which, under the microscope, appears like an oolitic rock, consisting of a greenish amorphous mass, containing innumerable small flattened needles of brown iron ore.

BERTHIERITE or **HAIDINGERITE.** These names are applied somewhat indiscriminately to three minerals, containing protosulphide of iron, together with trisulphide of antimony.—*a.* $3Fe^2S.2Sb^2S^3$. Found at Chazelles in Auvergne, crystalline or massive, with imperfect cleavage in several directions. Specific gravity 4·284: hardness 2·0 to 3·0. Iron-black or dark steel-grey. Opaque with metallic lustre. Fuses readily before the blowpipe on charcoal, yielding antimonial fumes and deposit, and leaving a black magnetic slag (Berthier, Ann. Ch. Phys. [2] **xxxv.** 351).—*b.* $3Fe^2S.4Sb^2S^3$. Found in a mine near Chazelles. Fibrous, with granular transverse fracture, almost destitute of lustre (Berthier, Pogg. Ann. **xxix.** 458).—*c.* $Fe^2S.Sb^2S^3$ or $FeSbS^2$. Found at Anglar in the Département de la Creuse. Crystalline, composed of fine parallel fibres. Steel-grey, inclining to bronze (Berthier). Minerals having this composition are also found in other localities.

BERTHOLLETIA EXCELSA. A Brazilian tree belonging to the order *Lecythidaceæ.* The kernels of the fruit, called Brazilian or Pava nuts, contain sugar, gum, and a pale yellow odourless fat oil, which solidifies at 0° C., and contains stearin, palmitin, and elain. (Caldwell, Ann. Ch. Pharm. xcviii. 120.)

BERYL. $3Gl^2O . Al^4O^3 . 6SiO^2$ $Si^3G^3Al^2O^9$.—A mineral species comprising several varieties, among which are found two very beautiful and costly gems, viz. *emerald*, and *aquamarine* or *precious beryl.* The crystals belong to the hexagonal system, being regular six-sided prisms variously modified, sometimes by the truncation of the lateral edges, at other times of the terminal edges. The most ordinary combinations are ∞P . oP and ∞P . oP . P. (*fig.* 98); sometimes, however, much more complicated modifications occur, like *fig.* 99, composed of the hexagonal prism ∞P. the terminal face oP, the primary hexagonal pyramid P, a sharper hexagonal pyramid of the first order 2P, a pyramid of the second order 2 P 2, and a symmetrical 12-sided pyramid 3 $P\frac{3}{2}$, whose faces (denoted in the figure by *z*) replace the combination-edges between 2P2, and ∞P. The prismatic faces are often deeply striated in the vertical direc-

Fig. 98.

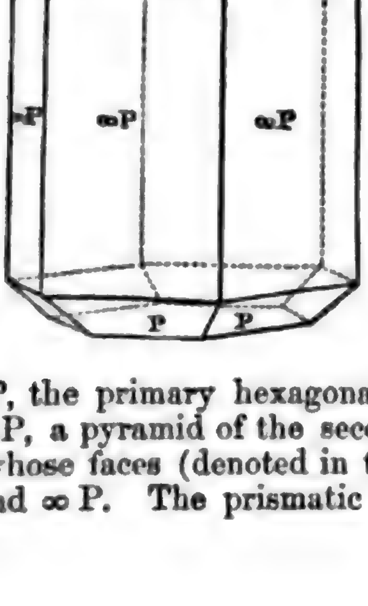

Fig. 99.

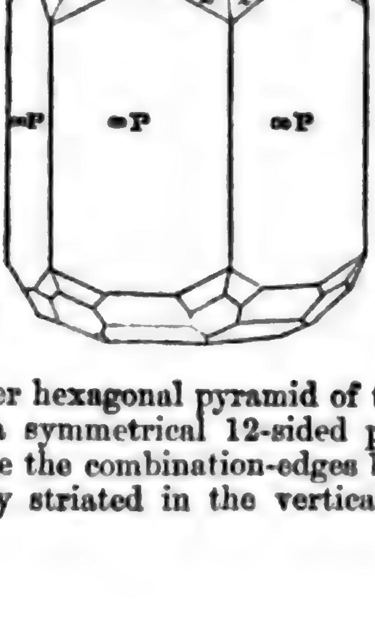

tion. Cleavage tolerably perfect, parallel to oP. Fracture conchoïdal and uneven. Specific gravity 2·67 to 2·76. Hardness 7·5 to 8·0. The most usual colour of the beryl is green, of various shades between yellow- and blue-green, arising from the presence of iron in various stages of oxidation; yellow, blue, rose-coloured, and colourless beryls are also found. The brilliant green of the emerald is due to the presence of oxide of chromium. Lustre vitreous. The best specimens of emerald and aquamarine are perfectly transparent; but the transparency is generally greatly diminished by cracks and striæ, the coarser varieties being opaque in the mass and translucent only at the edges. Beryl is difficult to fuse by itself before the blowpipe, melting to a glass at the edges only; with borax it fuses readily to a transparent glass; with phosphorus-salt, it leaves a skeleton of silica.

Beryl from Limoges was found by C. Gmelin to contain 67·54 SiO^2, 17·63 Al^4O^3, and 13·51 Gl^2O (= 98·68); a specimen from Fahlun, analysed by Berzelius, gave 68·35 SiO^2, 17·60 Al^4O^3, 13·13 Gl^2O, 0·72 Fe^4O^3 and 0·72 TaO^2. These and numerous other analyses agree nearly with the formula above given (calc. 67·46 SiO^2, 18·74 Al^4O^3, 13·80 GlO), which, by substituting $al = \frac{2}{3}Al$, may be reduced to that of a metasilicate $(Gl\mathit{al})\,SiO^3$.

Beryls are found in various parts of the world; the finest emeralds come from Peru, where they are found traversing clay-slate, hornblende slate, and granite; fine specimens are also obtained from Katharinenburg in Siberia; inferior varieties from the Heubach valley in the district of Pinzgau in Salzburg; varieties are also found in some old mines in Mount Zabarah in Upper Egypt, from which spot the ancients are supposed to have derived their emeralds. Fine transparent beryls or aquamarines are found in Brazil, in the granite district of Nertschinsk in Siberia, in the Ural and Altai mountains, and in the granite of the Morne mountains in the county of Down, Ireland. Opaque beryls, sometimes of very large size, are found at Langenbilau in Silesia; at Bodenmais in Bavaria, near Limoges in France; at Kinloch, Runnoch, and Cairngorm, Aberdeenshire; and in the counties of Dublin and Wicklow. Between the Connecticut and Marimac rivers, near Crofton in North America, enormous specimens have been found, measuring from 4 to 6 feet in length, and weighing between 2000 and 3000 pounds.

BERYLLIUM. Syn. with GLUCINUM.

BERZELIANITE. Selenide of Copper.

BERZELIITE. *Berzelite, Kühnite, Chaux arseniatè anhydre, Magnesian Pharmacolite.* $As^2(Mg^3Ca^3)O^8$.—A massive mineral occurring near Langbanshytta in Sweden. It has an uneven fracture, and exhibits traces of cleavability in one direction. Yellowish-white to honey-yellow, with waxy lustre; translucent on the edges. Perfectly soluble in nitric acid. Before the blowpipe, it exhibits the usual reactions of arsenic, and with soda shows evidence of a trace of manganese. (Kühn, Ann. Ch. Pharm. xxxiv. 271.)

BERZELIN. A mineral found in the older volcanic ejections near Lake Albano in Italy, together with hauyne, augite, and mica. It crystallises in octahedrons or dodecahedrons, belonging to the regular system, sometimes forming twin-crystals; cleavage tolerably distinct, parallel to the faces of a cube. The crystals are often uneven and rounded. It occurs also in spherical and stalactitic forms, massive and imbedded. Fracture varying from conchoïdal to uneven; colour white or grey; lustre vitreous to dull; varies from transparent to perfectly opaque; streak white; hardness 5·0; specific gravity 2·428 to 2·727. According to an imperfect analysis by L. Gmelin, its composition is similar to that of leucite. When pulverised and ignited, it yields a small quantity of water. Melts with difficulty before the blowpipe to a tumefied glass; with borax readily to a clear glass. Dissolves slowly in nitric acid, yielding a jelly of silica when heated. Similar crystals have been found in nephelin-dolerite from Meiches in Oberhessen. (Handw. d. Chem. ii. [1] 1023.)

The same name has been applied to native selenide of copper.

BERZELITE. This name has been given to Mendipite, Petalite, Thorite, and Berzeliite.

BETA. *Beet.*—A genus of plants, belonging to the natural order Chenopodiaceæ, distinguished by the large quantity of sugar contained in their roots. The three principal species are:—1. *Beta vulgaris*, common beet, well known for its sweet crimson roots, which are used as a salad.—2. *Beta cycla*, chard beet, inferior in the size and flavour of its roots, but distinguished by its remarkably thick-ribbed leaves, which are used in France in soups; or the ribs only are cut out and stewed like sea-kail.—3. *Beta altissima*, field-beet or mangold-wurzel, sometimes, though erroneously, regarded as a hybrid between the two former. This is by far the most important species, as it is extensively cultivated for feeding cattle, and in France and Germany also for the extraction of sugar.

The root of mangold-wurzel contains crystallisable sugar, identical in every respect with cane-sugar. Payen gives for the average composition of the root, 83·5 per cent. water, 10·5 sugar, 0·8 cellular substance and pectose, 1·5 nitrogenous matter (albumin, &c.), and 3·7 pectin and salts. The salts consist of nitrates and ammonium-salts, together with alkaline and earthy phosphates, sulphates, chlorides, oxalates and malates, or, according to some chemists, citrates. The root has also been stated to contain two or three peculiar acids, which have not been thoroughly examined. The dried leaves contain, according to Sprengel, 15·44 per cent. ash. The seed contains 11·6 per cent. water, and in 100 pts. of dry substance, 0·09 sulphur and 6·58 ash. (Way and Ogston.)

The following table exhibits the composition of the ash of the seed, leaves, and roots:—

	Ash of seed.	Ash of leaves.	Ash of roots.	
	Way.	Ogston.	Sprengel.	Ettl.
Potash (anhydrous) . . .	16·1	36·3	23·9	19·5—26·6
Soda " . . .	6·8	21·3	53·1	22·4—30·5

Chloride of sodium . . .	15·3			

BETULIN. $C^{48}H^{64}O^{3}$.—A resinous substance extracted from the outer bark of the birch-tree (*Betula alba*), or from the tar prepared therefrom. It was discovered by Löwitz (Crell. Chem. Ann. 1788, i. 302), and analysed by Hess (J. pr. Chem. xvi. 161). It belongs to the series of resins, including sylvic acid, which are produced by oxidation from hydrocarbons of the form $C^{5n}H^{8n}$. To extract it, the dried bark is exhausted with boiling water, then dried again and treated with boiling alcohol. The solution on cooling deposits the betulin, which is pressed, dried, and recrystallised from ether. It forms small crystalline nodules, which melt at about 200° C. The melted matter is colourless and transparent, and gives off vapours which smell like the bark when heated. It may be distilled in a current of air. It is not dissolved by alkalis.

BETULORETIC ACID. According to Kossmann (J. Pharm. [3] xxiv. 197) birch-resin consists of an acid, $C^{36}H^{66}O^{5}$, which is converted by nitric acid into picric acid, but is not decomposed by sulphuric acid.

BEUDANTIN. See NEPHELIN.

BEUDANTITE. A ferruginous mineral occurring at Horhausen and Montabaur in Nassau, and near Cork in Ireland. It crystallises in rhombohedrons cleavable parallel to the base, and having the rhombohedral faces horizontally striated. Colour black to olive-green. Streak light green. The fresh crystals have a waxy lustre. Hardness above 4·0. The Nassau mineral has a specific gravity of 4·0018, and melts readily before the blowpipe (Sandberger). The Irish variety has a specific gravity of 4·295, and is infusible (Rammelsberg). It contains sulphate of lead, associated with ferric sulphate, arsenate, and phosphate, the two latter replacing each other isomorphously; it also contains water (Pavy, Phil. Mag. [3] xxxvii. 161). According to Rammelsberg, it is $2(Pb^{2}O.SO^{3}) + Fe^{4}O^{3}.SO^{3} + 3Fe^{4}O^{3}.P^{2}O^{5} + 9H^{2}O$; according to Sandberger, $Pb^{2}O.SO^{3} + 3Pb^{2}O(As^{2}O^{5}; P^{2}O^{5}) + 3[3Fe^{4}O^{3}(As^{2}O^{5}; P^{2}O^{5})] + 24H^{2}O$. (Handw. d. Chem. ii. 1029.)

BEZETTA. *Tournesol en drapeaux. Schminkläppchen. Bezetta rubra et cærulea.*—A dye or pigment prepared by dipping linen rags in solutions of certain colouring matters. Red bezetta is coloured with cochineal, and is used as a cosmetic.

Blue bezetta (*Tournesol en drapeaux*), which is chiefly used for colouring the rind of Dutch cheeses, is prepared at Gallargues near Nîmes in the department of Gard, from a euphorbiaceous plant, *Chrozophora tinctoria* or *Croton tinctoria*. The fruits and the tops of the plants are gathered, and the juice being expressed, rags of coarse cloth are dipped into it, then dried, and afterwards exposed to the fumes of mules' or horses' dung. This last operation is called *aluminadou*. The cloths are turned from time to time, to ensure uniform coloration and prevent any part from being exposed too long to the fumes of the dung, which would turn them yellow. They are then dried a second time, again soaked in the juice, mixed this time with urine, and lastly exposed for some time to the action of the sun and wind. The quantity thus manufactured amounts to about 50 tons yearly. The blue of bezetta is reddened by acids, like litmus, though not so quickly, but differs from the latter in not being restored by alkalis. According to Joly, the same dye may be obtained from other euphorbiaceous plants, *Chrozophora oblongata*, *C. plicata*, *Croton tricuspidatum*, *Mercurialis perennis*, and *M. tormentosa*. The juice exists in all these plants in the colourless state, and turns blue only on exposure to the air. (Handw. d. Chem. ii. [1] 1030; Gerh. Traité, iii. 820.)

BEZOAR. This name, which is derived from a Persian word implying an antidote to poison, was given to a concretion found in the stomach or intestines of an animal of the goat kind, *Capra ægragus*, which was once very highly valued for this imaginary quality, and has thence been extended to all concretions found in animals.

According to Taylor (Phil. Mag. No. 186 p. 36 and No. 186 p. 192), bezoars may be divided into nine varieties:—1. Phosphate of calcium, which forms concretions in the intestines of many *mammalia*.—2. Phosphate of magnesium: semitransparent and yellowish, and of specific gravity 2·160.—3. Phosphate of ammonium and magnesium: a concretion of a grey or brown colour, composed of radiations from a centre.—4. Oxalate of calcium.—5. Vegetable fibres.—6. Animal hair.—7. Ambergris.—8. Lithofellic acid.—9. Ellagic or bezoardic acid.

Of true bezoars there are three kinds, *oriental*, *occidental*, and *German*. The true oriental bezoars found in the *Capra ægragus*, the gazelle (*Antilope Dorcas*), and other ruminant animals, are spherical or oval masses, varying from the size of a pea to that of the fist, and composed of concentric layers of resinous matter with a nucleus of some foreign substance, such as pieces of bark or other hard vegetable matter which the animal has swallowed. They have a shining resinous fracture, are destitute of taste and odour, nearly insoluble in water and aqueous hydrochloric acid, but soluble for the greater part in potash-ley. When heated, they emit an agreeable odour and burn away, leaving but a small quantity of ash. These characters suffice to distinguish the oriental bezoars from those varieties which contain a considerable quantity of inorganic matter. There are two kinds of them, the one consisting of ellagic, the other of lithofellic acid. The latter have a more waxy lustre and greener colour than the former, and are also distinguished by their smaller specific gravity, viz. 1·1, while that of the ellagic acid stones is 1·6. They contain, besides lithofellic acid, a substance resembling the colouring matter of bile, and are perhaps biliary calculi. Oriental bezoars are greatly prized in Persia and other countries of the East for their supposed medicinal properties. The Shah of Persia sent one in 1808 as a present to Napoleon.

The occidental bezoars are found in the lama (*Auchenia Lama*), and in *A. Vicunna*: they resemble the oriental in external appearance, but differ totally in their chemical characters, inasmuch as they consist chiefly of phosphate of calcium, with but little organic matter.

German bezoars, which are chiefly obtained from the chamois or gemsbock (*Antilope rupicapra*), consist chiefly of interlaced vegetable fibres or animal hairs bound together by a leathery coating.

BEZOARDIC ACID. Syn. of Ellagic Acid.

BEZOARDICUM ANIMALE. An antiquated medicament made from the dried hearts and livers of vipers, and supposed to be an antidote against poison: hence its name.

BEZOARDICUM MINERALE. A name applied by the older chemists to antimonic acid, especially to that prepared from butter of antimony by the action of nitric acid.

BI-COMPOUNDS. See Di-Compounds and Nomenclature.

BILDSTEIN. Syn. with Agalmatolite.

BILE. *Gall. Galle.* (Lehmann, "Physiological Chemistry," Cavendish Society's Edition, ii. 61; also Gmelin's Handbuch, viii. 38. Strecker, Ann. Ch. Pharm. lxv. 1; lxvii. 1; lxx. 149. Gundelach and Strecker, *ibid.* lxii. 205).—Bile, as secreted by the cells of the liver, is taken up by the biliary ducts, which unite to form the hepatic duct, by which the secretion is either discharged directly into the duodenum, or is conveyed through the cystic duct into the gall-bladder, wherein it becomes accumulated and to some extent inspissated. Cystic bile when taken from a healthy animal recently killed, is a mucous, transparent, ropy liquid, of green or brown colour. It has a bitter but not astringent taste, sometimes leaving a sweetish after-taste, and a peculiar odour, which, when the bile is warmed, is often very much like that of musk.

Its specific gravity is about 1·02. It does not diffuse itself readily through water, unless the mixture be stirred. Its reaction is, for the most part, faintly alkaline, sometimes neutral, never acid, excepting in peculiar states of disease. Bile in its ordinary state, before the mucus is removed, putrefies very readily; but when freed from mucus, it is much less prone to putrefactive decomposition.

The chemical composition of bile varies to a certain extent according to the nature of the animal which yields it; but every kind of bile contains two essential constituents, viz. a resinous and a colouring matter, associated with small quantities of cholesterin, fats, salts of fatty acids, and certain mineral salts, chiefly chloride of sodium and phosphates, with smaller quantities of phosphate and carbonate of sodium, phosphate of calcium, phosphate of magnesium, and extremely minute quantities of iron and manganese, but no alkaline sulphates. No salts of ammonia are found in fresh healthy bile, but during the putrefaction of bile, ammonia is produced. Bile also contains mucus mixed with cells of epithelium.

The *resinous matter of bile* is the most abundant and important of its constituents. It consists, in nearly all cases, of the sodium or potassium salts of two nitrogenised acids, one containing sulphur, the other free from that element. The former of these acids, called taurocholic acid, is resolved by the action of alkalis into *taurine* and *cholic acid*, a crystalline acid containing neither nitrogen nor sulphur, and changing, under certain circumstances, into an amorphous isomeric acid called choloidic acid, differing from it only by the elements of water:

$$\underset{\substack{\text{Taurocholic}\\\text{acid.}}}{C^{26}H^{45}NSO^7} + H^2O = \underset{\substack{\text{Cholic}\\\text{acid.}}}{C^{24}H^{40}O^5} + \underset{\text{Taurine.}}{C^2H^7NSO^3};$$

and the latter, called glycocholic acid, is resolved in like manner into cholic acid and *glycocine:*

$$\underset{\substack{\text{Glycocholic}\\\text{acid.}}}{C^{26}H^{43}NO^6} + H^2O = \underset{\substack{\text{Cholic}\\\text{acid.}}}{C^{24}H^{40}O^5} + \underset{\text{Glycocine.}}{C^2H^5NO^2}$$

All kinds of bile, excepting that of the pig, contain one or both of these acids. Pig's bile contains an acid called glyco-hyocholic acid, analogous to glycocholic acid, and, like that compound, resolvable by the action of alkalis into glycocine and hyocholic acid, an acid not containing nitrogen:

$$\underset{\substack{\text{Glycohyo-}\\\text{cholic acid.}}}{C^{27}H^{43}NO^5} + H^2O = \underset{\substack{\text{Hyocholic}\\\text{acid.}}}{C^{25}H^{40}O^4} + \underset{\text{Glycocine.}}{C^2H^5NO^2}.$$

The *colouring matter of bile*, *bile-pigment*, or *cholochrome*, is also a nitrogenised acid, and is decomposed by nitrous acid, with evolution of nitrogen and formation of a crystallised acid, *cholochromic acid*, which is free from nitrogen. (Thudichum, Chem. Soc. Qu. J. xiv. 114.)

The bile of carnivorous and omnivorous animals, including man, contains a brown pigment, the *cholepyrrhin* of Berzelius: that of birds, fishes, and amphibia has usually an intense green pigment, *biliverdin*. The brown pigment is always combined either with soda or with lime; in the latter case, it is insoluble, and appears in the form of brown granules when the bile is examined by the microscope.

The analysis of bile is conducted as follows:

The bile is first mixed with half its volume or more of 83 per cent. alcohol, which throws down mucus and epithelium; the precipitate is rinsed with spirit, then with water, afterwards dried and weighed.

The bile thus freed from mucus, is evaporated to dryness, first over the water-bath and then under the air-pump on a sand-bath heated to 100° C.; the residue is left to cool in vacuo, after which, air dried by passing over chloride of calcium is introduced into the receiver, and the weighing is completed as quickly as possible, because the dried bile is extremely hygroscopic.

The residue is next digested for a considerable time with *ether*, which takes up fat and cholesterin. The total quantity of these matters may then be determined by evaporating the ethereal extract; but the different substances contained in it cannot be separately estimated, unless very large quantities of bile are operated upon; in that case, the fatty acids (stearic and margaric or palmitic acids) may be separated from the cholesterin by precipitation as lead-salts.

The residue insoluble in ether, which contains the essential constituents of the bile, is next to be treated with cold *absolute alcohol*, which dissolves the salts of the biliary acids, together with part of the bile-pigment; the greater part of the alcohol is then removed by evaporation; ether added to the concentrated solution as long as any turbidity is produced; and the liquid left to stand for some time in a cool place.

The alkaline taurocholate and glycocholate are thereby precipitated, and their quantity may be estimated by washing the precipitate with ether, and weighing it after drying over the water-bath. It always, however, contains a certain portion of bile-pigment, which cannot be completely separated unless it consists of pure cholepyrrhin, in which case it may be separated by chloride of calcium. The quantity of soda or potash associated with the biliary acids and the bile-pigment, may be determined by decomposing a weighed portion of the ether-precipitate with sulphuric acid.

The taurocholic and glycocholic acids cannot be completely separated one from the other. An approximate separation may be effected by dissolving the precipitate in alcohol, and treating it with neutral acetate of lead, which precipitates only the glycocholic acid; but the best way of estimating the relative quantities of the two acids, is to determine the amount of ***sulphur*** in the ether-precipitate, by fusing it with nitre or by one of the other methods given under ANALYSIS (ORGANIC), p. 225. Every 6 pts. of sulphur correspond to 100 pts. of taurocholate of sodium.

The residue of the bile, insoluble in absolute alcohol, must now be determined with the view of checking the analysis. It contains pigment, partly free and partly combined with lime; also alkaline and earthy phosphates, with chloride and carbonate of sodium, very rarely sulphate of potassium, but often a little taurine; its amount is generally too small to allow of the quantitative separation of these substances, unless very large quantities of bile are operated upon. Altogether the determinations which have been made of the amount of pigment, cholesterin, fats, fatty acids, and mineral constituents of bile, cannot be regarded as more than approximations to the truth.

Pettenkofer's Test for Bile.—When bile is mixed with a strong syrup of sugar, and then with strong sulphuric acid, so that it becomes heated, it assumes a deep violet-red or purple tint, which disappears on addition of water. This reaction is produced by cholic, choloidic, glycocholic, and taurocholic acids (or the corresponding acids in pig's bile), but not by any other substance; it is, therefore, perfectly characteristic of bile, and affords a very delicate indication of its presence. The best mode of applying it for the detection of small quantities of bile in blood or other animal fluids, is as follows:—The alcoholic extract of the liquid to be tested for biliary matter, is dissolved in a little water, and mixed with a single drop of a solution of sugar (1 pt. of sugar to 4 pts. of water), and pure strong sulphuric acid is then added by small quantities, till the turbidity at first produced, disappears, cooling after each addition; it then for a few moments exhibits a yellowish colour, which, however, soon changes to a pale cherry-red, then to deep carmine, then to purple, and finally to an intense violet tint. For the success of the experiment, care must be taken not to add too much sugar; otherwise a black mass will be formed, which will completely mask the reaction. The temperature of the mixture must be allowed to rise to about 50° C. but not higher. The reaction takes place with any kind of sugar, and likewise with acetic acid.

Composition of the Bile of various animals.—***Human bile*** consists mainly of taurochlorate of sodium, with very little glycocholate (Gorup-Besanez). ***Ox-bile***, on the contrary, contains chiefly glycocholate (Strecker). ***Pig-bile***, as already observed, consists mainly of the sodium-salt of an acid analogous to glycocholic acid; viz. glycohyocholic acid (Gundelach and Strecker), together with a small quantity of a sulphuretted acid, yielding taurine by decomposition: ***tauro-hyocoholic acid***; it likewise contains a very strong base containing sulphur.

The bile of most other animals consists mainly of taurocholate of sodium or potassium. That of the ***dog*** contains only taurocholate of sodium; that of the ***sheep***, and that of the *kangaroo* contain taurocholate, with very little glycocholate. In the bile of several kinds of fish, viz. *turbot*, *cod*, *pike*, and ***perch***, Strecker found taurocholate, with mere traces of glycocholate; a similar result was obtained by Schlossberger (Ann. Ch. Pharm. cviii. 166) with the bile of the ***shad-fish***. According to (Bensch (Ann. Ch. Pharm. lxv.) and Strecker, the bile of ***sea-fish*** contains potassium-salts, that of *fresh-water fish* chiefly sodium-salts. The bile of the ***Boa Anaconda*** (Schlieper, Ann. Ch. Pharm. lx. 109) and that of the ***Python tigris*** (Binder, *ibid.* cii. 91) consist mainly of taurocholate. *Goose-bile* appears likewise to consist essentially of taurocholate of sodium, though Marrson (Arch. Pharm. [2] lviii. 138), and more recently Heintz and Wisliscenus (Pogg. Ann. cviii. 547) state that the sulphuretted acid of goose-bile differs in composition from taurocholic acid; Heintz and Wisliscenus assign to it the composition $C^{29}H^{49}NSO^{6}$; but the analyses are not quite satisfactory.

Taurocholate of sodium contains about 6 per cent. of sulphur: now in the dried bile of the dog, Bensch found 6·2 per cent, sulphur; in that of the fox, 5·96 per cent.; of the wolf 5·03; of the bear 5·75; of the pig 0·32; of the calf 5·62; of the sheep 6·46; of the goat 5·99; of the domestic fowl 5·57; and of several fishes 6·46 per cent.

In normal human bile, Frerichs found 14 per cent. or rather more of solid ***constituents;*** Gorup-Besanez, in the bile of two recently executed criminals, found 10·19 and 17·73 per cent. solid matter; in that of an old man, 9·13 per cent; and in that of a boy of twelve years old, 17·19 per cent. solid matter. Ox-bile contains 10·13 per cent. solid constituents; pig's bile 10·6 to 11·08 per cent. (Gundelach and Strecker); dog's bile 5·1 per cent.; cat's bile 5·6 per cent. (Bidder and Schmidt); sheep's bile 5·3; rabbit's bile 1·8; goose bile 6·9; kangaroo's bile 14·13; and crow's bile 7·3; per cent. solid constituents. The concentration of the bile appears to increase with the time it remains in the gall-bladder.

The proportion of *ash* in the dried residue amounts in normal human bile to 6·14 per cent. Gorup-Besanez), in ox-bile to 12·7 (Berzelius); in calf's bile to 13·15 (Bensch); in sheep's bile to 11·86; in goat's bile to 13·21; in pig's bile to 13·6; in fox bile to 12·71; in that of the domestic fowl to 10·99; in that of fresh-water fish, to 14·11 per cent.; in that of the fresh-water turtle (*Emys geographica*) to 5·5; and in that of the salt-water turtle (*Emys insculpta*) to 6·3 per cent. (Wetherill, J. pr. Chem. lxxvi. 61). The fresh bile of *Python tigris* yields 1·21 per cent. of ash.

Ox-bile extracted from the gall-bladder without pressure, contains 0·134 per cent. *mucus;* human-bile 0·158 per cent. (Lehmann); Gorup-Besanez found in human bile 1·45 and 2·21 per cent. *mucus* and *bile-pigment.* The bile of the kangaroo contains 4·34 per cent. *mucus* and *colouring matter*, and 1·09 *cholesterin* and *fat;* that of the shad-fish contains 1·28 per cent. *mucus* and *colouring-matter*, and 0·23 per cent. *fat;* that of *Python tigris*, contains 0·89 per cent. *mucus* and 0·03 *fat;* goose-bile contains 2·56 per cent. mucus, 0·36 *fat* and *cholesterin.* (Marrson.)

The bile, like all the other normal secretions, is liable to alteration from disease, and sometimes contains heterogeneous constituents. *Albumin* is sometimes found in it, especially in fatty liver, in Bright's disease, and in the embryonic state. *Urea* has been found in the bile, in cases of fatty degeneration of the kidneys, and in animals whose kidneys have been extirpated; also in cholera. Bizio once discovered a dark-red non-bitter bile in a patient suffering from jaundice; it contained an emerald-green pigment, to which he gave the name of *erythrogen*, from its volatilising at 40° C. and giving off a red vapour. A similar substance was found by Lehmann in a case of acute yellow atrophy of the liver. In the bile of a child who died suddenly, Lehmann found a considerable quantity of *sulphide of ammonium*, but the previous history of the case was not known.

The normal constituents of the bile also vary in proportion, in various cases of disease. The bile has been found to be poor in solid constituents, in persons who have died from severe inflammatory affections, especially from pneumonia, and likewise in fatal cases of dropsy; it also contains an excess of water in diabetes, and in certain cases of typhus; in other cases of that disease, however, the bile becomes thicker than in health. The solid constituents of the bile are commonly *increased* in those abdominal diseases in which the motion of the blood in the larger veins is impeded, and in certain cases of heart-disease, in which the blood accumulates in excessive quantity in the hepatic veins. In cholera, the bile is also found to be dense, tough, and consistent. The proportion of *mucus* is often increased when the bile is very dilute; indeed in typhus, the gall-bladder sometimes contains scarcely anything else, the resinous constituents being almost, if not altogether absent; the same is observed in catarrh of the biliary ducts. (Lehmann.)

The separation of *crystals of cholesterin*, which is sometimes, though rarely, observed in morbid bile, appears to be associated with an increase in the relative quantity of that substance; this phenomenon has been observed by Gorup-Besanez in very concentrated bile. *Free fat* is always present in the bile, but in the normal state is held in solution by the taurocholate of sodium; fat globules have, however, been observed by Gorup-Besanez in the bile of persons who have died from typhus, and from tuberculosis in the colliquative stage. (Lehmann.)

The bile is very seldom *acid;* an acid reaction has been observed in typhus, but it may have arisen partly from spontaneous decomposition after death, partly from effusion of pus into the gall-bladder: for pus, when contained in an enclosed space, often becomes acid with great rapidity. (Lehmann.)

Putrefaction of Bile.—When bile is left to itself, either in a closed or in an open vessel, it undergoes gradual decomposition, acquiring an offensive odour and acid reaction, and yielding a solid deposit containing cholic acid and other substances. Thudichum (Chem. Soc. Qu. J. xiv. 118) found that ox-bile left for a year or two in large bottles, well stoppered, and completely filled with it, had assumed a slight acid reaction, a bright port wine colour, and had deposited a copious, flaky, green and brown deposit, mixed with white chalk-like particles and greenish crystals. This deposit was found to consist of cholochrome (bile-pigment) cholic acid, phosphate of calcium and magnesium in dichroic crystals, and mucus. The fluid part of the bile was found to contain principally choloidate of sodium with a little cholate; also taurine, valerate and acetate of sodium, and of ammonium, and phosphate of sodium, but no glycocine, glycocholic acid, or taurocholic acid. The decomposition appears to begin by the resolution of the glycocholate of sodium into cholate of sodium and glycocine, and of the taurocholate into cholate and taurine. The ammonia and acetic acid are probably formed by the decomposition of the glycocine (oxyacetamic acid); the origin of the valeric acid is obscure; these acids unite with a portion of the soda and precipitate some of the cholochrome and cholic acid, the rest of that acid remaining in solution as choloidate of sodium. From the experiments of Gorup-Besanez (Ann. Ch. Pharm. lix. 129) it appears that bile allowed to decompose in an open vessel, at a comparatively high temperature, 25° to 30° R., deposited chiefly choloidic acid, but when the decomposition took place in a cellar at 10° to 12° R., cholic acid was deposited instead of choloidic, the higher temperature favouring the transformation of cholic acid into its amorphous modification.

Human bile putrefies much in the same manner as ox-bile; but the actual products are usually modified by the decomposition of the albumin which is present in nearly all the bile that can be obtained for examination, viz. the bile of persons who have died of disease, and usually not obtained till some days after death. The alkaline products resulting from the decomposition of the albumin partially neutralise the acid products of the decomposition of the bile, and thereby prevent, to a certain extent, the formation of insoluble compounds. (Thudichum.)

Biliary calculi, or *Gall-stones.*—These concretions in man sometimes consist chiefly of chlolochrome, held together by some binding material, generally supposed to be mucus, or inspissated bile, but consisting, according to Thudichum (*loc. cit.*), of cholic or choloidic acid, or both. In most cases, a small nucleus of this character is formed, and becomes coated with cholesterin, which then forms the chief mass of the concretion. Earthy phosphates and carbonates are likewise present. Ox gall-stones consist mainly of cholochrome, cholic acid, and choloidic acid, with small portions of cholesterin, and unaltered bile mechanically enclosed: they also contain the phosphates and carbonates of calcium and magnesium, and an ammonia-compound, possibly sulphide of ammonium (Thudichum). The formation of these calculi is attributed by Thudichum to a decomposition of the bile, similar to the putrefaction which takes place when it is removed from the gall-bladder. (See Gall-Stones.)

BIMSTEIN. See Pumice-Stone.

BINARY THEORY OF SALTS. The theory which regards salts as compounds of a metal with an acid or chlorous radicle: *e. g.* acetate of potassium = $C^2H^3O^2.K$: nitrate of potassium, $NO^3.K$, &c. (See Acids.)

BINNITE. A native sulpharsenite of lead, from the Binnenthal in the Valais, where it is found imbedded in white granular dolomite. It sometimes forms distinct prismatic crystals, belonging to the rhombic system, but more frequently, broad, reedlike, crystalline aggregations, or crude masses: it is very brittle and friable. Colour, steel-grey to iron-black, or light lead-grey, with strong metallic lustre. Opaque. Streak reddish-brown. Hardness, 2·5 to 3·0. Specific gravity 5·0 to 5·5. Its composition appears to be liable to some variation. According to Waltershausen, it is a mixture in variable proportions of ***arsenomelane***, $Pb^2S.As^2S^3$, and ***scleroclase***, $2Pb^2S.As^2S^3$. (Handw. d. Chem. ii. [1] 1099.)

BIOTIN. Syn. with Anorthite.

BIOTITE. Uniaxial or Magnesia Mica. See Mica.

BIRCH. (*Betula alba.*)—The *bark* of this tree contains, according to John (Repert. Pharm. xxxiii. 327), one-third of its weight of resin, and a considerable quantity of tannin, whence it is used for tanning leather, and for black-dyeing, especially of silk. The white, easily separated epidermis of birch-bark, contains resin, tannic acid, extractive matter, and ash, consisting chiefly of sesquioxide of iron, silica, and lime. The red-brown bark on the lower parts of the stem of an old tree, yields by successive treatment with ether, alcohol, and aqueous potash, a resin, $C^{20}H^{30}O^2$, soluble in ether, a red-brown colouring matter, $C^{16}H^8O^2$, soluble in alcohol, and another red-brown substance, $C^{20}H^{18}O^9$, soluble in alkalis, and precipitated by acids. (Stahelin and Hochstetter, Ann. Ch. Pharm. li. 79.)

The *leaves* of the birch contain, according to Grossmann, 0·3 per cent. essential oil and wax, besides tannin, and a bitter yellow colouring matter. They are used as fodder in northern countries.

The dry *wood* of the birch contains, according to Karsten, 0·25 to 0·3 per cent. ash; according to Berthier 1·0 per cent. Berthier found also in 100 pts. of the ash, 16 pts. of soluble and 84 pts. of insoluble salts. Wittstein (Pharm. Centralb. 1851, p. 404), has analysed the ash of birch-wood growing on different soils: viz. *a.* on the palagonitic soil of Akareyri in Iceland, composed of weathered volcanic rocks; *b.* on the sterile calcareous soil of Morschen in Kurhessen, belonging to the Muschelkalk formation; *c.* on the sandy soil of Marburg in Kurhessen, belonging to the sandstone formation.

	a	*b*	*c*		*a*	*b*	*c*

Birch-fungus.—The fungus of the birch-tree contains woody fibre, phoblaphene (a substance also contained in pine-bark), fat, a bitter principle, uncrystallisable sugar, tannin, malic acid, tartaric acid, and citric acid. It yields 15·3 per cent. water, and 1·2 per cent. ash, containing in 100 pts.: 5·0 K^2O; 4·1 Na^2O; 48·8 Ca^2O; 5·5 Mg^2O; 3·1 Al^4O^3; 1·6 Fe^4O^3; 4·4 SO^3; 0·6 Cl; 15·6 P^2O^5; 4·7 SiO^2; 15·9 CO^2. (J. Wolff, Vierteljahrschrift f. prakt. Pharm. iii. 1.)

Birch-juice. Birch-water.—This liquid is obtained, like the juice of the maple, by boring the stems of the trees in February and March. A tree of average size yields about 8 litres of juice, consisting chiefly of sugar, together with nitrogenous substances and various salts, including acid tartrate of potassium. It easily ferments, and quickly turns sour when exposed to the air. In some localities, as in the Harz, in Courland, and in Livonia, it is used for the preparation of an effervescent wine.

Birch-oil.—All parts of the birch-tree appear to contain an essential oil. The young leaves and buds yield, by distillation with water, a colourless oil, which gradually turns yellow in the air, has the aromatic odour of newly developed birch-leaves, and a taste mild and sweetish at first, afterwards balsamic and burning. It is mobile at 14° C., becomes viscid at 0°, and solidifies to an amorphous mass at −10°. It dissolves in alcohol more readily than in ether: water is said to extract a stearoptene (?) from it. (Grossmann, Répert. Pharm. xxiii. 327.)

The bark of the *Betula lenta*, a North American tree, yields an essential oil identical with oil of wintergreen (salicylate of methyl): it does not however exist in the bark ready formed, but is produced from a crystalline substance, *gaultherin*, contained in the bark, by the action of a ferment in presence of water, in the same way as bitter-almond oil from amygdalin. (Procter, Amer. J. Pharm. Jan. 1844.)

Birch-Resin. See Betulin.

Birch-Tar. *Dagged. Black Doggert* or *Deggelt. Birch-tar Oil.*—In Russia and other northern countries, the bark of the white birch is subjected to a kind of downward distillation, in conical pits 20 or 25 feet deep, covered over first with a roofing of straw, and then of turf and mould, having holes to regulate the admission of air, as in the charcoal meilers. By this process, two products are obtained, namely, charcoal and tar, the latter amounting to 60 or 70 per cent. of the bark. It is a brown-black viscid liquid, used for coating wood, and also for lubricating carriage wheels, as it remains liquid even at very low temperatures.

This tar when distilled yields a brown strong-smelling acid oil, and on rectifying this oil, a liquid hydrocarbon, having the composition of oil of turpentine, passes over at 100° C., mixed with an oxygenated oil, the proportion of the latter gradually increasing as the distillation advances. The oxygenated oil may be removed by potash-ley, and the hydrocarbon, $C^{10}H^{16}$, is left behind. Its smell is like that of oil of turpentine, but more agreeable, recalling that of birch-bark. Specific gravity 0·87 at 20° C. Boils at 156°. Vapour-density 5·2 (calculation 2 vols. 4·8). At −16° it deposits a small quantity of stearoptene. Sparingly soluble in water, readily in alcohol and ether. It absorbs oxygen rapidly from the air, giving off carbonic anhydride, and being converted into a resinous mass. It is also oxidised by nitric acid, giving off hydrocyanic acid, and yielding two acid resins. It absorbs 32 per cent. chlorine, without forming a crystalline compound. Betulin is perhaps formed from this hydrocarbon by oxidation. (Sobrero, J. Pharm. [3] ii. 207.)

BIRDLIME. The best birdlime is made of the middle bark of the holly, boiled seven or eight hours in water, till it is soft and tender; then laid in heaps in pits in the ground and covered with stones, the water being previously drained from it; and in this state left for two or three weeks to ferment, till it is reduced to a kind of mucilage. This being taken from the pit, is pounded in a mortar to a paste, washed in river water, and kneaded, till it is free from extraneous matters. In this state it is left four or five days in earthen vessels, to ferment and purify itself, when it is fit for use.

It may likewise be obtained from the mistletoe, the *Viburnum lantana*, young shoots of elder, and other vegetable substances.

It is sometimes adulterated with turpentine, oil, vinegar, and other matters.

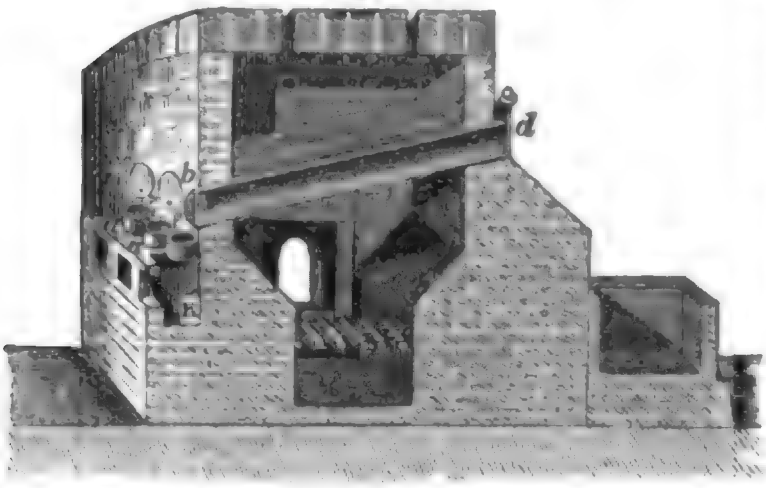
Good birdlime is of a greenish colour, and sour flavour; gluey, stringy, and tenacious, and in smell resembling linseed oil. By exposure to the air, it becomes dry and brittle, so that it may be powdered; but its viscidity is restored by wetting. It reddens tincture of litmus. Exposed to a gentle heat, it liquefies slightly, swells in bubbles, becomes grumous, emits a smell resembling that of animal oils, grows brown, but recovers its properties on cooling, if not heated too much. With a greater heat, it burns, giving out a brisk flame and much smoke. The residue contains sulphate and chloride of potassium, carbonate of calcium, and alumina, with a small portion of iron. U.

BISMUTH. *Symbol* Bi. *Atomic weight* 208 (Schneider); 210 (Dumas).— The metal bismuth has long been known, but was formerly often confounded with tin and lead. It is principally found in the metallic state, but also occurs in combination with sulphur, oxygen, and tellurium. In Cornwall and Cumberland it is found associated with ores of cobalt, and in Siberia with lead, in the form of *needle-ore* or *bismuth-lead-ore*.

For the arts it is prepared almost exclusively from native bismuth, and the great source for it is Saxony, where it occurs in metallic veins in gneiss and clay-slate, accompanying ores of silver, copper, lead, and tin.

The process of extraction is very simple, the mineral being merely heated in close vessels, so as to melt the bismuth, and thereby separate it from the gangue, or accompanying rock. The fusion is performed in iron tubes, laid in an inclined position, in a furnace (*fig.* 100). The ore is introduced at the upper end, *d*, which is then plugged. The other end, *b*, is closed with an iron plate having an aperture, *o*, through which the melted metal runs into earthen pots, *a*, heated by a few coals placed in the space, K, below, so as to keep the metal in the melted state. It is then ladled out and run into moulds. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 304.)

Fig. 100.



As thus prepared, the metal is impure, containing sulphur and arsenic, copper, nickel, iron, and other metals. It may be purified by placing it in a crucible with about $\frac{1}{10}$ its weight of nitre, and keeping it melted at a temperature not too much above its point of fusion, the mixture being continually stirred. The nitre, at first liquid, soon solidifies, forming with the impurities a slag, which collects on the surface of the metal. By repeating this operation a second time, the metal is obtained pure.

Small quantities of bismuth existing in lead-, copper-, and silver-ores, often become concentrated in the secondary products of metallurgic operations, especially in the process of separating silver from lead by cupellation. The lead oxidises faster than the bismuth, so that towards the end of the operation a blackish litharge is obtained, containing bismuth; and by reducing this mixed oxide, and again expelling the resulting alloy of lead and bismuth, the lead is oxidised and metallic bismuth remains. (Jahresber. d. Chem. 1859, 711.)

To obtain chemically pure bismuth, the metal is dissolved in nitric acid; and to the clear solution, a large excess of water is added, which precipitates the bismuth as basic nitrate, the other substances remaining in solution. The precipitate is well washed, dried, mixed with black flux, and reduced at a gentle heat in a crucible, at the bottom of which a regulus of pure metal is found.

Properties. — Bismuth is a metal of a greyish-white colour, with a distinct roseate tinge. When pure, it crystallises more readily than any other metal. It may be obtained in beautiful crystals by the following method. A few pounds are melted in a crucible, and then poured into an earthen dish previously made hot. When the surface of the metal has become covered with a crust, it is pierced on two opposite points with a rod of red hot-iron, and the liquid metal allowed to run out. On afterwards carefully removing the crust, the sides of the interior are found lined with beautiful crystals, often in pyramidal cubes like the crystals of chloride of sodium. They possess an iridescent lustre, arising from a very thin film of oxide which has been formed on their surface while still hot, and exhibits the colours of thin plates. Native bismuth crystallises in cubes, and combinations of the cube with the octahedron; also in regular tetrahedrons, with cleavage very distinct, parallel to the faces of the octahedron (Kopp's

Krystallographie). In Dana's *Mineralogy* (iii. 20), on the other hand, the crystalline form is stated to belong to the hexagonal system. Bismuth appears therefore to be dimorphous. Its specific gravity is 9·83, and it exhibits the singular anomaly, that when it has been exposed to great pressure, its density becomes less. Pure bismuth which has been exposed to a pressure of 200,000 pounds, was found to have the specific gravity 9·556. It melts at 264° C., and expands about $\frac{1}{32}$ in solidifying. Hence its specific gravity is greater in the liquid than in the solid state. At a high temperature, it may be distilled, and then sublimes in laminæ. It is very brittle, has a laminated, crystalline fracture, and is easily reduced to powder. Of all metals it exhibits in the highest degree the phenomena of diamagnetism.

Exposed to dry or moist air, it does not alter, but when exposed in contact with water in an open vessel, it becomes covered with a film of oxide of bismuth. Heated in the air, it burns with a bluish flame, forming yellow fumes. It decomposes water at high temperatures only. Concentrated hydrochloric acid acts on it with difficulty; sulphuric acid attacks it only when hot and concentrated. Nitric acid briskly attacks it and effects complete solution.

Bismuth forms three classes of compounds in which it is *di-*, *tri-*, and *pent-atomic*, respectively. The tri-atomic compounds are the most stable and the most numerous, *e. g.* $BiCl^3$, BiI^3, Bi^2O^3. Several di-atomic bismuth-compounds are also known, viz. $BiBr^2$, $BiCl^2$, BiI^2, Bi^2O^2, and Bi^2S^2. The only pent-atomic bismuth-compounds hitherto obtained are the pent-oxide Bi^2O^5, together with the corresponding acid and salts. E. A.

BISMUTH ACICULAR. Plumbo-cupreous sulphide of bismuth. See NEEDLE-ORE.

BISMUTH, ALLOYS OF. Bismuth unites readily with other metals, forming easily fusible compounds.

A native *arsenide of bismuth* containing 3 per cent. of the latter metal, occurs at Palmbaum, near Marienberg. It has a radiated texture like native sulphide of antimony. Specific gravity 5·392. Hardness = 2 (Breithaupt). 14 pts. of bismuth fused with 1 pt. of arsenic yield an alloy which expands strongly in solidifying.

Antimony unites in all proportions with bismnth, forming brittle alloys; that which contains equal parts of the two metals expands considerably in solidifying.

The most remarkable alloy of bismuth is that known as "fusible metal," which consists of 1 pt. of *lead*, 1 of *tin*, and 2 of *bismuth*. It melts at 93·75 C. According to Erman, it dilates in an anomalous manner when heated. It expands regularly from 32° to 95° C., and then contracts gradually to 131°; at which point it occupies a less bulk than it did at 32°; it then expands till it reaches 174°, and from that point its expansion is uniform. On account of this property of expanding as it cools, while still in the soft state, it is much used for taking impression from dies, as even the faintest lines are reproduced with minute accuracy. An alloy of bismuth with potassium is obtained when bismuth is fused with cream of tartar, 5 pts. bismuth to 4 pts. tartar. (For the other alloys of bismuth see the several metals.) E. A.

BISMUTH, BROMIDES OF. The *tri-bromide*, $Bi'''Br^3$, is formed by heating bismuth with excess of bromine. It is a steel-grey substance, like fused iodine; melts at 200° C., and boils at a dull red heat, with formation of hyacinth-red vapours. Heated with metallic bismuth, it yields a brown crystalline mass, probably a *di-bromide* $BiBr^2$, but it has not been obtained pure. (Weber.) E. A.

BISMUTH, CHLORIDES OF. *Trichloride*, $B'''Cl^3$.—Bismuth and chlorine readily combine, with evolution of heat and light if the metal be finely divided. On heating bismuth in a tubulated retort, in a current of chlorine, trichloride of bismuth distils as a white easily fusible substance. It readily attracts moisture from the air, becoming converted into a crystallised hydrate. The same substance is produced when bismuth is dissolved in aqua-regia, and the excess of acid evaporated. Chloride of bismuth dissolves in water containing hydrochloric acid; by pure water it is decomposed into hydrochloric acid, which dissolves a portion of the chloride, and a precipitate consisting of oxychloride of bismuth:

$$BiCl^3 + H^2O = BiClO + 2HCl.$$

When a solution of nitrate of bismuth is poured into solution of common salt, a white crystalline precipitate is formed, which is also *oxychloride* of bismuth, $BiCl^3.Bi^2O^3$ or $BiClO$. It is used for paint, and is known as "pearl white." Chloride of bismuth forms crystallisable double salts with the chlorides of potassium, of sodium, and of ammonium. They are isomorphous with, and analogous in composition to, the corresponding double chlorides of antimony.

DICHLORIDE OF BISMUTH, $BiCl^2$, is produced by heating the trichloride with metallic bismuth, also by the direct action of chlorine upon bismuth, provided the action be moderated by confining the current of chlorine to the upper part of the retort. Partial reduction of the trichloride is likewise effected by phosphorus, zinc, tin, mercury, and silver. The dichloride is a brown crystalline mass easily fusible and easily decomposed by water or by a strong solution of sal-ammoniac. At a high temperature, it is resolved into metallic bismuth and trichloride. (R. Weber, Pogg. Ann. cvii. 596.) E. A.

BISMUTH CUPREOUS. See TANNENITE and WITTICHITE.

BISMUTH, DETECTION AND ESTIMATION OF. *Blowpipe reactions.*—All bismuth-salts, and likewise the sulphide, are easily reduced by mixing them with carbonate of sodium, and heating the mixture on charcoal in the inner blowpipe flame. A brittle bead of metallic bismuth is thereby produced, and a lemon-yellow oxide, similar to lead-oxide, but darker, is deposited on the charcoal around. This deposit disappears when heated in the reducing flame, without colouring the outer flame, a character by which it is distinguished from lead. Oxide of bismuth is easily reduced on charcoal without addition of soda.

In *borax* on platinum-wire, bismuth-oxide dissolves to a clear glass, yellow while hot, and colourless when cold, if not supersaturated; in the latter case, yellowish-red while hot, yellow when cold. In the inner flame on charcoal, the borax-glass becomes grey and turbid, afterwards perfectly clear. The addition of *tin* makes it grey at first, but after complete reduction, colourless and transparent.

In *phosphorus-salt* on platinum-wire, a small quantity of bismuth-oxide forms a colourless glass; with a large quantity, the glass is yellow while hot, colourless, or sometimes enamel-white, on cooling. On charcoal, especially with addition of tin, the glass is transparent and colourless while hot, but becomes blackish-grey and opaque on cooling. (Berzelius and Plattner.)

Liquid Reactions.—The salts of bismuth are mostly colourless. They have an acid reaction, and their solutions when diluted with *water*, become milky, and yield a white precipitate, consisting of an insoluble basic salt, while an acid salt remains in solution. This reaction is best seen with the chloride, as the oxychloride formed is almost absolutely insoluble. *Iron*, *copper*, *lead*, and *tin*, precipitate bismuth from its solutions in the metallic state. *Sulphydric acid* and *sulphide of ammonium* throw down a brown-black precipitate of trisulphide of bismuth, insoluble in excess of sulphide of ammonium. *Caustic alkalis* and their *carbonates*, *phosphates*, *oxalates*, and *tartrates*, throw down white precipitates, insoluble in excess of caustic potash or soda. *Chromate of potassium* throws down a yellow precipitate of chromate of bismuth, insoluble in caustic potash. Soluble *sulphates* produce no precipitate. This last character, together with the insolubility of the precipitated chromate, hydrate, &c., in caustic potash, distinguishes bismuth from lead. From antimony, which resembles it in the decomposition of its salts by water, it is distinguished by its behaviour with sulphydric acid, and by the insolublility of the basic salts thrown down by water, in tartaric acid.

Quantitative Estimation.—The best reagent for precipitating bismuth from most of its solutions, is carbonate of ammonium, which, when added in excess, throws down the bismuth completely, provided the liquid be left to stand for some hours in a warm place. The precipitate, after being washed and dried, must be separated from the filter as completely as possible, the filter separately burned, and the precipitate ignited in a porcelain crucible; a platinum crucible would be attacked by it on ignition. It consists of trioxide of bismuth, Bi^2O^3, containing 89·66 per cent. of the metal.

If the solution contains hydrochloric acid, the bismuth cannot be estimated by precipitation with carbonate of ammonium or any other alkali, because the precipitate so formed would contain oxychloride of bismuth, and on igniting it, part of the bismuth would be volatilised as chloride. In this case, therefore, the bismuth must be precipitated by sulphydric acid, the sulphide of bismuth oxidised and dissolved by nitric acid, and the diluted solution precipitated by carbonate of ammonium.

Atomic Weight of Bismuth.—The first approximately correct determinations of the atomic weight of bismuth were made in 1815 by Lagerjhelm (Ann. Ch. xciv. 161), who, from the proportion of bismuth in the sulphide Bi^2S^3, in the oxide Bi^2O^3, and the sulphate $Bi^2(SO^4)^3$, estimated the atomic weight at 214·8, 212·8, and 212·3, respectively. L. Gmelin (Handbook, iv. 428) found that these numbers were too high, and that the oxide Bi^2O^3 contained at least 10·33 per cent. oxygen; whence

$$Bi^2 : O^3 = 89{\cdot}67 : 10{\cdot}33; \text{ and } Bi = \frac{89{\cdot}67 \times 48}{2 \times 10{\cdot}33} = 208{\cdot}2 \text{ at most.}$$

This result was confirmed by Schneider in 1851 (Pogg. Ann. lxxxii. 303). Pure bismuth was oxidised by nitric acid in a flask (the small portions of metal carried off by the vapours, being collected and allowed for), the solution evaporated, and the residue gently ignited. Eight experiments thus made, showed that 100 pts. of trioxide of bismuth, Bi^2O^3, contain from 10·318 to 10·366 pts. oxygen; mean = 10·345: whence $Bi = \frac{89·655}{20·690} \times 48 = 208·0$.

Lastly, Dumas (Ann. Ch. Pharm. cxiii. 38), has determined the atomic weight of bismuth by decomposing the trichloride $BiCl^3$ (prepared by passing chlorine gas over bismuth, and distilling till the product passed over is colourless), with excess of carbonate of sodium, and estimating the chlorine in the filtrate by means of a standard silver-solution. Three experiments, with the purest portion of the distillate, gave the numbers 209·88, 210·08, and 210·27. Dumas considers 210 to be the correct number.

Separation of Bismuth from other Elements.—From the *non-metallic* elements (excepting *selenium*), and from the *alkali-metals*, bismuth is separated by carbonate of ammonium; from the *earth-metals*, and from *iron*, *cobalt*, *nickel*, and the other metals of the second group (p. 217), it is separated by sulphydric acid; from *tin*, *arsenic*, *antimony*, and *tellurium*, by sulphide of ammonium; and from *copper* and *cadmium*, by ammonia. The separation of bismuth from *cadmium* may also be effected by cyanide of potassium, which dissolves the latter as cyanide of cadmium and potassium, and precipitates the bismuth. The precipitated bismuth, however, always contains potash, and must therefore be dissolved in nitric acid, and precipitated by carbonate of ammonium. Another mode of separating these two metals, given by Löwe (J. pr. Chem. lxvii. 464), is to heat the solution containing them with acid chromate of potassium, which throws down the bismuth as $Bi^2O^3.2Cr^2O^3$, and retains the cadmium in solution.

The separation of bismuth from *lead* cannot be effected by caustic potash, although lead is soluble in that reagent, and bismuth insoluble; for, when the metals are mixed in solution, the oxide of lead precipitated by potash always carries some bismuth-oxide down with it. The two metals may, however, be separated:—1. By sulphuric acid. The acid is to be added in excess, the solution evaporated till the excess of sulphuric acid begins to volatilise, and then diluted with water, whereupon the sulphate of lead is left undissolved, while the sulphate of bismuth dissolves completely, provided sufficient excess of sulphuric acid is present. The sulphate of lead is then collected on a filter, and washed with water containing sulphuric acid, and the bismuth is precipitated from the filtrate by carbonate of ammonium, after the excess of acid has been partly neutralised by ammonia. This method is not quite exact, because sulphate of lead is not perfectly insoluble in acid liquids; sulphuric acid, however, dissolves less of it than any other acid.—2. Another mode of separating lead from bismuth, is to dissolve the two metals or their oxides in nitric acid diluted with a very small quantity of water, then add hydrochloric acid in sufficient quantity to convert the metals into chlorides, and afterwards a considerable quantity of strong alcohol mixed with a little ether. The chloride of bismuth is thereby held in solution, while the chloride of lead is completely precipitated, and may be collected on a weighed filter, and washed with alcohol containing ether. Lastly, the alcoholic solution of chloride of bismuth is diluted with water, the alcohol evaporated, and the bismuth precipitated by sulphuretted hydrogen. This method becomes more exact as the alcohol used is stronger.—3. Ullgren separates bismuth from lead by precipitating the two metals as carbonates, redissolving them in acetic acid, and immersing in the liquid a weighed strip of clean sheet-lead, which must be completely covered by the liquid; the vessel is then closed and left to itself for several hours. The bismuth is thereby precipitated as a metallic powder. It is rinsed off the surface of the lead, which is then dried and weighed, and the precipitated bismuth is collected, dissolved in nitric acid, and precipitated by carbonate of ammonium, or estimated by simply evaporating the solution and igniting the residue. The lead in the solution is also precipitated by carbonate of ammonium, and the carbonate of lead is converted into oxide by ignition, and weighed, a deduction being made of the quantity of lead-oxide corresponding to the lead which has been dissolved.—4. When lead and bismuth are mixed in the metallic state, they may be separated by passing chlorine over the heated alloy, chloride of bismuth then volatilising, while chloride of lead remains. Great care is, however, required in regulating the heat, as too high a temperature would volatilise some of the chloride of lead, and if the heat be too low, a portion of the chloride of bismuth will remain.

For the separation of bismuth from *mercury*, *silver*, *gold*, *platinum*, and its allied metals, see the several metals.

Valuation of Bismuth-ores.—Ores containing only metallic bismuth, are assayed by heating them in a crucible perforated at the bottom, and standing over a receiver, into which the melted metal runs. The process is not quite exact, as a small quantity of the metal remains mixed with the ore; but it is sufficient for a check on the results of the smelting on the large scale. If the ore likewise contains sulphide of bismuth, it is ignited with two or three times its weight of black flux, sometimes with addition of metallic iron, also of borax, if much earthy matter is present. If the ore also contains other metals, which are reduced together with the bismuth, the metallic button must be dissolved, and the several metals separated by analysis in the wet way, as above described. (Kerl, Hüttenkunde, ii. 355.)

BISMUTH, FLUORIDE OF. Soluble in water and deposited as a white powder, when the aqueous solution is evaporated. (Berzelius.)

BISMUTH, IODIDE OF. BiI^3.—Obtained by mixing 1 at. of trisulphide of bismuth (which has been prepared by precipitation) with 3 at. of iodine, and gently heating the mixture in a capacious loosely covered glass globe, on the sides of which the compound condenses. The iodine simply takes the place of the sulphur (Schneider.) It is likewise produced by throwing iodine in small portions into a tube in which bismuth is strongly heated, and distilling out of contact with the air (Weber). It forms large brilliant grey hexagonal tables, which, according to Nicklès (Compt. rend. l. 872) are isomorphous with the tri-iodides of arsenic and antimony. Metallic bismuth decomposes it in the same manner as the tribromide. (Weber).

An *oxyiodide* of bismuth, BiIO, is formed when the tri-iodide is heated for some time in a crucible, and collects below the crystallised iodide thus obtained, in a mass of copper-coloured rhombic laminæ. In a close vessel, it may be partially volatilised without alteration, but when strongly heated in contact with the air, it is converted into oxide. It is not decomposed by water or by alkaline solutions; hydrochloric acid dissolves it without alteration; nitric acid decomposes it, with separation of iodine. (Schneider, J. pr. Chem. lxxix. 424.)

A *sulphiodide*, BiIS, is obtained by adding to melted iodide of bismuth, as much sulphur as it is capable of dissolving; it is likewise produced in the preparation of the tri-iodide by Schneider's method, and collects at the bottom of the vessel, together with a small quantity of the iodide, in small, shining, steel-grey needles. It appears to have the same form as the trisulphide. (Schneider, J. pr. Chem. lxxix. 422.)

E. A.

BISMUTH, OXIDES OF. Bismuth forms two definite compounds with oxygen, *Bismuthous oxide* or *trioxide of bismuth*, Bi^2O^3, and *bismuthic oxide* or *anhydride*, Bi^2O^5. An intermediate oxide, Bi^2O^4, is known, but it may be regarded as a compound of the other two—a *bismuthate of bismuth*, $Bi^2O^3 . Bi^2O^5$. A dioxide, Bi^2O^2, appears also to exist; it is formed when a solution of a bismuth-salt is treated with protochloride of tin. A corresponding sulphide is known.

BISMUTHOUS OXIDE, or TRIOXIDE OF BISMUTH, Bi^2O^3, is formed when the metal is roasted in air, but is best obtained by gently igniting the subnitrate. It is a pale yellow powder, which melts at a red heat, and solidifies on cooling to a glass having a deeper yellow tint. It occurs native, as *bismuth-ochre*, associated with iron and some other impurities (Bi^2O^3 86·4 per cent.; Fe^4O^3 5·1; CO^2 4·1; water 3·4), at Schneeberg in Saxony, at Joachimsthal in Bohemia, and with native gold at Beresof in Siberia. (Dana, ii. 141.)

The hydrated oxide of bismuth, $BiHO^2$. or $Bi^2O^3H^2O$, is obtained as a white precipitate when a solution of subnitrate of bismuth is decomposed by an alkali. If the hydrate be boiled with potash, it loses water, and is changed into a yellow crystalline powder which is the anhydrous oxide.

The hydrate is occasionally used in analysis for converting into oxides certain metallic sulphides soluble in alkalis. For this purpose, the alkaline solutions are boiled with the hydrated oxide.

Both the hydrate and the anhydrous oxide dissolve in the stronger acids, forming the normal bismuth salts, which have the composition $Bi'''A^3$, the symbol A denoting an acid radicle, *e. g.*:

$$BiCl^3;\ Bi(NO^3)^3 = \left.\begin{matrix}(NO^2)^3\\ Bi'''\end{matrix}\right\}O^3;\ Bi^2(SO^4)^3 = \left.\begin{matrix}(SO''^2)^3\\ (Bi''')^2\end{matrix}\right\}O^6, \&c.$$

Many of these salts crystallise well, but cannot exist in solution unless an excess of acid is present. On diluting the solutions with water, a basic salt is precipitated, and an acid salt remains in solution.

BISMUTHIC OXIDE OR ANHYDRIDE, Bi^2O^5;—in combination: BISMUTHIC ACID.—Prepared by passing chlorine through a concentrated solution of potash which contains hydrated trioxide of bismuth in suspension. A blood-red substance then separates, which is a mixture of hydrated bismuthic acid, and trioxide of bismuth. This is treated with dilute nitric acid, which dissolves the oxide, but, in the cold, does not attack the acid.

Bismuthic oxide is a bright red powder, which loses part of its oxygen at a temperature little above 100° C. and becomes converted into the intermediate oxide, Bi^2O^4, bismuthate of bismuth. Acids also decompose it, reducing it to the state of bismuthous oxide, which then combines with the acid.

The bismuthates are little known, and of no importance; according to Arppe, bismuthic acid forms with potash, a salt which is an *acid bismuthate of potassium:* $Bi^2KHO^4 = BiKO^3.BiHO^3$. E. A.

BISMUTH, OXYCHLORIDE OF. (p. 591.)

BISMUTH OXYGEN-SALTS OF. See the several acids.

BISMUTH, PHOSPHIDE OF. Melted bismuth takes up a small quantity of phosphorus, being thereby rendered more brittle and less laminar. Phosphoretted hydrogen gas throws down from solution of nitrate of bismuth a black phosphide of the metal, which gives off all its phosphorus by distillation. (Berzelius.)

BISMUTH, SELENIDE OF. Bismuth and selenium unite when heated together with faint evolution of light and heat, and form a silver-white mass, having a crystalline fracture, and fusing at a red heat: the fused mass has a specular surface. (Berzelius.)

BISMUTH, SULPHIDES OF. Bismuth readily unites with *sulphur*. When the two substances in fine powder are fused together, they combine, with disengagement of heat. Two distinct compounds are known.

Disulphide of Bismuth, $Bi''S$.—According to Wertheim, it is obtained crystallised by melting together bismuth and trisulphide of bismuth in equivalent quantities. The mixture is then allowed to cool slowly, on which the sulphide crystallises from the liquid metal, which may be poured off from the crystals. More recently it has been shown that these crystals, although giving by analysis numbers corresponding to BiS, are really a compound of trisulphide of bismuth with metallic bismuth. According to Schneider, disulphide of bismuth may be prepared in the moist way, by mixing an alkaline solution of bismuthous oxide with an alkaline solution of stannous oxide, and precipitating with sulphuretted hydrogen. The tin remains dissolved, and a black precipitate is formed, which, when washed and dried in the water-bath, is found to have the composition $BiS.H^2O$. It is a black lustreless powder, which, under the burnisher, takes the form of black laminæ.

Trisulphide of Bismuth, Bi^2S^3, occurs native as bismuth-glance, or *bismuthine*, in Cumberland and Cornwall, also in Saxony, at Bastnäs in Sweden, and according to Shepard, at Haddam in Connecticut, associated with chrysoberyl. It crystallises in acicular prisms of the trimetric system, isomorphous with native sulphide of antimony. $\infty\bar{P} \,.\, \infty\breve{P}\infty \,.\, \infty P\infty \,.\, \infty P3 \,.\, oP$. Inclination of $\infty P : \infty P = 91° 30'$. Cleavage perfect parallel to oP and $\infty\breve{P}\infty$; less perfect parallel to $\infty\bar{P}\infty$. It occurs also massive, with foliated or fibrous structure. Specific gravity 6·4 to 6·55. Hardness = 2 to 2·5. Opaque, with metallic lustre, lead-grey colour and streak. Sectile. (Dana, ii. 33.)

The same compound is prepared in the dry way, by fusing pulverised bismuth with one-third of its weight of sulphur, and removing the excess of sulphur by a second fusion. A laminated mass is thus obtained, composed of crystals having the same form as the native sulphide. According to Marx, it expands to the amount of one-fourth its volume in solidifying. The trisulphide is also obtained as a brown-black precipitate, when sulphydric acid gas is passed into the solution of a bismuth-salt. E. A.

BISMUTH, SULPHOCHLORIDE OF. BiSCl, or $BiCl^3.Bi^2S^3$.—This compound is best obtained by gradually adding pulverised trisulphide of bismuth to melted ammonio-bismuthous chloride ($2NH^4Cl.BiCl^3$), and washing the resulting mass with water acidulated with hydrochloric acid. It is also formed by heating the same double chloride with sulphur, or in sulphydric acid gas. It forms small, metallic-shining, blue-grey crystalline needles, which yield a red powder. Heated in carbonic acid gas, it gives off chloride of bismuth and leaves the sulphide; heated in hydrogen, it gives off hydrochloric and sulphydric acids, and leaves bismuth. It is decomposed by strong hydrochloric and strong nitric acid; also by alkalis, which remove the chlorine and leave an oxysulphide. (R. Schneider, Pogg. Ann. xciii. 464.)

BISMUTH, TELLURIC. Bi^2STe. See Tellurium.

BISMUTH, TELLURIDE OF. The two metals unite in all proportions by fusion.

BISMUTH-BLENDE. Native silicate of bismuth. See Silicates.

BISMUTH-GLANCE, or **BISMUTHINE.** Native trisulphide of bismuth (see above).

BISMUTH-NICKEL. *Grünauite. Saynite.*—A sulphide of bismuth and nickel, found, together with quartz and copper pyrites, at Grünau in Sayn Altenkirchen, crystallised in regular octahedrons, sometimes perfect, sometimes having the summits more or less replaced by faces of the cube. Cleavage octahedral. Specific gravity 5·13. Hardness 4·5. Colour, light steel-grey to silver-white, often yellowish or greyish from tarnish. Its composition in 100 parts is given by the following analyses:

S	Bi	Ni	Fe	Co	Cu	Pb	
38·46	14·11	40·65	3·48	0·28	1·68	1·58	Kobell.
31·99	10·49	22·03	5·55	11·24	11·59	7·11	Schnabel.
33·10	10·41	22·78	6·06	11·73	11·56	4·36	„

Before the blowpipe it melts to a grey, brittle, magnetic globule, colouring the charcoal greenish-yellow. Dissolves in nitric acid, excepting the sulphur. (Dana, ii. 44.)

BISMUTH-OCHRE. Native trioxide of bismuth (p. 594).

BISMUTH-RADICLES, ORGANIC. The only compounds of this class as yet obtained, are the *Bismuthides of Ethyl*, viz. *Bistriethyl*, discovered by Löwig and Schweizer (Ann. Ch. Pharm. lxxv. 355), and further examined by Breed (*ibid.* lxxxii. 106), and *Bisethyl*, discovered by Dünhaupt in 1854 (*ibid.* xcii. 372).

BISETHYL. C^2H^5Bi.—The *chloride* of this radicle, $C^2H^5BiCl^2$ (?) is obtained, together with a precipitate of chloride of hydrargethyl, by the action of bistriethyl on chloride of mercury (p. 596). The chloride of bisethyl remains in solution and may be obtained by spontaneous evaporation in crystals, which however do not dissolve completely in water, but leave a white powder. On adding iodide of potassium to the aqueous solution, then diluting with water till turbidity is produced, boiling till the solution becomes clear, and leaving it to cool, *iodide of bisethyl* separates in yellow six-sided laminæ, which appear to have the composition $C^2H^5BiI^2$. A solution of this compound in hydrated alcohol treated with ammonia, forms a yellowish-white precipitate of the *hydrated oxide*, which, after drying in vacuo, ignites spontaneously in the air, giving off a dense yellow vapour. The oxide appears also to be formed by the spontaneous oxidation of bistriethyl, 2 atoms of ethyl being eliminated. *Sulphide of bisethyl* is formed by treating the iodide with sulphydric acid; and the nitrate and sulphate by acting on the iodide with the corresponding silver-salts. (Dünhaupt.)

BISTRIETHYL, or TRIETHYL-BISMUTHINE. $(C^2H^5)^3Bi$. *Bismethyl.*—Formed by the action of iodide of ethyl on bismuthide of potassium.

Preparation.—Bismuthide of potassium, finely pounded, and without admixture of sand, is introduced into a small flask; iodide of ethyl added in excess; the flask closed, and immediately connected with a long narrow distillation-tube passing into a receiver surrounded with ice, all these manipulations being performed as quickly as possible. In a few minutes, the action begins, the mixture becomes heated, and the excess of iodide of ethyl distils over. Water free from air is then introduced into the flask, which is immediately closed and heated in the water-bath, till the mass becomes soft and the iodide of potassium is dissolved. The same operations are repeated with a considerable number of flasks; the disintegrated contents transferred as quickly as possible into a large flask filled with carbonic anhydride; shaken up several times with a large quantity of ether; the ethereal solution mixed with the de-aërated water; and the ether completely distilled off in the water-bath. The bistriethyl remains at the bottom of the water, and is purified by distilling it with water (it cannot be distilled alone, without decomposition), shaking it up with a small quantity of dilute nitric acid to free it from oxide, and drying over chloride of calcium. During all these operations, the air must be carefully excluded (Breed). 3 lbs. of bismuthide of potassium and 1 lb. of iodide of ethyl, yield 4 or 5 oz. of pure bistriethyl. (Dünhaupt.)

Properties.—Transparent, very mobile liquid, sometimes colourless, but often slightly tinged with yellow. Has an unpleasant odour like that of stibtriethyl, and its vapour, when inhaled, even in small quantity, produces a very disagreeable burning sensation on the tip of the tongue (Breed). Insoluble in water, sparingly soluble in ether, readily in absolute alcohol.

Decompositions.—1. Bistriethyl heated in a retort, begins to boil at about 50° C., giving off a gas free from bismuth, which burns with a clear flame, while metallic bismuth separates out in the retort. If the heat be continued, the thermometer rises above 160° C., and continues to rise till a sudden and violent explosion takes place, which shatters the apparatus (Breed). The dilute ethereal solution is also decomposed when left to evaporate in the air, leaving a white residue of hydrated oxide of bismuth (Dünhaupt).—2. Bistriethyl exposed to the air, gives off thick yellow vapours and takes fire with slight explosion, diffusing a dense yellow smoke of bismuth-oxide; this effect is best shown by moistening a piece of filtering paper with the liquid and exposing it to the air.—3. Fuming nitric acid decomposes bistriethyl, with explosion and vivid combustion.—4. Bistriethyl burns in chlorine gas with separation of charcoal, and takes fire in contact with bromine. In general, its reactions resemble those of stibtriethyl (Breed).—5. Bistriethyl added to solutions of metallic salts (*e.g.* to nitrate of silver or corrosive sublimate), does not simply throw down the oxide, but is itself decomposed. On adding an alcoholic solution of bistriethyl to a not too dilute solution of protochloride of mercury, the former being poured slowly and with constant stirring into the latter, a very large precipitate of mercurous chloride is immediately obtained, chloride of bismuth and hydrochloric ether being doubtless formed at the same time. But if the process be reversed, and a hot dilute alcoholic solution of corrosive sublimate be poured in a thin stream and with constant stirring into a dilute alcoholic solution of bistriethyl to which a few drops of hydrochloric acid have been added, to prevent separation of oxide of bismuth, no precipitate is formed at first; but after some time, a bulky precipitate appears, which however is again completely dissolved if the liquid be heated. The reaction is terminated when a drop of the liquid no longer produces a white precipitate in a solution of corrosive sublimate; by a little care, it may be arranged that neither liquid shall predominate. If the liquid be then heated on the water-bath till it becomes perfectly clear, separated, if necessary, from a small quantity of metallic mercury by decantation, and then left to cool, light, crystalline, silvery, iridescent laminæ separate out and gradually fill the whole fluid. These crystals consist of *chloride of hydrargethyl*, $C^2H^5Hg^2Cl$; the solution from which they are deposited contains *chloride of bisethyl*, $C^2H^5BiCl^2$ (Dünhaupt):

$$(C^2H^5)^3Bi + 4HgCl = 2C^2H^5Hg^2Cl + C^2H^5BiCl^2.$$

Combinations.—Bistriethyl combines with *Bromine*, *Iodine*, *Sulphur*, &c.; but the compounds are less stable than those of stibtriethyl.

Bromide of Bistriethyl appears to be formed when bromine is added to an alcoholic solution of bistriethyl; but the solution deposits bismuth when evaporated.

Iodide of Bistriethyl.—When iodine is added to an alcoholic solution of bistriethyl, heat is evolved, the colour of the iodine disappears, and iodide of bistriethyl is formed. This compound is less stable than iodide of stibtriethyl; when its alcoholic solution is left to itself for a while, iodide of bismuth separates out. (Breed.)

An iodide having the composition $C^6H^{15}Bi^3I^5$, or $(C^2H^5)^3BiI^2.Bi^2I^3$, is obtained by adding iodine to a tolerably strong alcoholic solution of bistriethyl, till its colour [no longer?] disappears, filtering from the precipitate, and adding to the filtrate a large quantity of water at 40° C. A small quantity of a ruby-coloured liquid separates; and if the watery liquid be poured off from this, a large quantity of beautiful red needle-shaped crystals are formed as it cools; these must be immediately collected and dried in vacuo. The same compound is formed when bistriethyl is left for a considerable time in contact with dilute nitric acid and then mixed with iodide of potassium. It is sparingly soluble in water, but dissolves pretty readily in alcohol and ether; the solutions have a pale yellow colour. The compound heated on platinum foil gives off a strong yellow vapour which takes fire on coming in contact with flame. (Dünhaupt.)

Another iodine-compound, having the formula $(C^2H^5)^4Bi.2C^2H^5I$, is contained in the above-mentioned ruby-coloured liquid; but it is very instable. (Dünhaupt.)

Sulphide of Bistriethyl, has not been obtained in the separate state. Bistriethyl which has been long exposed to the air under water, gives with sulphuretted hydrogen, first a yellow, then a brown precipitate, consisting of $(C^2H^5)^3BiS.Bi^2S^3$. (Dünhaupt.)

BISMUTH-SILVER. A mineral sometimes occurring in acicular or capillary crystallisations, but more generally amorphous, as at Schapbach in Baden; it is found also in the cupreous shale of Mansfeld, Thuringia. It is soft and sectile, opaque, with metallic lustre and tin-white or greyish colour, subject to tarnish; fracture uneven. Contains, according to Klaproth's analysis, 27 per cent. bismuth, 33 lead, 15 silver, 4·3 iron, 0·9 copper, and 16·3 sulphur. A *bismuth-silver* from the mine of San Antonio near Copaipo, Chili, was found by Domeyko to contain 60·1 per cent. silver, 10·1 bismuth, 7·8 copper, 2·8 arsenic, and 19·2 gangue. It occurs disseminated, and has one or more imperfect cleavages, and is probably either monometric or rhombohedral. (Dana, ii. 16.)

BISMUTITE. Native carbonate of bismuth. See CARBONATES.

BISSA-BOL. A gum resin from Arabia, resembling myrrh. (Vaughan, Pharm. J. Trans. xii. 227.)

BISTRE. A brown pigment, consisting of the finer parts of wood-soot, separated from the grosser by washing. The soot of beech-wood is said to yield the best bistre. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 307.)

BITTER-ALMOND OIL. A peculiar volatile oil obtained by distilling bitter-almonds with water. It was discovered by Martrès in 1803; Stange showed that the crystallised acid which is produced from it is benzoic acid; Robiquet, and Liebig and Wöhler explained its formation; and Liebig and Wöhler (1832, Ann. Ch. Pharm. xxii. 1) first fully examined it. It is also obtained from the amygdaliferous parts of most *Pomeæ* and *Amygdaleæ;* from the leaves of the cherry-laurel (*Cerasus lauro-cerasus*), and of *Cerasus padus*, from peach and cherry-kernels, &c. It is possible that many of these oils are not identical, but isomeric, with bitter-almond oil, and that it is owing to their presence that different specimens of the commercial oil yield with the same reagent such different results. The chief constituent of the oil is hydride of benzoyl, always accompanied by hydrocyanic acid and other compounds (see BENZOYL, HYDRIDE OF). The oil does not exist ready-formed in bitter-almonds, but is produced by the action of water and a peculiar ferment, *emulsin* or *synaptase*, upon the amygdalin contained in the almonds, which is thereby converted into hydride of benzoyl, hydrocyanic acid, and glucose:

$$\underset{\text{Amygdalin.}}{C^{20}H^{27}NO^{11}} + 2H^2O = \underset{\substack{\text{Hydride}\\ \text{of benzoyl.}}}{C^7H^6O} + CNH + \underset{\text{Glucose.}}{2C^6H^{12}O^6}.$$

The oil is thus prepared: Bitter-almonds are crushed, and freed from fixed oil by cold pressing, then stirred up to a thin paste with 4—6 pts. cold or lukewarm water, and the mixture allowed to stand for twenty-four hours before distillation. If distilled over the open fire, it is very apt to froth over, unless it is stirred continually; for this reason it is best distilled with vapour of water. This may be done by covering the bottom of the still with a thick layer of coarse sand saturated with water, and pouring the almond-paste upon it. The frothing may also be avoided by removing most of the solid matter before distilling. The first portion of the distillate is richest in oil, and in hydrocyanic acid also, and is therefore clear; the latter portions, containing less hydrocyanic acid, are milky. The distillation is continued as long as the liquid which comes over smells of bitter-almonds; the oil in the receiver is then separated from the water, which, as it contains a good deal of oil in solution, is again distilled, when the oil passes over with the first portions of the water. The addition of chloride of sodium facilitates the separation of the oil. 1000 pts. almonds do not yield more than 7 or 8 pts. oil.

Bitter-almond oil is colourless when freshly prepared, but soon becomes yellow; it has a peculiar strong aromatic smell, besides that of prussic acid, and a burning taste; is heavier than water; boils at about 180° C., and burns with a smoky flame. Its poisonous action is entirely owing to the presence of prussic acid. (For methods of purifying the oil, see BENZOYL, HYDRIDE OF.)

Bitter-almond oil was formerly much used in perfumery, but it is now replaced in great measure by nitrobenzene (*essence de Mirbane*). Being an expensive article, it is very liable to adulteration, usually with alcohol (which, if added in moderation, does not materially affect its smell), light ethereal oils, or nitrobenzene. Light oils, whose smell is masked by that of hydride of benzoyl, may be detected by allowing the latter to oxidise into benzoic acid by exposure to the air, when the smell of the former becomes evident, or by their effect on the specific gravity of the oil, a method which applies to alcohol also. Alcohol may also be detected by agitating the oil with twice its volume of nitric acid of specific gravity 1·42; with unadulterated oil, no immediate action is produced; but, if 8—10 per cent. alcohol be present, red fumes are given off with effervescence. By using acid of 1·5 specific gravity, as little as 3—4 per cent. alcohol may be detected (Redwood). A good reagent for detecting adulterations is a strong solution of an acid sulphite of alkali-metal, which dissolves the pure oil entirely, but leaves behind all impurities which are not of the nature of aldehydes.

Owing principally to the presence of hydrocyanic acid, bitter-almond oil behaves with several reagents differently from hydride of benzoyl. By *heat* and by oxidising agents generally, *e.g.* by nitric acid, it is acted on in the same manner as hydride of benzoyl. With *sulphuric acid*, it yields stilbous acid, and (perhaps) benzoate of hydride of benzoyl. A mixture of Nordhausen sulphuric acid with bitter-almond oil yields, on addition of water, a crystalline body, which presents the properties of mandelic acid. Dry *chlorine* acts upon it as upon hydride of benzoyl; with moist chlorine it forms stilbesic acid and *benzoate of hydride of benzoyl*. To this latter compound, which is frequently regarded as identical with stilbous acid, Liebig assigns the formula $C^{21}H^{18}O^4 = 2C^7H^6O + C^7H^6O^2$. Bitter-almond oil saturated with moist chlorine solidifies finally to a crystalline mass, which, when washed with cold ether, leaves this compound as a crystalline powder. It is insoluble in water, slightly soluble in cold ether, abundantly in alcohol. When heated, it melts and volatilises undecomposed. Heated with alcoholic potash, it yields potassic benzoate. With *hydrochloric acid*, it yields either hydrocyanate of hydride of benzoyl or mandelic acid. With *chloride of* *sulphur*, it yields stilbous acid. With *sulphide of ammonium*, it yields hydride of thiobenzoyl, hydride of sulphozobenzoyl, and sulphydrate of azobenzoyl. With *bisulphide of carbon* and *ammonia*, it yields sulphocyanobenzylene. With *cyanide of potassium*, it yields sometimes benzoin, sometimes benzamide. Solid *potash* converts it into benzoic acid; aqueous or alcoholic potash (especially the latter) into benzoin. With *ammonia*, it yields very various products, according to circumstances; these are azobenzoide, azobenzoidin, azobenzoyl, benzamil, benzhydramide, benzoylazotide, dibenzoylimide, hydrobenzamide, stilbazide. Most of these compounds were discovered by Laurent, and many are very imperfectly known. *Baryta-* or *lime-water* converts it into benzoin. F. T. C.

BITTER-ALMOND WATER. A pharmaceutical preparation, employed in medicine, consisting of a solution of bitter-almond oil in water. It is prepared in the same manner as bitter-almond oil; but, since the water must be of a known strength, the quantity of almonds and water to be employed and of distillate to be collected is fixed by the pharmacopœia. These quantities vary in different pharmacopœias: in the Prussian, 2 lbs. almonds are pressed and macerated with 10 lbs. water, 4 ozs. alcohol added, and 2 lbs. of distillate collected. The Parisian pharmacopœia collects 2 lbs. the Saxon 3 lbs. of distillate for each pound of almonds. The addition of alcohol does not seem to have any advantage. Heat must be carefully avoided in the pressure and maceration of the almonds. Bitter-almond water is generally a more or less milky liquid, smelling and tasting strongly of crude bitter-almond oil; it decomposes by exposure to the air, and must therefore be kept in stoppered bottles completely full. Its strength is very uncertain, however closely the pharmacopœia directions are adhered to. It is usually valued by the amount of prussic acid which it contains, which may be readily determined by Liebig's volumetric method (see HYDROCYANIC ACID, under CYANOGEN); the Prussian pharmacopœia requires it to contain 0·14 per cent. prussic acid. *Laurel-water*, prepared from laurel leaves, and *cherry-water* from wild cherries, contain the same constituents as bitter-almond water. The latter may be distinguished from laurel-water by becoming milky immediately on addition of ammonia, an effect which is not produced on laurel-water till after some time; or, according to Lepage, by chloride of gold, which gives with both waters a yellow colour, which, in bitter-almond water, disappears in eight hours, while in laurel-water it remains for twenty-four hours. (J. Ch. méd. xxiv. 365.) F. T. C.

BITTER PRINCIPLE. Many vegetable substances yield bitter extracts, which were formerly supposed to contain a common constituent, called *Principium amarum*. More exact investigation having shown, however, that many of these vegetable bitters are definite chemical compounds of very various composition, *e.g.* picric acid and the vegetable alkaloids, the term bitter principle is now restricted to the brown amorphous bitter extractive matter obtained from many plants by boiling with water, evaporating the extract to dryness, exhausting with hydrated alcohol, evaporating, and treating the residue with absolute alcohol, which dissolves resins, &c., and leaves the bitter substance undissolved. The products thus obtained, are not, generally speaking, of definite constitution. From some plants, however, more definite bitter principles are obtained, *e. g. absinthin* from wormwood, *aloin* from aloes, &c.

BITTERN. The mother-water which remains after the crystallisation of common salt from sea-water or the water of salt-springs. It contains a considerable quantity of sulphate and chloride of magnesium, to which its bitterness is owing, also more or less bromine and iodine.

BITTER SPAR or **RHOMBSPAR.** *Brown-spar. Pearl-spar. Talc-spar. Dolomite. Chaux carbonatée magnésifère.*—This mineral crystallises in rhombohedrons, which were formerly confounded with those of calcspar, but differ in the angles, the primary form being an acute rhombohedron of 106° 18′, and 73° 42′ (mean). The crystals are generally rhombohedrons R, with more acute or more obtuse rhombohedron in combination, the base 0R and the hexagonal prisms ∞R often occurring. The rhomb R generally has its faces curved like a saddle; $\frac{1}{2}R$ is more generally lenticular. Cleavage parallel to R. Fracture conchoïdal, uneven, splintery, and earthy. Colour white, greyish, or yellow, with a somewhat pearly lustre. Rarely transparent, but exhibits various degrees of translucence down to complete opacity. Hardness 3·5 to 4·5. Specific gravity 2·8 to 3·0. Its formula is $(Ca^2; Mg^2)CO^3$, the calcium and magnesium replacing one another in any proportion, so that it presents all varieties of composition, from that of calcspar to that of magnesite. Iron (*ferrosum*) and manganese (*manganosum*) also occur, replacing the other metals in subordinate proportions. In the state of powder, it dissolves readily in warm hydrochloric acid, but in lumps the acid scarcely acts upon it. Before the blowpipe, it becomes caustic, but does not melt. It is usually imbedded in serpentine, chlorite, or steatite, and is found in the Tyrol, Salzburg, and Dauphiny; in Scotland, on the borders of Loch Lomond, in chlorite slate, and near Newton Stewart in Galloway, also in the Isle of Man. It bears the same relation to dolomite, or massive magnesian limestone, that calcspar bears to common limestone.

BITTERSWEET. *Stipites Dulcamara.* The stems of *Solanum Dulcamara* (*q.v.*)

BITUMEN. This term includes a considerable number of inflammable mineral substances, mainly consisting of hydrocarbons. They are of various consistence, from thin fluid to solid, but the solid bitumens are for the most part liquefiable at a moderate heat. The purest kind of fluid bitumen, called *Naphtha*, or *Rock-oil*, is a colourless liquid of specific gravity 0·7 to 0·84, and with a bituminous odour. It often occurs in nature combined with asphalt and other solid bitumens. *Petroleum* is a dark-coloured, fluid variety containing much naphtha. *Maltha* or *mineral tar* is a more viscid variety. The solid bitumens are *Asphalt*, already described (p. 425), *Mineral tallow*, or *Hatchetin*, and *Elastic bitumen*, *Mineral Caoutchouc* or *Elaterite*. (See the several substances in alphabetical order. For the practical uses of bitumen, see *Ure's Dictionary of Arts, Manufactures and Mines*, i. 308.)

BIURET. $C^2H^5N^3O^2$ (dried at 100° C.); $C^2H^5N^3O^2.H^2O$ (crystallised).—A product of the decomposition of urea and nitrate of urea. It is isomeric with acid cyanate of ammonium, $2CHNO.NH^3$, and may be regarded as a secondary amide, $N\left\{\begin{matrix}(CH^2NO)^2\\H\end{matrix}\right.$, whereas urea is a primary amide containing the same radicle, $N\left\{\begin{matrix}CH^2NO\\H^2\end{matrix}\right.$, and isomeric with neutral cyanate of ammonium, $CHNO.NH^3$.

The formation of biuret from urea is represented by the equation

$$\underbrace{2CH^4N^2O}_{\text{Urea.}} = \underbrace{C^2H^5N^3O^2}_{\text{Biuret.}} + NH^3.$$

To prepare it, urea is melted in an oil-bath for some time at 150° to 170° C.; and as soon as the evolution of ammonia ceases and the residue becomes pasty, this residue is treated with a very small quantity of boiling water; the liquid, after filtration, is precipitated by a solution of subacetate of lead; the precipitate, consisting of cyanurate and ammelidate of lead, is separated by filtration; and the liquid, after being treated with sulphuretted hydrogen to remove the excess of lead, and again filtered, is evaporated till it crystallises. Biuret is then deposited in small granular crystals, which may be purified by recrystallisation from water. It is also obtained, though in small quantity, by the action of heat upon nitrate of urea.

Biuret dissolves very easily in water and in alcohol, and crystallises from the latter liquid in long anhydrous leafy crystals, and from water in hydrated crystals, which give off their water of crystallisation when exposed to dry air or dried at 100° C. It dissolves without decomposition in cold strong sulphuric acid, and is not altered by boiling with nitric acid, unless the acid is very strong. Its solution is not precipitated by lead or silver salts, by gallic acid, or by tannin. On adding a few drops of a solution of copper salt to a solution of biuret, and then a slight excess of potash, a deep red colour is produced. This reaction takes place also with solutions of biuret in acids or in ammonia, and affords a very delicate test of its presence. Biuret when heated, melts, gives off vapours of ammonia, and ultimately leaves pure cyanuric acid:

$$3C^2H^5N^3O^2 = 2C^3H^3N^3O^3 + 3NH^3.$$

(Wiedemann, Pogg. Ann. lxxiv. 67.)

BIXIN. A colouring matter contained in annotto (the red paste obtained by crushing the seeds of the *Bixa orellana*). According to Chevreul, annotto contains two colouring matters, viz. *orellin*, a yellow dye, soluble in water and alcohol, but sparingly in ether, and *bixin*, an orange-coloured dye, sparingly soluble in water, easily in alcohol and ether. According to Kerndt, bixin is $C^{16}H^{20}O^3$, and when exposed to the air, and in the moist state, is partly converted into orellin. According to Preisser, Ann. Ch. Pharm. lii. 382), bixin is obtained in small slightly yellowish crystals, by treating lumps of pure annotto with carbonate of sodium, precipitating with basic nitrate of lead, decomposing the precipitate with sulphuretted hydrogen, and evaporating the colourless filtrate. It is bitter, soluble in water, alcohol, and ether, volatile when heated, turned yellow by sulphuric and nitric acids, orange-yellow by chromic acid. Treated with ammonia in contact with the air, it is converted into a dark red-brown substance, *bixein*, which is the red-colouring matter of annotto. It combines with lead-oxide and alkalis, and is turned blue by sulphuric acid. (Preisser.)

According to Girardin (J. Pharm. [3] xxi. 174), the name of bixin is applied commercially to a variety of annotto, having six to ten times the colouring power of common annotto, a superiority which it appears to owe to a quicker process of extraction.

BLACK BAND. A variety of carbonate of iron. See IRON and CARBONATES.

BLACK CHALK. This mineral has a bluish-black colour, a slaty texture, soils the fingers, and is meagre to the touch. It contains about 64 silica, 11 alumina, 11 carbon, with a little iron and water. It is found in primitive mountains, and also sometimes near coal formations. It occurs in Caernarvonshire and in the island of Isla.

BLACK JACK. The miners distinguish blende, or mock lead, by this name. It is an ore of zinc.

BLACK LEAD. See GRAPHITE and PLUMBAGO.

BLACK WADD. One of the ores of manganese.

BLANCHININE. The name of an alkaloid said to exist in *China blanca.*

BLANQUETTE. A kind of crude soda, less powerful than barilla, obtained at Aigues-Mortes, by the incineration of *Salsola Tragus* and *S. Kali.*

BLAPS OBTUSA. This insect contains, according to Hornung and Bley (J. pr. Chem. vi. 237), a red colouring matter, fatty and volatile oil, resin, formic acid, uric acid, chitin, wax, and other constituents.

BLEACHING. The chemical art by which the various articles used for clothing are deprived of their natural dark colour and rendered white.

The oldest method of bleaching, which is still practised in some localities, and for particular kinds of goods, especially for hempen and flaxen goods, consists in extending the tissues on the grass of a meadow, so as to expose them for some days to the united action of light, air, and water, then washing them in alkaline ley, and repeating this series of operations a considerable number of times.

This mode of bleaching is effective, but slow, and involves a great amount of labour. About 1785, Berthollet proposed the use of chlorine for bleaching vegetable tissues; but its introduction met with considerable opposition from manufacturers, because the mode of applying it being but imperfectly understood, its action was uncertain, and moreover it was found to injure the tissues; gradually, however, these difficulties have been overcome, and the use of chlorine for bleaching cotton goods has entirely superseded the old method. Chlorine was first used in the form of aqueous solution; afterwards solutions of chlorine in caustic alkalis, that is to say, solutions of hypochlorite of potassium or sodium, the so-called chlorides of potash and soda, were used; but these compounds are now almost entirely superseded by the *hypochlorite of calcium*, the so-called *chloride of lime* or *bleaching powder*. This substance is prepared on a large scale by exposing slaked lime to the action of chlorine gas, whereby a solid mixture of hypochlorite and chloride of calcium is produced. It is soluble in water, and the solution is used for steeping the goods to be bleached. By itself it exerts no bleaching action whatever; but by exposing the fabrics wetted with it to the action of the carbonic acid in the air, or more quickly by steeping them in a bath of dilute sulphuric or hydrochloric acid, the salt is decomposed, and the liberated hypochlorous acid exerts its bleaching action on the tissues.

The strength of the chlorine-liquor is a matter of great importance. The stronger the liquor, the more rapid will be its action; but on the other hand, the greater will be the chance of injury to the goods. In practice it is not found safe to use a solution marking more than 2° or 3° of Baumé's hydrometer, or 0·5° of Twaddell's, equivalent to specific gravity 1002·5; and even this must be carefully removed by subsequent washing, and in some cases by the use of hyposulphite of sodium or other antichlors. (See ANTICHLOR.)

Wool and silk are for the most part bleached with sulphurous acid, chlorine and the hypochlorites being found to exert an injurious action upon them.

The rationale of bleaching is not thoroughly understood, but the most probable explanation of the action is, that it is due in all cases to oxygen in the peculiar active form called ozone. That active oxygen does possess this bleaching power is well-known: witness the action of peroxide of hydrogen on vegetable colours. Now in the old method of bleaching by exposure, light is an essential element of the action, the bleaching taking place much more quickly in sunshine than under a clouded sky. But Schönbein's investigations have also shown that ordinary atmospheric oxygen passes into the active state under the influence of light and moisture. Chlorine abstracts hydrogen from the colouring matter, and the oxygen thus set free produces the bleaching action. The action of sulphurous acid appears at first sight to be apposite to this, viz. deoxidising; but it is known from Schönbein's investigations, that an aqueous solution of sulphurous acid or an alkaline sulphite exposed to air and light quickly brings a portion of the oxygen in contact with it into the active state; hence also the bleaching action may in this case be due to oxidation. Sometimes, however, the sulphurous acid appears to unite directly with the colouring matter of the tissue to form a colourless compound.

The actual process of bleaching by means of chlorine or sulphurous acid is always preceded or accompanied by certain cleansing operations, consisting in washing with water, and boiling with alkaline leys or soap, the object of which is to remove resinous, fatty, and other impurities, either natural to the fibre or introduced accidentally or intentionally in the course of manufacture. All these substances impair the whiteness of the fabric, and often interfere greatly with the processes of dyeing and printing. Indeed, their removal by the means above mentioned, constitutes a very important part of the bleaching process, a large portion of the colouring matter being got rid of at the same time, so that the chlorine or sulphurous acid serves to give only the last finish. Cotton and linen goods are cleansed by washing with water and boiling with alkaline leys: formerly potash and soda were used for the purpose, but they are now nearly superseded by lime, at least for the first cleansing, as this substance, besides being much cheaper than the alkalis, is less likely to injure the fabric. Silk and wool are cleansed by scouring or boiling with water and soap, as they cannot bear the action of pure alkaline solutions.

Bleaching of Cotton. — The series of operations in the bleaching of cotton, may be thus generally described:

1. Boiling, or as it is technically called *bucking* or *bowking*, with milk of lime (1lb. of lime to 14 lbs. of cloth, and about as much water as will cover the cloth). This operation converts the resinous and fatty matters into lime-soaps.

2. Washing with water, in the dash-wheel, or other suitable machine, to remove the excess of lime and various soluble and mechanical impurities introduced in the process of manufacture.

3. *Souring* in hydrochloric acid of specific gravity 1·010 or 2° Twaddle, to decompose the lime-soaps and remove the lime. Dilute sulphuric acid is sometimes used, but hydrochloric acid is preferable, as chloride of calcium is much more soluble than the sulphate.

4. Washing again to remove excess of acid.

5. Bowking with a solution of soda-ash and resin (170 lbs. soda-ash, and 30 lbs. resin, to 3500 lbs. of cloth, and about the same quantity of water as in the lime-process). An imperfect soap is thus produced, which removes the rest of the fatty matter and dirt.

6. Washing, and then immersing the cloth in the chlorine-bath; this is called *chlorinating* or *chemicking*. The solution, which should be quite clear, has a specific gravity of 1002·5 or ½° Twaddle.

7. Souring in hydrochloric or sulphuric acid of 2° Twaddle, to set free the hypochlorous acid; then washing and drying.

The strength of the various liquors must be regulated according to the quality of the goods to be bleached, and the manner in which the operations are conducted: the preceding proportions of lime, soda, resin, &c. are given merely as examples. Sometimes carbonate of soda is used in the cleansing operations, sometimes a mixture of soda-ash and quick lime, which of course produces caustic soda. It is often found advantageous to perform the souring and chlorinating in two successive operations, the goods being washed between the two. This treatment is found to be less likely to injure the fibre than long-continued exposure to the action of the liquid in one operation. In all the operations, it is important to keep the cloth completely immersed in the liquid, and never to leave it exposed to the air before washing; because the acid or alkaline liquids, if allowed to become concentrated on it by drying, are sure to destroy the fibre.

Bleaching of Linen. — Linen contains a much larger quantity of colouring matter than cotton, and in bleaching loses nearly a third of its weight, whereas cotton loses only one-twentieth. This large amount of colouring matter is not natural to the flax, but is chiefly produced in the operation of steeping or *water-retting*, by which the textile fibres surrounding the stem of the plant are separated from the woody portion.

The colouring matter of steeped flax is insoluble in water, acids, and alkalis, but becomes soluble in alkalis after exposure to light or to the action of chlorine. Generally speaking, it is not found advantageous to rely on the action of chlorine alone for the bleaching of linen; the old method of exposure on the grass,—*crofting*, as it is called,—being almost always resorted to in addition. Moreover, it is not found possible to get rid of the colour entirely in one series of operations, several alternate exposures to oxygen or chlorine and to alkali being required to render the material perfectly white.

The following is an outline of the Irish method, as practised in the neighbourhood of Belfast:

1. *Steeping.*—After the linen has been scoured in the fulling-mill, warm water is poured upon it, and it is left immersed for two or three days, till acid fermentation sets in.—2. Boiling with potash-ley, soda-ley, or lime-water.—3. Washing.—4. *Crofting* or exposure on the grass for two or three days.—2′, 3′, 4′. The bowking, washing and crofting are repeated several times, six repetitions sufficing for the finer linens, and as many as twelve being sometimes required for the coarser.—5. *Souring* with hydrochloric- or sulphuric-acid of 2° Twaddle.—6. Washing, as in 3.—7. Soaping, that is, rubbing with solid soap or with very strong soap-suds.—8. Boiling in alkaline-ley of about ½ per cent.—9. Washing, as in 3 and 6.—10. Crofting for two days.—11. Chlorinating with a solution of hypochlorite of potassium, prepared by treating common bleaching powder with carbonate of potash. The liquor used is very weak.—12. Washing, as in 3 and 6.—13. Souring, as in 5, but with somewhat weaker acid.—14. Washing.—15. Soaping, as in 7.—16. Scalding, by immersing the cloth in soap-suds mixed with a little potash-ley of ½° B., and heating the liquid to boiling.—17. Washing.—18. Crofting.—19. Washing and drying.

Bleaching of Silk.—Raw silk contains, besides the true fibre, about 40 per cent. of foreign matter, viz. albumin, gelatinous substances, wax, fat, resin, and colouring matter. These substances are removed by boiling the silk in a strong solution of soap, then washing and rinsing. The silk after this treatment, is nearly white, but to render it quite white, it is sulphured, that is to say, suspended in the moist state in a large box in which sulphur is burned. About 1 lb. of sulphur is required for 20 lbs. of silk, and to obtain perfect whiteness, about four sulphurings, of twelve to sixteen hours each, are required.

As the silk loses considerably in weight, when cleansed in the manner above described, it is sometimes thought better to subject raw silk to the bleaching process without previous cleansing. For this purpose, a bath is used composed of 7 pts. hydrochloric acid and 3 pts. nitric acid, sometimes with addition of sulphuric acid, the liquid being diluted with water to 3° Bm. In this mixture, the skeins of silk are suspended, and repeatedly moved about for two or three hours, then wrung, twice washed, and afterwards sulphured. Sometimes the bleaching in the acid mixture is preceded by softening in a soap-bath; sometimes this softening process is made to intervene between the acid bath and the sulphuring.

Bleaching of Wool.—Wool is never bleached in the fleece, because its whiteness would be destroyed in the subsequent operations of spinning and weaving; the bleaching is, therefore, always performed on the yarn or on the woven fabric. A considerable portion of the dirt which adheres to the wool while on the animal, is removed by the washing which precedes shearing; this washing also removes the sweat, which is a kind of soap, chiefly composed of fatty matter and potash. But there still remains a quantity of free fat, which is generally removed by steeping and agitating it for ten or fifteen minutes in soap and water, or soda-ley, sometimes in putrid urine diluted with two or three measures of water, sometimes even in pure water. To prepare the wool for spinning, it is then greased with oil, as, without this preparation, it would be too harsh and very liable to tear. The grease thus added must of course be removed in the subsequent bleaching process. The treatment consists in passing the wool through a soda-bath, then through a soap-bath, washing in lukewarm water, and suspension in the sulphur chamber, this series of operations being repeated several times, and finally passing the bleached wool through a blue-bath, which is a very weak solution of soap containing hydrate of alumina and indigo. The sulphuring is sometimes omitted, and the cleansing is effected entirely by ammonia.

Bleaching of materials for Paper.—The rags used for making paper are bleached in the same manner as cotton goods. After being properly sorted and chopped or torn in pieces, they are bowked with lime-water, soured, washed in the rag-engine, which is a combined washing machine and filter, then chlorinated, soured, and washed again, and finally treated with a solution of hyposulphite of sodium to remove the last traces of chlorine. (See ANTICHLOR.)

"For bleaching old paper: Boil the printed paper for an instant in a solution of caustic soda. Steep it in soap-suds, and then wash it; after which it may be reduced to pulp. The soap may be omitted without much inconvenience.—For old written paper to be worked up again: Steep it in water acidulated with sulphuric acid, and then wash it well before it is taken to the mill. If the water be heated, it will be more effectual.—To bleach printed paper without destroying its texture: Steep the leaves in a caustic solution of soda, either hot or cold, and then in a solution of soap. Arrange them alternately between cloths, as paper-makers do thin sheets of paper when delivered from the form, and subject them to the press. If one operation do not render them sufficiently white, it may be repeated as often as necessary.—To bleach old written paper without destroying its texture: Steep the paper in water acidulated with sulphuric acid, either hot or cold, and then in a solution of oxygenated muriatic acid; after which immerse it in water, so that some of the acid may remain behind. The paper, when pressed and dried, is fit for use." *Ure.*

The *bleaching of straw* is effected by steeping it in hot water, heating it repeatedly during several days, and immersing it in weak solution of chloride of lime or of soda, alternately with weak alkaline leys.

Bleaching of Horse-hair.—White horse-hair requires further bleaching to adapt it to many purposes. The process consists in washing it in soda-solutions, not too strong, and at the heat of the hand, then hanging it up in the sulphur-chamber, and repeating these processes several times.

[For further details, see *Ure's Dictionary of Arts, Manufactures, and Mines,* i. 318, also *Muspratt's Chemistry,* i. 299.]

BLEACHING POWDER. *Chloride of Lime, Oxymuriate of Lime.* See HYPOCHLORITES, under CHLORINE.

BLEINIERITE. Basic Antimonate of Lead (p. 326).

BLENDE. Native SULPHIDE OF ZINC. (See ZINC.)

BLÖDITE. Probably the same as ASTRACANITE (i. 429).

BLOOD. The blood of the higher animals forms a rather viscous opaque liquid, heavier than water, and of more or less intense red colour, arterial blood being always lighter than venous. It is transparent in very thin strata. The specific gravity of normal human blood averages about 1·055, but under certain circumstances varies between 1·045 and 1·075; it is slightly less in women than in men, and still less in children. The specific gravity of arterial blood is rather less than that of venous. The blood of most domestic animals differs but little in specific gravity from that of man (specific gravity of bullock's blood = 1·060; of sheep's = between 1·050 and 1·058). The blood has always an alkaline reaction. When warm it has a peculiar odour, generally more powerful in the male than in the female.

From two to five minutes after the blood has left the circulation, it begins to *coagulate,* a film gradually extending from the surface and circumference, so that the whole becomes gelatinous in the course of from seven to fourteen minutes. The *coagulum* (*fibrin* and *blood-corpuscules*) then gradually contracts and separates from the watery portion of the blood (*serum*); and in from twelve to forty hours, the blood is completely resolved into serum and thick red clots, which swim beneath it. The blood of men coagulates more slowly, but yields a denser coagulum than that of women; in the embryo it coagulates imperfectly. Arterial blood coagulates more rapidly than venous. The presence of air and a rise of temperature promote coagulation; cold retards it.

The constituents of blood are partly in solution and partly suspended (blood-corpuscules). Swammerdam, in 1664, first observed corpuscules in the blood of the frog; he described them as oval. Leeuwenhoek (Phil. Trans. 1664, p. 23) found that human blood consisted of round bodies swimming in an opaline liquid, and that the colouring matter of the blood of mammalia, fish, and frogs was contained in these corpuscules, which were round in men, oxen, sheep, and rabbits, but oval in birds, frogs and fish. Later observers discovered that all blood-corpuscules are flattened. The coloured corpuscules consist of a colourless enevelope, the contents of which are red, or by transmitted light yellow, and each is slightly depressed and concave in the centre. In general they do not possess any nucleus, and only a few of them exhibit something approaching to one. The size of the red corpuscules varies considerably in different animals, the smallest being found in the blood of the *Moschus javanicus,* and having a diameter of 0·00208 mm. (Gulliver), and the largest in that of the *Cryptobronchus japonicus* (0·05623 mm. broad, and 0·0333 mm. long, V. d. Hoeven). The human corpuscules have a diameter of 0·00752 mm., those of the carnivora between $\frac{1}{[illegible]}$ and $\frac{1}{135}$ mm. and their thickness is generally $\frac{1}{4}$ or $\frac{1}{3}$ of their diameter. The blood-corpuscules of embryos are larger than those of the grown up animals of the same species. Milne-Edwards asserts that the size of the corpuscules is closely connected with the size of the organs of respiration. To prevent their shrinking up during measurement, C. Schmidt moistens a glass plate with an exceedingly thin layer of the blood to be examined, so that it dries up immediately. The corpuscules thus adhere by their flat sides to the glass, and remain of this same size when the serum has dried up. The blood of different animals may frequently be distinguished under the microscope by the size of the corpuscules.

According to Schmidt, the specific gravity of the blood-corpuscules of a healthy man varies between 1·0885 and 1·0889; in cholera it sometimes increases to 1·1025 or 1·1027. The red corpuscules *sink* in the serum; they are generally equally coloured; a few, however, are sometimes darker, sometimes lighter than normal corpuscules. The difference in colour is dependent upon the absolute amount of hæmatin in the corpuscules, the proportion of which relative to the serum influences the general colour of the blood. The form of the corpuscules also affects the colour of the blood, for if these be swollen by addition of water, they become more spherical, and the blood appears of a darker colour. Mulder supposes that the bright colour of arterial blood is due to the greater thickness of the enveloping membrane of the corpuscules. Nasse states that by the action of carbonic acid gas, the cells become darker in colour and turbid in the centre. All substances such as caustic alkalis, and several organic acids, which burst the corpuscules, or otherwise liberate their contents, turn the blood dark brownish-red, while those, such as nitrate and iodide of potassium, phosphate and carbonate of sodium, &c. which contract and so thicken the external membrane, render the blood of a lighter colour.

The average proportion by weight of moist blood corpuscules in a healthy man = 51·2 % (47·2—54·2 %). According to Vierordt, 1 cubic millimetre of blood contains 5,055,000 corpuscules. The amount of dry corpuscules in the blood of man is variously given = 12·9 % (Prévost and Dumas), 14·1 (13·1—15·2 %) (Becquerel and Rodier), 11·65 (Nasse). The blood of women contains fewer corpuscules than that of men, amounting to 36·924 % moist corpuscules (C. Schmidt), and 12·72 dry (11·3—13·75 %) (Becquerel and Rodier). The blood of middle-aged men and animals contains more corpuscules than that of older or younger individuals of the same species. The amount of corpuscules also varies in the blood of different animals, that of birds containing most, that of the carnivorous and herbivorous mammalia less, and that of cold-blooded animals by far the least, as will be seen from the following table, in which the *percentages* of dry corpuscules are given:

Chicken.	Pigeon.	Ox.	Sheep.
15·71 (Pr. and Du.)	15·57 (Pr. and Du.)	9·70 (Andral.)	9·35 (Pr. and Du.)
14·46 (Nasse.)		12·18 (Nasse.)	9·80 (Andral.)
15·00 (Poggiale.)	14·30 (Poggiale.)	12·30 (Poggiale.)	9·24 (Nasse.)
			10·20 (Poggiale.)

Dog.	Frog.	Eel.	Carp.
12·38 (Pr. and Du.)	6·90 (Pr. and Du.)	6·00 (Pr. and Du.)	8·23 (Berthold.)
12·38 (Nasse.)	4·58 (Berthold.)		
12·60 (Poggiale.)			

The proportion of corpuscules in the blood of different vessels also varies. In general, arterial blood contains fewer corpuscules than venous, the blood of the portal vein fewer than that of the jugular vein, while that of the hepatic vein contains far more than that of the portal vein, jugular veins, vena cava or splenic vein (Lehmann). Lehmann found 55·652 % moist corpuscules in the arterial blood of a horse, 48·996 in jugular blood, 55·688 in that of the vena cava.

Insufficient nourishment and long abstinence, as well as repeated blood-letting, diminish the quantity of blood-corpuscules; the amount increases if large quantities of fat are taken in the food. It is also influenced by disease, a constant increase being observed in plethora, in the earlier stages of heart-disease, in spinal irritation, and in cholera. Decrease occurs in all cases where the consumption of blood is greater than the supply, *e. g.* diarrhœa, intermittent fever, affections of the brain, and chlorosis (8·613 % Becquerel and Rodier). The percentage of water in the corpuscules bears a pretty constant relation to that of the serum, so that when the amount of water decreases in the serum, it also decreases in the corpuscules.

Colourless blood-corpuscules are always present in blood, but at least in the case of the warm-blooded animals, in much smaller quantity than the coloured corpuscules. They are generally almost spherical, but sometimes lenticular; they have a granulated envelope, and generally a round nucleus, which is more rarely oval or kidney-shaped, and strongly refracts light: sometimes it is formed of several small nuclei grouped together. They are identical with the lymph- and chyle-corpuscules, and do not differ much from the pus- and mucus-corpuscules. They are unelastic, and their envelope is so viscous that the corpuscules readily adhere to one another. They circulate less rapidly in the blood than the coloured corpuscules, and contain an albuminous liquid holding very minute granules in suspension. Dilute acetic acid gradually dissolves the external membrane. In human blood they measure 0·01128 mm. in diameter. They are specifically lighter than the red corpuscules, since they contain more fat and no hæmatin. In healthy blood they bear to the red corpuscules the ratio of 1 : 1·373 (Donders and Moleschott); the number increases during digestion and diminishes by fasting, the increase commencing thirty minutes after partaking of food, and lasting two hours. They increase in certain diseases, frequently in pneumonia and tuberculosis. In leuchæmia this increase often amounts to one-fourth of the blood-corpuscules. The splenic blood contains large quantities of colourless corpuscles, about one-fourth or one-third of the total amount of corpuscules.

Gases.—As early as 1674, free gases were supposed to be dissolved in blood, and the question was finally set at rest by the experiments of Magnus. The objection raised by Lagrange to Lavoisier's theory, that if combustion took place only in the lungs, the other parts of the body would have a lower temperature, led him to suppose that the blood merely dissolved the inhaled oxygen, and afterwards distributed it throughout the system. Fourcroy was, however, of opinion that combustion took place principally in the lungs, and that only a part of the oxygen was dissolved by the blood. H. Davy remarked that blood in contact with oxygen absorbs a certain quantity of the gas, giving off carbonic acid in exchange, and Nasse observed that blood in an atmosphere of hydrogen evolved carbonic acid. It has also been remarked that in an atmosphere of nitrogen, arterial blood evolves oxygen, but not venous blood. Mayow, Vogel, and others, obtained carbonic acid from the blood by means of the air-pump. Magnus also used the air-pump in his experiments, but collected the gas under mercury, and found the gases in *arterial* blood to consist of 14·5% N, 62·3% CO^2, and 23·2% O, in *venous*, 13·1% N, 71·6% CO^2, and 15·3% O. L. Meyer undertook a series of experiments on the gases of blood, under the guidance of Bunsen. The blood was diluted with ten times its bulk of water, and the gases were collected by boiling the liquid in vacuo at a very gentle heat: the free gases were thus obtained. A few crystals of tartaric acid were then added, and the blood again boiled, whereby the combined gas was liberated. The following table contains the quantities of gases (at 0° and 0·760m.) in 100 vols. of blood.

	Free Gas.	O.	N.	Free CO^2.	Combined CO^2.	Total. CO^2.	Total Gas.
Art. Carot. (Dog) (1)	20·88	12·43	2·83	5·62	28·61	34·23	49·49
„ „ „ (2)	25·50	14·29	5·04	6·17	28·58	34·75	54·08

Blood at 0° and 1 met. absorbs 1·151 vol. carbonic acid, besides 0·481, independently of the pressure (combined CO^2). Defibrinated calf's blood, free from air, absorbs under different pressures the same amount of oxygen (9·3% vol. at 0° and 0·760 m.) Serum absorbs a much smaller proportion of gases than defibrinated blood. The red colouring matter absorbs a considerable quantity of oxygen, and evolves a *little* carbonic acid. G. Harley found that blood, or defibrinated blood, absorbed oxygen when shaken up with air, and evolved carbonic acid, but in less quantity than corresponded to the oxygen absorbed.

It is difficult to explain satisfactorily why blood should absorb so much more carbonic acid than pure water at the same temperature; it is perhaps partly owing to the neutral alkaline carbonate in blood forming acid carbonate, but this does not account for all the carbonic acid absorbed. Liebig has remarked that water containing 1% phosphate of sodium absorbs twice as much carbonic acid as pure water, while water containing 15% chloride of sodium only takes up half as much. It is also supposed that oxygen, of which blood absorbs from 10 to 13% of its vol., and water only 0·925%, combines in a loose way with blood, like nitric oxide with ferrous sulphate, since the vol. of gas absorbed does not increase proportionally with the pressure (Liebig). It has also been shown that part of the oxygen thus taken up by blood cannot again be separated. (See GASES, ABSORPTION OF.)

Constituents of the coloured blood-corpuscules.—Berzelius has shown that the coloured corpuscules contain an albuminous substance (*globulin*) differing from albumin. Schmidt separated the corpuscules by means of sulphate of sodium, and found them to contain 87·59 globulin and 12·31% hæmatin. Mulder considers the outer membrane of the corpuscules to be binoxide of protein, a hypothetical substance; others have taken it for fibrin. Its composition does not appear to be fixed, since the membrane of different corpuscules is variously affected by the same reagents.

Blood-crystals; Hæmatocrystallin.—O. Funke first completely investigated the nature of the crystalline substance of the red corpuscles. Funke and Kunde obtain the crystals by adding to a drop of blood, water, ether, alcohol, or chloroform, allowing the mixture to dry slightly on a glass plate, and then covering the whole with a glass cover. Lehmann passes a slow stream of oxygen or nitrous oxide for about fifteen minutes into a mixture of blood and water, and afterwards carbonic acid, till the liquid turns bright red and becomes turbid, whereupon it crystallises. When a considerable quantity of blood is to be operated upon, it is best to leave it to coagulate, press the clot to remove the serum, cut it in pieces, and wash it on a linen filter with water till the filtered liquid amounts to about 1½ times or twice the volume of the water used. The liquid is then to be poured into a glass cylinder, oxygen gas passed into it for about half an hour, and then carbonic acid for ten or fifteen minutes, after which it is left at rest. If no crystals form after about two hours, the liquid must be mixed with ¼ of its volume of alcohol (Lehmann.) Light promotes the crystallisation, which is not caused by evaporation of water, since blood will crystallise as readily with twice its volume of water as with only half that quantity. It cannot be doubted that both oxygen and carbonic acid, by their chemical action on the contents of the corpuscules, are instrumental in the formation of the crystals. The form of the crystals varies in the blood of different animals; those obtained from the blood of men, most mammalia, and fish, form prisms; from the rat, mouse, and guinea-pig, tetrahedrons; from the squirrel, hexagonal tablets; and from the German marmot, rhombohedrons (of about 120°), or very thin hexagonal plates.* The tetrahedral crystals dissolve with peach-blossom-colour in 600 pts. of water, the prismatic with dark-red colour in 94 pts. water. Nitric acid turns the crystals almost black, but dissolves them on warming, and acquires a yellow colour. Their solution is decolorised by chlorine, which precipitates white flakes; it is turned dark brownish-red by carbonic oxide, and rendered turbid and brownish-red by nitrogen. The same sized crystals from the same blood often differ in intensity of colour and have probably not always the same composition. They seem to be an albuminous substance.

The solution of the tetrahedral crystals coagulates at about 63° C., that of the prismatic crystals between 64° and 65°. The crystals exhibit, according to Lehmann's analysis, the percentage composition of the albuminoïds:

Carbon	55·41	55·24	55·18
Hydrogen	7·08	7·12	7·14
Nitrogen	17·27	17·31	16·40
Sulphur	0·25	0·21	0·25
Oxygen	19·99	25·12	20·03
	100·00	100·00	100·00

Hæmatin is peculiar to the blood-corpuscules of vertebrate animals, and in some way combined with the remaining albuminous contents of the corpuscules. It is obtained as an amorphous blackish-brown substance, by treating the corpuscules with sulphate of sodium, extracting the residue with alcohol containing sulphuric acid, and treating with ammonia, water, alcohol, and ether. It is insoluble in water, alcohol, ether, acetic ether, and oils, both fat and volatile, but readily soluble in alcohol containing sulphuric or hydrochloric acid. It is not dissolved by concentrated mineral acids. Aqueous or alcoholic solutions of alkalis or their carbonates dissolve hæmatin in all proportions. A sulphuric acid solution of hæmatin which has been turned red by addition of alkali, exhibits dichroïsm, appearing green by transmitted and red by reflected light. If hæmatin be allowed to stand in contact with pure concentrated sulphuric acid, it may be obtained perfectly free from iron, without suffering any perceptible change in its properties. Berzelius found in the dry blood corpuscules of men and oxen 0·38 % metallic iron, and since Mulder has found 6·64 % iron in hæmatin, the corpuscules would contain 5·72 % hæmatin, and the blood 0·732 %. Becquerel and Rodier found in blood, 0·0565 % iron, and 14·11 % corpuscules, which would give 6·02 pts. hæmatin to every 100 pts. corpuscules. In disease, the proportion of hæmatin to the whole blood probably varies with the corpuscules. It is not known whether there is a fixed relation between hæmatin and the albuminoïd of the corpuscules. Mulder assigns to it the formula $C^{44}H^{22}N^{3}O^{6}$. The arterial blood of the horse contains rather less hæmatin than that of the outer jugular vein; the corpuscules of the liver-blood contain far less than those of the *vena porta*. The proportion of iron to dry corpuscules in arterial blood = 1 : 394; in that of the jugular vein 1 : 390; of the vena porta 1 : 312; of the liver 1 : 500 (Lehmann.) Poggiale found 0·126 % ferric oxide in human blood, in that of the ox 0·125, calf 0·111, dog 0·145, sheep 0·106, chicken 0·075.

A substance called *hæmatoïdin* has been observed in blood extravasated in the tissues of living animals. It is sometimes amorphous, in grains and little globules; sometimes in crystals belonging to the monoclinic system. It is transparent, strongly refracting, yellowish-red or ruby-red, insoluble in water, alcohol, ether, acetic acid, and dilute mineral acids. It generally turns ardent red on addition of potash, gradually disintegrates, and splits up into red granules, which gradually dissolve. The hæmatoïdin is not reprecipitated by neutralising the alkali. By the action of concentrated sulphuric acid, the sharp contour of the crystals vanishes, and the colour of the round concretions first turns brownish-red, then green, blue, and rose, and finally dirty yellow. In the liquid, iron may sometimes be detected, but not always. According to Robin, its formula is $C^{14}H^{18}N^{2}O^{3}$.

The nature of the *nuclei* which sometimes occur in the corpuscules is unknown.

A considerable quantity of the *fat* of blood occurs in the corpuscules, nearly the whole of the so-called phosphorised fats being contained therein. Lehmann found 2·214 and 2·284% fat in the dry corpuscules from bullock's blood. The ethereal

---

* Figures of these crystals are given in Funke's Atlas of Physiological Chemistry (Leipzig, 1853, also published by the Cavendish Society); and in the Handwörterbuch der Chemie, 2te Aufl. ii. [2] 136.

extract of these corpuscules yielded 22 % acid ash, consisting of acid phosphate of sodium, from which it is probable that phosphoglyceric acid is contained in the corpuscules. The corpuscules in the blood of different vessels do not contain the same amount of fat. In the moist corpuscules of the carotid artery of the horse, were found 0·608 % fat; in the external jugular vein 0·652 %; in the vena porta 0·752; in liver-blood 0·684. Dry corpuscules separated from arterial blood by sulphate of sodium contained 1·842 % fat; from venous blood 3·595 %.

The solid constituents of the corpuscules contain rather less than 6 % *extractive matter*, the nature of which is unknown. They also contain a free or loosely combined nitrogenised organic acid.

Moist corpuscules contain on the average 68·8 % *water* (Lehmann). Taking into account the amount of serum enclosed in the coagulum, the corpuscules contain a much smaller proportion of soluble *salts* than the serum. It will be seen from the analyses by Schmidt (p. 611), which are the most trustworthy, that the corpuscules contain principally phosphates and potassium salts, and, in smaller quantity, chlorine, sulphuric acid, soda, and earths, while the serum contains proportionally less chloride of potassium and phosphate of sodium, and more chloride of sodium, sulphuric acid and earths. In man the moist corpuscules contain 0·7282 % salts. The blood of those animals which contained most corpuscules also contains most alkaline phosphates (Nasse). The corpuscules contain less earthy phosphates than the serum. Iron belongs almost exclusively to the red corpuscules (hæmatin). Clear serum contains no iron. (Nasse and Schmidt).

Fibrin. — As already stated, the spontaneous coagulation of the blood is caused by the separation of the fibrin, which at the same time encloses all the corpuscules and a portion of the serum. As soon as the blood has left the body, a film gathers on the surface of the liquid, extending in the form of a star, from the sides of the vessel towards the centre; a clot, adhering to the sides of the vessel, then forms. Often, within two minutes after the blood has been collected, it becomes viscid and gelatinous, and after a time a few drops of liquid, gradually increasing in quantity, separate from the jelly, till the coagulum swims in the serum. According to circumstances the coagulum is more or less contracted, consistent, viscous, and elastic. If the coagulation be observed under the microscope, exceedingly fine straight threads will be seen to shoot out from various points between the corpuscules, and, gradually increasing in length, to cross one another, so that finally the whole forms a network enclosing the corpuscules. If the amount of fibrin is small in comparison to the corpuscules, the coagulum is comparatively light; denser, on the contrary, when the amount of fibrin is large. A large quantity of water diminishes the consistence of the coagulum. Various salts have the property of retarding or entirely preventing the coagulation of blood. The alkalis and their carbonates and acetates have this effect, and rather strong solutions of nitrate of potassium, nitrate of calcium, and chloride of ammonium in a less degree. Most dilute acids also maintain the fluidity of blood, though they render it rather more viscous. The venous blood of a healthy man contains between 0·203 and 0·263 % fibrin (Scherer), 0·220 (average, Becquerel and Rodier), 0·250 % (Denis). Arterial blood contains more fibrin than venous. (See Fibrin.)

Constituents of the Serum.—The average specific gravity of serum = 1·028; it is less variable than the specific gravity of blood. The amount of *water* in the serum varies between 88 and 95·6 %, averaging 90·5 or 90·6 % (Nasse). Women's blood contains more water than that of men. According to C. Schmidt, the serum of man contains 90·884 % water, and that of woman 91·715; and, according to Nasse, the serum of pregnant women is more aqueous than of others. At an advanced age, the amount of water increases considerably. The following table contains the percentages of water in the serum of different animals:—

Ox.	Sheep.	Dog.	Chicken.
90·8 (Nasse.)	91·5 (Du. and Pr.)	92·6 (Du. and Pr.)	92·5 (Du. and Pr.)
91·6 (Berthold.)	91·8 (Nasse.)	91·2 (Nasse.)	93·1 (Nasse.)

Pigeon.	Frog.	Eel.
94·5 (Du. and Pr.)	95·0 (Du. and Pr.)	90·0 (Du. and Pr.)

According to most observations, the serum of arterial blood contains more water than that of venous blood. Simon found in the arterial blood of two horses, 2·734 % more water than in the venous blood, and, according to Nasse, arterial blood contains 5·0 % more water than venous. As a general rule, the amounts of water in the serum and of corpuscules in the blood are inversely proportional. An absolute diminution of water has only been remarked in cholera.

Albumin is the most abundant of the constituents of the serum, amounting to between 6·3 and 7·1 % of normal blood, and between 7·9 and 9·8 % of normal serum. Neutral albuminate of sodium, which becomes turbid on addition of water, occurs not only in morbid blood, but also in the blood of the spleen. The serum of the blood of the vena porta gives less turbidity, and that of the liver-blood more, than of the spleen. When the alkaline serum of liver-blood is neutralised with acetic acid, the albumin does not coagulate on boiling till after several hours, while that of the vena porta and other veins, as well as of the arteries, speedily coagulates on addition of acetic acid and boiling. Hoppe is of opinion that the albumin in serum is not dissolved, but merely suspended in a state of fine division. According to Becquerel and Rodier, normal man's blood contains 6·94 % (6·2—7·3 %) albumin, and that of women 7·05 (6·5—7·55) %. The blood of pregnant women was found to contain from the 2nd to the 7th month, 7·0—6·8 % albumin, and in the last two months, 6·8—6·4 %. (J. Regnault). Arterial blood contains less albumin than venous, and the amount in liver-blood increases considerably during digestion; it decreases in scurvy, puerperal fever, and Bright's disease, and increases in intermittent fever, cholera, &c. In typhus, it amounted to 6·5 %, and in Bright's disease to only 4·93 %.

Fats.—But few free fats are found in serum; they occur chiefly saponified. Chevreul and Babington first discovered the presence of normal fats in blood. Oleic, margaric, and stearic acids, both free and saponified, have been detected in the serum of bullock's blood, and cholesterin is constantly present. Boudet describes, as a fat peculiar to the serum, a substance extracted from its residue by hot alcohol (serolin), which Gobley considers as a mixture of oleïn, margarin, cholesterin, and cerebrin. According to Chevreul, phospholeïc acid (cerebrin) is contained in the fibrin and serum. Compared with the corpuscules, that of the serum is more crystalline, less viscous, and colourless. Normal serum contains 0·2 % fat, and its solid residue 2·22 % (Simon, Nasse, Becquerel). The amount of fat in the blood is not increased by food rich in fat, nor is it diminished by nourishment free from fat. During digestion, the amount of fat in chyle and in the blood of the vena porta, has been found to increase considerably, so as occasionally to render the serum turbid. According to Becquerel and Rodier, the blood of women contains 0·57 p. m. fat and soaps, and that of men 0·69 p. m. Serum of arterial blood contains less fat than that of venous, and the vena porta blood is richer than the jugular. Becquerel and Rodier have found that, almost at the commencement of every acute disease, the proportion of fat (especially cholesterin), in blood increases, as well as in some chronic diseases, particularly in liver diseases, Bright's disease, tuberculosis, and cholera.

Little is known of the *extractive matter* of the serum; it varies between 0·25 and 0·42 %. Lehmann found more in the arterial than in the venous matter of the horse.

Sugar (grape-sugar), is a normal constituent of blood. The blood of the vena porta contains but traces, while that of the liver contains larger quantities. In normal bullock's blood, it varies between 0·00069 and 0·00074 % (Lehmann). The blood of a dog contained 0·0015, and of a cat 0·0021 %. In the blood of diabetic patients Lehmann never detected more than 0·047 % sugar. The amount varies with the nature of the food. *Urea* occurs in healthy blood to the amount of 0·0142—0·0177 %. It has been detected by evaporating large quantities of serum and adding nitric or oxalic acid to the residue. The quantity increases considerably in Bright's disease (1·5 % in serum, Bright and Babington), and in cholera (0·14 %). *Uric acid* has been found in the blood of healthy as well as of diseased persons. Garrod found between 0·0012 and 0·0055 in the serum in a case of Bright's disease. *Creatine, creatinine, hippuric acid*, and *hypoxanthine*, have also been detected. According to Musing, *alcohol* has been detected in the blood of men who had died from drinking brandy. Matteucci states that goat's blood warmed with sulphuric acid evolves *caproic acid*. Scherer has detected *lactic acid* in a case of puerperal fever. Fourcroy and Vauquelin and others state that they have found bile-constituents in healthy blood; they sometimes occur in morbid blood. *Leucine* and *tyrosine* occur in small quantities in liver and portal blood, in diseases of the liver. Little is known of the *colouring matters* proper to the serum. An intense yellow coloration of the serum is often due either to bile-pigment, which may be detected not only in icterus, but also in pneumonia. Black, scarcely yellow, brown, or red granules of pigment are said to have been detected in the heart, large vessels, liver, and spleen, after intermittent fever. Blood contains *neutral carbonate of sodium* (0·1628 % in bullock's blood, Lehmann), probably as acid carbonate (Lehmann, Liebig). Meyer concludes from his experiments that it is not present as acid carbonate. Blood seldom contains *sulphates*, and never more than traces; it contains *silicic acid* (Millon), and according to G. Wilson, traces of *fluorine*. Normal blood never contains *ammonia*, but that alkali is sometimes found in disease (cholera, &c.)

Salts.—The serum of man's blood contains 0·88 % (av.) salts, that of women 0·81 %. Lehmann gives the following composition of the ash according to the best analyses: 61·087 % chloride of sodium. 4·085 chloride of potassium, 28·880 carbonate of sodium, 3·195 phosphate of sodium (Na^2HPO^4), 2·784 sulphate of potassium. The serum of grown-up animals contains more salts than that of the young; the serum of the calf, however, contains 1·12 % salts, while that of the cow contains 0·99, and of the ox 0·87 % (Nasse and Poggiale). The blood of cats, goats, and sheep, contains the most salts; of birds, men, and pigs, less; and of dogs and rabbits the least. Arterial blood serum is somewhat richer in salts than venous, and the serum of portal blood contains considerably more than that of the jugular vein. The kind of nourishment has great influence on the amount of salts, and of their several constituents. Plouviez and Poggiale found that in the blood of animals to whose food common salt had been added for several months, the percentage of salt rose from 0·44 to 0·64, an increase due chiefly to chloride of sodium. The amount of salts is also greatly influenced by disease, being particularly small in violent inflammations, and increasing in typhus, &c. Weber found 1·19 % *silica* in the ash of bullock's blood.

The amount of salts, exclusive of iron, in man's blood = 0·728 %, woman 0·896, dog 0·713 %. Some chemists think they have detected *manganese* in blood, but its presence is doubtful. Millon found *copper* in the blood of soldiers whose food had been prepared in copper vessels, and others have detected traces in the blood of men and beasts. It is said always to occur in the ash of the blood of *Limulus Cyclops*. Millon also detected *lead* in blood.

ANALYSIS OF BLOOD.—The amount of *water* in blood is easily estimated by evaporating a weighed quantity, and drying the residue at 120°—130° C.

To determine the *fibrin*, the blood, as it runs from a vein, is received in a tared vessel, and stirred for 5 to 10 minutes with a glass rod, the weight of which is included in the tare, till the fibrin is completely separated. The blood, together with the separated fibrin, is then weighed, strained through linen, and the fibrin which remains thereon is placed for some time in water, then dried, well boiled with alcohol and ether, to free it from fat, and weighed after drying at 120° C. (Becquerel and Rodier).—Another method of estimation is to leave a weighed quantity of blood to coagulate at rest, tie up the clot in a fine linen bag, after it has contracted as much as possible, knead it first by itself, afterwards with water, and treat the residue as above. (Scherer.)

Estimation of Albumin and other Matters coagulable by Heat.—A weighed quantity of the blood, slightly acidulated with acetic acid, is added by drops to boiling water, the liquid is poured through a weighed filter, and the coagulum collected thereon; it is then washed on the filter with boiling water, and dried, first at a gentle heat, afterwards at 120° to 130° C. The residue may be freed from fat by treatment with boiling ether. If the blood had not been previously freed from fibrin, the weight of that substance, determined as above, must be deducted from the total weight of the coagulum.

Estimation of the Extractive Matter.—The filtrate obtained in the last determination is evaporated on the water-bath in a tared platinum basin, the residue dried at 120° C., weighed, and burnt in a muffle at as low a heat as possible. The weight of the ash, deducted from that of the total dried residue, gives approximately the amount of extractive matter.

Estimation of Fat.—A quantity of blood (which need not be weighed) is dried at 100° C., the residue is pulverised and dried at 120°, and a weighed portion thereof is treated with ether in a flask: the ether is passed through a small filter into a tared platinum capsule; and the treatment of the residue with ether is repeated several times. The collected ethereal solution is carefully evaporated, and the residue dried at 100° C. As the weight of the solid constituents of the blood has been previously determined, the quantity of blood from which this amount of fat has been obtained may be calculated from that of the residue which was subjected to treatment with ether.

Estimation of Mineral Constituents.—A weighed quantity of the blood is dried, mixed with ignited carbonate of sodium, then dried and incinerated in the muffle at the lowest possible temperature. (See ASH OF ORGANIC BODIES, p. 418.)

Separate Estimation of the Serum and Coagulum, with their Constituents.—The fresh blood is collected in a tared cylindrical vessel, having a ground edge, and not too shallow; it is covered with a glass plate and left to stand till the coagulation is complete, after which the edge of the clot is detached from the side of the vessel by means of a needle. The blood is then weighed, and after the clot has contracted as much as possible, the serum is poured off, and the quantity of albumin, &c., contained in it is determined as above described. The clot and the inner surface of the vessel are then freed from serum as completely as possible by wiping with bibulous paper, and the clot is weighed on the vessel. This weight, deducted from the total weight of the blood, gives the proportion of serum.

The clot contains the blood-corpuscules, the fibrin, and a certain quantity of serum; the amount of water contained in it may be determined by drying at 120° to 130° C., but there is no known method of directly estimating the amount of the blood-corpuscules. Prevost and Dumas estimated it approximately on the assumption that the water contained in the clot is all due to adhering serum, and accordingly deducting from the weight of the dried clot an amount of serum-constituents corresponding to the quantity of water in the clot, together with the amount of fibrin separately determined. As, however, the blood-corpuscules themselves contain water, this method necessarily makes the quantity of dry corpuscules too small.

According to C. Schmidt, the clot contains a quantity of serum amounting to $\frac{1}{8}$ of its volume, and the weight of the moist blood-cells is four times as great as that of the dry clot, as determined by the method of Prevost and Dumas. Hence, when the constituents of the serum and coagulum have been determined as above, and from the weight of the coagulum, a deduction is made of the quantity of serum-constituents corresponding to $\frac{1}{8}$ of the weight of the moist coagulum, the composition of the corpuscules may be calculated.

The separation of hæmatin from globulin cannot be effected; but if the quantity of iron in the dry coagulum be determined, the amount of blood-pigment may be calculated on the supposition that this pigment contains 6·64 per cent. of iron. (Strecker, Handw. d. Chem. ii. [2] 115).

1000 pts. Blood-corpuscles contain:

Water	688·00
Solid constituents	312·00
Density	1·0885

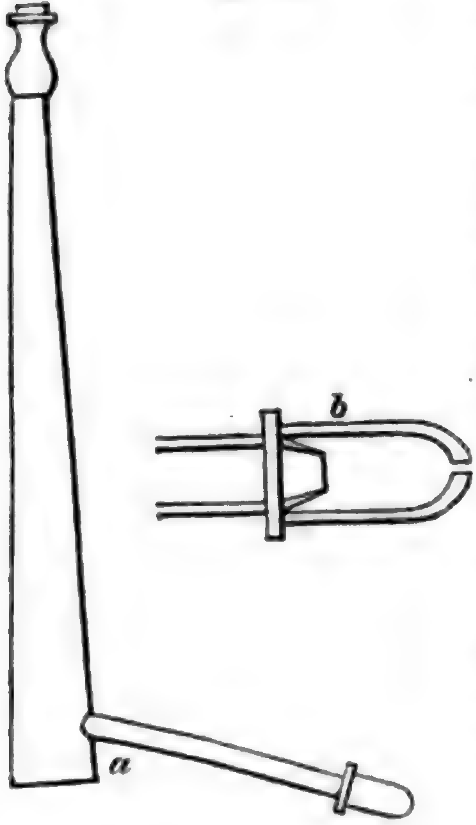
C. E. L.

BLOODSTONE. A variety of JASPER (*q. v.*)

BLOWPIPE. An instrument for directing a stream of air through a flame, either by blowing with the mouth or with bellows. The flame of a candle, of a lamp with a simple wick, or of an ordinary gas-jet, consists of three parts. The dark central portion immediately surrounding the wick or burner, consists of combustible gaseous matter, not yet burned; this is surrounded by a highly luminous cone, which deposits soot on a cool body held within it; and outside of all is a thin pale blue envelope which gives little light, but has a very high temperature. It is here that the combustion is most complete, the carbon and hydrogen finding sufficient oxygen to convert them into water and carbonic acid. But in the middle luminous cone, the supply of oxygen is not sufficient for complete combustion, and consequently the hydrogen, which burns most easily, takes up the whole or the greater part of it, while the carbon is set free in the form of minute solid particles. If now a jet of air be directed through the middle of the flame, a double combustion takes place, the combustible matter uniting on the outside with the oxygen of the air, and in the interior with that which is supplied by the blast. In this manner, an intensely hot flame is produced, applicable for fusions, reductions, and a variety of operations in chemical analysis; and likewise for soldering metals and working glass.

The best and cheapest form of the mouth-blowpipe for chemical purposes, is that invented by Black. It consists of a tube of tin-plate (*fig.* 101), about 7 inches long, and $\frac{3}{4}$ of an inch broad, tapering to $\frac{1}{4}$ of an inch, where a small mouth-piece is soldered. At the wide end *a* is inserted a small cylindrical tube of brass, about 2 in. long, supporting the nozzle, which may be of brass or platinum.

Fig. 101.

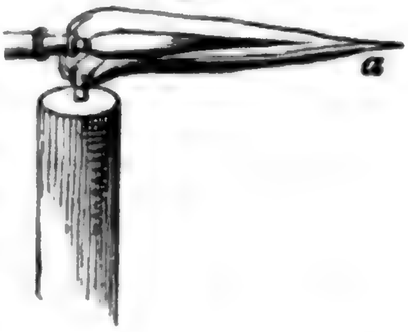


The tube is slightly conical at the end where the jet is fixed, and the latter is thus made to fit on without a screw, which would soon be injured by the high temperature to which it is exposed, and would then be difficult to remove for the purpose of cleaning. The nozzle is drilled from a solid piece of metal, and in the form shown at *b* in the figure. One of the chief excellencies of this form of blowpipe, is the efficient manner in which it condenses and retains the moisture of the breath, and prevents its projection on the heated assay. The blowpipe may also be provided with a moveable trumpet-shaped mouthpiece, against which the lips, partially open, may be pressed during the act of blowing; in this manner, a strong blast may be kept up for a considerable time with very little fatigue. The use of such a mouthpiece is strongly recommended by Plattner in his valuable treatise on the blowpipe; but it is scarcely necessary, excepting when the blast has to be kept up for a long time, as when the blowpipe is used for quantitative analysis.

To use the mouth-blowpipe with success, it is necessary to acquire the art of keeping up a steady blast of air for some time. For this end, the air must be supplied from the mouth, not directly from the lungs, which could not, without fatigue, afford a sufficient stream. The mouth-piece of the instrument being placed between the lips, the mouth is to be filled with air till the cheeks become distended as in playing on a wind instrument. The current of air is then forced through the tube by the action of the muscles of the cheeks, and during the blast, the communication between the chest and mouth is closed, respiration being carried on through the nostrils. The mode of effecting this is difficult to describe, but the right method of blowing is easily acquired by a little practice.

The quality and intensity of the flame vary considerably according to the strength and direction of the blast. If the nozzle of the blowpipe is inserted into the middle of the flame, a little above the wick, as shown in *fig.* 102, an elongated flame is produced, consisting of an outer and an inner cone, the former having a yellow, the latter a blue colour. The outer flame is an *oxidising* flame. An oxidable substance, such as lead or copper, placed at or just beyond the point *a* of this flame, is strongly heated in contact with the oxygen of the air, and is therefore brought just into the condition for taking up oxygen. The greatest heat is at the point of the inner flame, the combustible gases being there supplied with just the quantity of oxygen required to consume them; and between this and the point of the exterior flame, is a quantity of combustible manner, very hot, but not yet burned, and therefore disposed to take oxygen from any compound containing that element. This part of the flame is therefore a *reducing* flame. A piece of ordinary glass containing lead, turns black and opaque when heated in this part of the flame, in consequence of the reduction of the lead; but by afterwards heating it in the outer flame, the lead is reoxidised, and the transparency restored.

Fig. 102.



But the reducing power of a flame produced in the manner just described, is not very great, as any one may convince himself by trying to reduce oxide of copper or oxide of tin in it without the aid of a reducing agent. The flame is for the most part an oxidising flame, especially if the aperture of the blowpipe is large and gives a good supply of air. To obtain a good reducing flame, it is necessary to use a blowpipe with a small aperture, and to adjust the point, not within, but just outside the flame, and to blow rather over than through the middle of the flame. In this manner, the flame is less altered in its general characters than in the former case, the chief part consisting of a large and luminous cone, containing a considerable quantity of free carbon in a state of intense ignition, and just in the condition for taking up oxygen.

Substances to be heated in the blowpipe flame, are supported, sometimes on charcoal, sometimes in spoons or forceps made of platinum, or on platinum foil or wire, sometimes on small capsules made of clay or bone-earth. Charcoal is used chiefly in experiments of reduction. The substance to be heated is placed in a small hole scooped in the side of the charcoal, not at the ends, because in the latter position, it is more likely, when in the fused state, to sink into the pores of the charcoal. Clay basins are chiefly used in the quantitative assaying of ores. They are made of fire-clay kneaded into a stiff paste with water, pressed into shape in a box-wood mould (*fig.* 103), then dried and calcined. Instead of these, however, very thin porcelain basins, which may be procured ready made, may be used with advantage. Basins or cupels of bone-earth made in a similar manner, are used for cupelling silver and gold with lead. The oxide of lead formed in the process, sinks into the porous support leaving the silver or gold in the form of a metallic button.

Fig. 103.

Blowpipe Analysis.—The blowpipe is an indispensable instrument in qualitative analysis, as it serves to recognise the presence of many substances with greater facility and certainty than could be obtained by analysis with liquid reagents, especially when the quantity of substance to be operated on is but small. Generally speaking, however, it is not safe to trust to the indications of the blowpipe alone, inasmuch as many substances give but indistinct reactions when submitted to this mode of examination, and are apt to be completely overlooked when present together with others whose indications are more decided. In a mixture of iron, nickel, and cobalt, for example, it would be scarcely possible by the blowpipe alone to recognise anything but cobalt, even though that metal might be present in small proportion only as compared with the others. It is best, therefore, to use the blowpipe, and in general, the mode of analysis by the dry way, as a means of determining the general character of a compound or mixture, and detecting certain of its constituents, and thus obtaining an indication of the best mode of proceeding with the more complete analysis by the wet way.

A concise account of the behaviour of the several elementary bodies, and their principal inorganic compounds when heated *per se*, and with certain reagents, is given in the article Analysis (Inorganic), (p. 213); and these characters will be described in greater detail in treating of the several elements and compounds. page 614 (taken from Conington's "Handbook of Analysis,") exhibits in a convenient form the colours imparted by metallic oxides to borax and microcosmic salt, when heated therewith in the oxidising and reducing flames. [For further details, see "Chemical Manipulation," by C. Greville Wliliams, London: Van Voorst; also, especially for the method of Quantitative Analysis with the blowpipe: Plattner's "Probierkunst mit dem Löthrohre," or the translation of that work "On the Use of the Blowpipe, &c.," by Dr. Muspratt, London, 1850.]

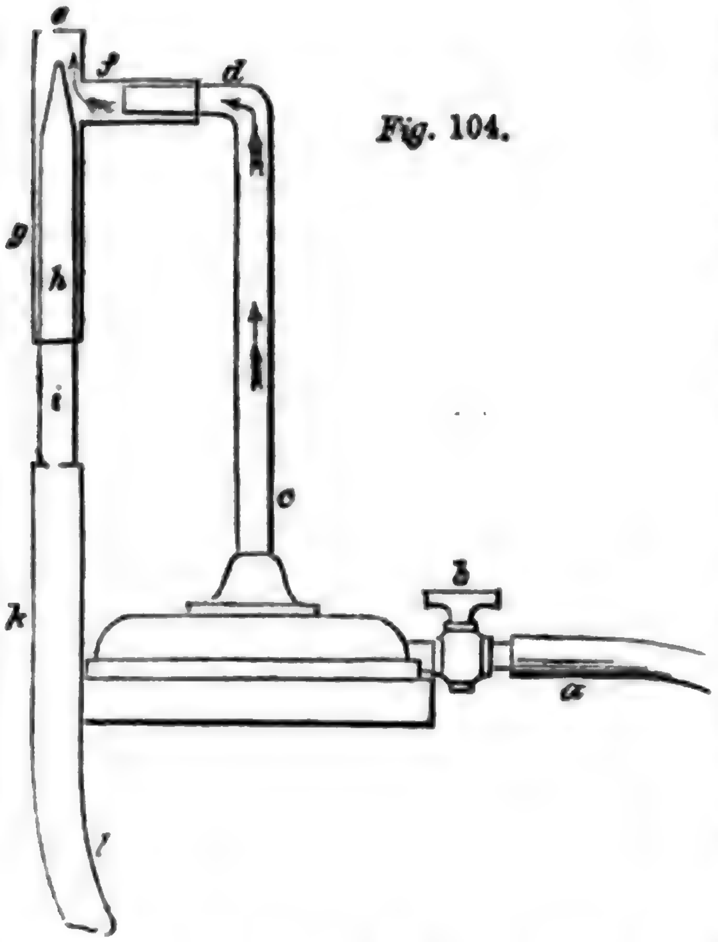

Fig. 104.

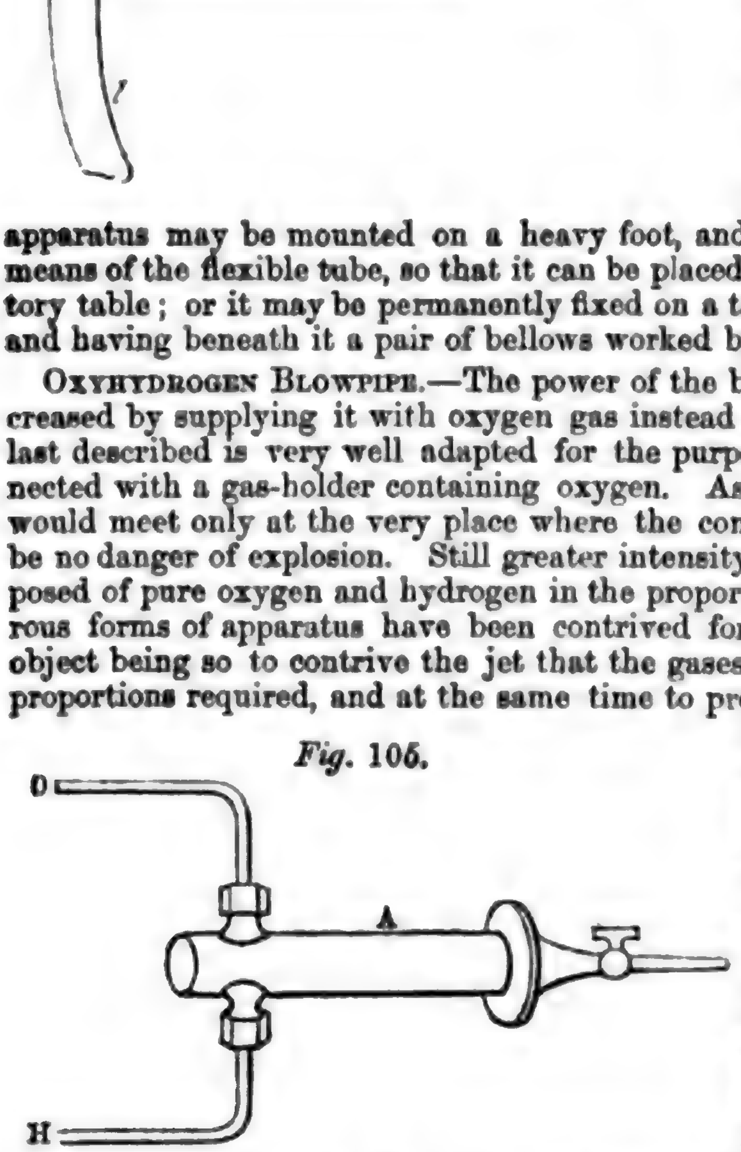
Table Blowpipe.—For sealing and bending glass tubes and constructing glass apparatus of various forms, it is convenient to have the blowpipe mounted on a fixed support, and when a flame of considerable power is required, the blast must be supplied by bellows worked with the foot. A very convenient form of blowpipe for these purposes is that invented by Herapath, and represented in *fig.* 104. *a* is a flexible tube attached to a stopcock *b*, which communicates with a tube *c d*, bent at right angles at *d*, where a T-shaped tube *e f g* slips on by means of the piece *f*. The blowpipe jet *h i* passes into the longer arm of the T-piece, and fits somewhat tightly; *k l* is a second piece of flexible tube terminating in a mouth-piece, or connected with a blowing apparatus. On turning on the gas, it passes in the direction marked by the arrows, and is to be inflamed at *e*. On blowing with the mouth, or by means of a pair of bellows into the tube *k l*, the ignited gas takes the form of a blowpipe flame of great power, the nature of which is entirely under control by means of the stopcock *b*, and also by regulating the quantity of air supplied through the tube *k l*. The T-shaped piece is moveable at *f*, so that the jet may be directed to any position. The apparatus may be mounted on a heavy foot, and connected with the gas-supply, by means of the flexible tube, so that it can be placed in any required position on the labotory table; or it may be permanently fixed on a table specially devoted to the purpose, and having beneath it a pair of bellows worked by a treadle.

Oxyhydrogen Blowpipe.—The power of the blowpipe flame may be immensely increased by supplying it with oxygen gas instead of atmospheric air. The apparatus last described is very well adapted for the purpose, the flexible tube *k l* being connected with a gas-holder containing oxygen. As the oxygen and the combustible gas would meet only at the very place where the combustion is to take place there would be no danger of explosion. Still greater intensity of heat is obtained by a flame composed of pure oxygen and hydrogen in the proportions required to form water. Numerous forms of apparatus have been contrived for burning this gaseous mixture, the object being so to contrive the jet that the gases shall be there mixed in the exact proportions required, and at the same time to prevent danger of explosion by premature mixture. The best form is that shown in *fig.* 105, in which A is a brass tube filled with a number of layers of wire gauze pressed closely together, or with a bundle of very thin brass wires placed parallel to the axis of the tube, and firmly wedged together by a stout conical wire driven into the middle, so as to form a collection of extremely narrow tubes. The gases are supplied by the tubes O H, connected with gas-holders or loaded caoutchouc bags, one containing oxygen the other hydrogen. To the other end of the brass tube A

Fig. 105.



is attached a jet, the extremity of which is formed of platinum. The gases mix in the tube A, and pass on through the meshes of the wire-gauze or the interstices between the thin brass wires to the point of the jet, where they are set on fire. The proportions in which the gases are supplied are regulated by stopcocks on the tubes O H. The appearance of the flame, which should be a very narrow cone of a pale blue colour, indicates when the right proportion is attained, and this having been once determined, the position of the stopcocks may be marked, so as to ensure the right proportion of the two gases in all future experiments. The use of the wire-gauze or bundle of thin wires in the tube A is to supply a mass of good conducting material, which shall prevent the flame from passing backwards through that tube (see Flame). The heat produced by the oxyhydrogen flame is the greatest that can be produced by any artificial means, except by the electric current. Thick platinum wires melt in it like wax in the flame of a candle. By itself, however, it gives but little light; but any non-volatile and incombustible solid substance held in it becomes intensely luminous. If the point of the flame be directed on the rounded edge of a cylinder of quick lime, a pure white light of dazzling brilliancy is produced, inferior only to the electric light. It is called the *Drummond light*, and has been used for lighthouses.

BLUE, PRUSSIAN. See Cyanides of Iron.

BLUE, SAXON. The best Saxon blue colour may be made with the following composition: mix one ounce of the best powdered indigo with four ounces of sulphuric acid in a glass bottle or flask, and digest it for an hour at the heat of boiling water, shaking the mixture at different times; then add 12 oz. of water, stir the whole well, and filter when cold. Poerner adds 1 oz. of good dry potash at the end of twenty-four hours, and lets this stand as much longer before diluting with water. The cloth should be prepared with alum and tartar.

BODENITE. A mineral related to allanite, discovered by Kerndt in the oligoclase between Boden and Mauersberg, near Marienberg in Saxony. Found only in ill-defined prisms [rhombic?] of 110° to 112°, without trace of cleavage. Hardness 6·5. Specific gravity 3·523. Reddish or blackish-brown. Streak dirty white. Opaque with vitreous lustre. When strongly heated, it exhibits incandescence like gadolinite. Fusible only on the acute edges. Decomposed by strong acids. Analysis gave: 26·12 SiO^2; 10·33 Al^4O^3; 12·04 Fe^2O; 17·44 Y^2O; 10·46 Ce^2O; 7·56 La^2O; 1·61 Mn^2O; 6·32 Ca^2O; 2·33 Mg^2O; 1·21 K^2O; 0·84 Na^2O; and 3·01 H^2O: whence may be deduced the formula $6(3M^2O.SiO^2) + 2Al^4O^3.SiO^2$, the water being regarded as basic. Associated with this mineral are found black amorphous grains of another mineral, *Maromontite*, containing the same elements, but not exhibiting incandescence when heated. (Kerndt, J. pr. Chem. xliii. 219, 228.)

BOG-BUTTER. A fatty substance found in the peat-bogs of Ireland. It was first examined by Luck (Ann. Ch. Pharm. liv. 125), afterwards more exactly by Brazier (Chem. Gaz. [1852], 375). It is very soluble in alcohol, and crystallises from the solution in a network of slender needles. It melts at 51° C. (Luck), the crude fat at 45°, but after repeated crystallisation from alcohol and then from ether, at 52° to 52·7° (Brazier). It gives off the odour of acrolein when heated. By saponification with potash, it yields an acid, *Butyrolimnodic acid* (Bogbuttersäure), to which Luck assigned the improbable formula $C^{33}H^{33}O^4$; but according to Brazier, this acid has the same composition as palmitic acid, $C^{32}H^{32}O^4$, or $C^{16}H^{32}O^2$, and melts at 53° C.

BOG-HEAD COAL. See Coal.

BOG-ORES. See Iron.

BOHEIC ACID. $C^7H^{10}O^6 = C^7H^8O^4.H^2.O^2$.—An acid occurring in small quantity in black tea, together with quercitannic acid (Rochleder, Ann. Ch. Pharm. lxiii. 202.) To prepare it, a decoction of black tea is precipitated at the boiling heat with acetate of lead; the filtered liquid is left to stand for twenty-four hours, and again filtered to separate a small sediment; the clear solution is mixed with a quantity of ammonia sufficient to neutralise the acid reaction; the yellow precipitate stirred up with absolute alcohol, and decomposed by sulphuretted hydrogen; and the filtrate left to evaporate in vacuo over oil of vitriol. The residue is dissolved in water, and the solution is left to evaporate in vacuo, then dried at 100° C., this treatment being repeated three times, and the residue finally left for three weeks in vacuo.

The acid when pulverised is of a pale yellow colour, like quercitannic acid. Melts at 100° C. into a mass which draws out into threads. It cakes together when exposed to the air, even for a few minutes, and deliquesces very quickly. Colours ferric hydrochlorate brown, without precipitation. Dissolves in all proportions in water and in alcohol.

By dry distillation, it yields a light charcoal, and a distillate which smells of acetic acid and blackens iron salts. The aqueous and alcoholic solutions decompose when evaporated in contact with the air. The acid is dibasic, the formula of its normal salts being $C^7H^8O^4.M^2.O^2$.

The *barium-salt*, $C^7H^8Ba^2O^6 + H^2O$, is obtained as a yellow precipitate by mixing the solution of the acid in aqueous alcohol, with a slight excess of baryta-water. The *normal lead-salt*, $C^7H^8Pb^2O^6 + H^2O$, is obtained by mixing the alcoholic solution of the acid, after concentration over potash in vacuo, with alcoholic acetate of lead, washing the precipitate with alcohol, and drying at 100° C. It is white, with a tinge of grey. A *basic lead-salt*, $C^7H^8Pb^2O^6.Pb^2O$, is obtained by precipitating the aqueous solution of the acid with an ammoniacal solution of acetate of lead. It forms an egg-yellow precipitate. (Rochleder.)

BOILING POINT. See HEAT.

BOLE. A massive mineral, having a perfectly conchoïdal fracture, a glimmering internal lustre, and a shining streak. Its colours are yellow-red, and brownish-black. It is translucent or opaque; soft, so as to be easily cut and to yield to the nail. It adheres to the tongue, has a greasy feel, and falls to pieces in water. Specific gravity 1·4 to 2. It may be polished. If it be immersed in water after it is dried, it falls asunder with a crackling noise. It is a hydrated silicate of aluminium, in which the aluminium is more or less replaced by iron (ferricum).

The following are analyses of bole:

	SiO^2	Al^4O^3	Fe^4O^3	Ca^2O	Mg^2O	K^2O	H^2O		
a. . .	41·9	20·9	12·2	—	—	—	24·9	= 99·9	(Wackenroder)
b. . .	42·00	24·04	10·03	0·52	0·43	—	24·03	= 101·05	(Löwig)
c. . .	41·05	25·03	8·09	0·45	0·50	—	24·02	= 99·14	„
d. . .	43·00	20·12	8·53	2·81	2·01	0·50	24·00	= 99·97	(Zellner)
e. . .	45·92	22·14	—	3·90	—	—	25·86	= 97·82	(Rammelsberg)
f. . .	47·03	18·46	6·36	1·00	—	0·90*	25·28	= 99·03	(Thomson)

a, from Säsebühl, near Göttingen; *b*, from Ettinghausen; *c*, from Cap de Prudelles; *d* from the Brechte Berg in Silesia. The composition of these specimens agrees nearly with the formula $4M^4O^3.9SiO^2.18H^2O$, which, by substituting $m = \frac{2}{3}M$, may be reduced to $m^8H^4Si^3O^{12} + 4aq$; *e*, from Stolpen in Saxony, is represented nearly by the formula $Ca^2O.2Al^4O^3.4SiO^2 + 4aq = (Ca^2al^{12}H^2)Si^4O^{16} + 3aq$; *f*, from the Giant's Causeway in Ireland, is nearly $M^4O^3.3SiO^2 + 6aq$, which may be reduced to $(m^2H^2)SiO^4 + aq$. All these are formulæ of orthosilicates. (*Rammelsberg's Mineralchemie*, 578; Dana, ii. 252.)

BOLOGNIAN STONE. Lemery reports that an Italian shoemaker, named Vincenzo Casciarolo, first discovered the phosphoric property of the Bolognian stone. It is the ponderous spar, or native sulphate of baryta. If it be first heated to ignition, then finely powdered, and made into a paste with mucilage, and this paste, divided into pieces a quarter of an inch thick, and dried in a moderate heat, be exposed to the heat of a wind furnace, by placing them loose in the midst of the charcoal, a pyrophorus will be obtained, which, after a few minutes' exposure to the sun's rays, will give light enough in the dark to render the figures on the dial-plate of a watch visible. U.

BOLETIC ACID. The name given by Braconnot to the acid existing in *Boletus pseudo-igniarius*, since shown by Bolley and Dessaignes to be identical with fumaric acid.

BOLETUS. A genus of mushroom, of which several species have been subjected to chemical examination by Braconnot and Bouillon La Grange (Ann. Chim. lxxx. 272); and more recently by Bolley, (Ann. Ch. Pharm. lxxxvi. 44), and Dessaignes (Compt. rend. xxxvii. 780).

The chief constituents of these fungi are extractive matter, nitrogenous principles, the so-called fungin (*q. v.*), sometimes mannite, perhaps also fermentable sugar and certain organic acids, called *fungic* and *boletic* acids by Braconnot, but probably consisting, according to Dessaignes, of malic or fumaric acid. The ash contains potash, lime, magnesia, phosphoric acid, &c. The species which have been examined are *Boletus bovinus* (Crell's Chem. Ann. 1785, p. 280), *B. igniarius* (Ann. Chim. li. 75), *B. juglandis* (*ibid.* lxxxvii. 226), *B. laricis* (*ibid.* lxxx. 272), *B. sulphureus* and *B. viscidus* (Trommsdorff's N. Journ. ix. 240).

Boletus laricis, is used on the continent in medicine under the name of *agaric*. It is in white, light, friable pieces, the outside of which is like dark-coloured leather. Its taste, at first sweetish, soon becomes bitter and acrid. Its infusion in water is yellowish, sweet tasted, and reddens vegetable blues.

Boletus igniarius is found in most countries, and particularly in the Highlands of Scotland, on the trunks of old ash and other trees. The French and Germans prepare it abundantly for making *tinder*, by boiling in water, drying, beating it, steeping it in a solution of nitre, and again drying it. In France it is called *amadou*, in this country *German tinder*. It has been recommended in surgery for stopping hæmorrhage from wounds. It imparts to water a deep brown colour and an astringent taste.

---

* Chloride of sodium.

BOLORETIN. A resin of earthy aspect, found in the fossil fir-wood of Danish peat-bogs, and in the needles which fall from the growing trees. The fresh shoots contain but little of it; but it increases with the age of the needles, and is most abundant in autumn and winter. It is prepared by treating with boiling alcohol the grey earthy matter found in hollow fossil fir-stems, and precipitating the foreign matters with acetate of lead. The solution on cooling deposits the boloretin as an earthy mass, which may be further purified by repeated solution in boiling alcohol, with addition of hydrochloric acid to precipitate lead. It is soluble in ether, but not in cold alcohol. Melts at 75°—79° C. Its composition is variable, but it appears always to contain the elements of oil of turpentine *plus* water. It does not, however, yield oil of turpentine when treated with phosphoric anhydride. (Forchammer, Ann. Ch. Pharm. xli. 44.)

BOLTONITE. A variety of olivin, Mg^4SiO^4, occurring in crystalline granules, disseminated through limestone at Bolton in Massachussets. Colour ash-grey, wax-yellow, or yellowish-white, with vitreous lustre. Streak white. Transparent or translucent. Specific gravity 3·008 (Silliman); 3·21 (Brush). Hardness in unaltered specimens = 6 or rather greater (Brush). Cleavage distinct in one direction. Infusible before the blowpipe; slightly attacked by hydrochloric acid. The following analyses agree nearly with the formula Mg^4SiO^4 or $2Mg^2O.SiO^2$: *a* by J. L. Smith (Sill. Am. J. [2] xviii. 372); *b* by G. J. Brush (*ibid.* xxvii. 395):

	SiO^2	Mg^2O	Fe^2O	Ca^2O	Al^4O^3	Loss by ignition.	
a.	42·31	51·16	2·77	. .	0·18	1·90	= 98·32
b.	42·82	54·44	1·47	0·85	trace	0·76	= 100·43

Analyses by B. Silliman (Sill. Am. J. [2] viii. 15) and v. Hauer (Kenngott's Uebersicht, 1854, 90) gave larger amounts of silica and alumina, and less magnesia; but the mineral appears to have been but imperfectly decomposed.

BOLUS. A highly ferruginous clay from Sinope in Asia Minor, containing, according to Klaproth, 32·0 SiO^2, 26·5 Al^4O^3, 21·0 Fe^4O^3, 17·0 H^2O, and 1·5 NaCl.

BONE. (E. v. Bibra, Chemische Untersuchungen über die Knochen und Zähne, &c. Schweinfurt, 1844, p. 1—258, 289—385; E. Frémy, Ann. Ch. Phys. [3] xlvii. 47—107; also Traité de Chimie, par Pelouze et Frémy, 2nd edition, vi. 261; C. J. Lehmann, Physiological Chemistry, iii. 12, and Gmelin's Handbuch, viii. 429.)—Bone-tissue is of two kinds, *compact* and *spongy*. The long tubular bones of the extremities are formed mainly of the compact tissue, while the flat bones, as those of the skull and pelvis, and the short round bones, consist of an external compact layer, enclosing a mass of the more porous or spongy tissue. The outer surface of bones is covered with a thin membrane (the *periosteum*), traversed by great numbers of nerves and bloodvessels, while the inner surfaces of their cavities and channels are lined with a still thinner membrane. These tubes and cavities contain a fatty substance called *marrow*. The substance of the bone itself exhibits a laminated structure, the individual layers being concentric with the tubes and channels containing the marrow. These layers consist of an amorphous substance, intersected by cavities, from which proceed innumerable intercommunicating channels.

The true bony tissue, distinguished from the external and internal membranes, the marrow, and the various fluids contained in the channels and cavities above-mentioned, consists essentially of an organic substance, called *bone-cartilage*, or *ossein*, and an inorganic substance, composed mainly of *tribasic phosphate of calcium*, Ca^3PO^4, together with smaller quantities of *phosphate of magnesium*, Mg^3PO^4, *carbonate of calcium*, and *fluoride of calcium*.

If a bone be incinerated without previously reducing it to powder, and washing out the blood and other extraneous fluids contained in its cavities, the ash will likewise contain small quantities of *alkaline sulphates*, *carbonates*, and *chlorides*, and of *iron*, but these are derived from the liquids just mentioned, and do not properly belong to the bone itself.

The bone-cartilage or ossein may be separated from the earthy matter by macerating a bone for some time in dilute hydrochloric acid. The calcium-salts then gradually dissolve, the mass becomes translucent and soft, and ultimately the cartilage is left free from mineral matter, and retaining the form of the bone. By boiling in water, it is converted into gelatin and dissolves, forming a solution clouded by suspended fat and vascular tissue, and solidifying in a jelly on cooling. When freed from these extraneous matters by digestion in alcohol and in ether, it is found to have the same proportional constitution as gelatin, as may be seen from the following table, in which the composition of bone-cartilage from various sources is compared with that of pure gelatin (isinglass).

Composition of Gelatin and Bone-cartilage.

	Carbon.	Hydrogen.	Nitrogen.	Oxygen.	
Gelatin:					
From Bone	50·40	6·64	18·34	24·64	Mulder.
„ „ (fossil) . .	50·40	7·11	18·15	24·36	v. Bibra.
„ Isinglass . . .	50·76	6·64	18·32	24·69	Mulder.
Bone-cartilage:					
From femur of Ox . .	50·13	7·07	18·45	24·35	v. Bibra.
„ Pipa . .	50·45	7·08	18·21	24·24	„
„ Rib of River Carp .	50·32	7·22	18·42	24·00	„
„ Ox . . .	49·81	7·14	17·32	25·67	Frémy.
„ Calf . . .	49·9	7·3	17·2	25·6	„
„ Owl . . .	49·05	6·77			„

Bone-cartilage also contains sulphur, which v. Bibra estimates at 0·216 per cent.

The chief difference between bone-cartilage and gelatin is, that the latter dissolves easily and immediately in boiling water, whereas the former is insoluble in water until it has been converted into gelatin, which requires long boiling.

According to Frémy, the bone-cartilage has likewise the same composition in young and in old animals. Fœtal bones, however, do not appear to yield gelatin when boiled with water; or at all events, Schwann (Mikrosk. Unters. 1839, p. 3), could not obtain that substance from the bones of a fœtal calf, nor Hoppel (Arch. f. pathol. Anat. v. 174) from those of a rabbit, down to the last hours of intra-uterine life. In *fossil bones*, the cartilage is often found to be converted into true gelatin. The cartilage of diseased bones does not appear to differ from that of healthy bones (v. Bibra and others). In the bones of certain water-birds, and in the spines of certain fishes, Frémy found a substance resembling ossein in physical characters, and isomeric with it, but differing from it in not yielding gelatin when boiled with water.

Quantitative Analysis.—The bone is first reduced to fine powder by rasping, then washed with water to remove soluble salts, &c., and digested with ether to remove fatty matters. Care must however be taken not to continue the washing with water too long, as by the prolonged action of water, small quantities of the phosphates of calcium and magnesium are dissolved out, the quantity thus removed increasing as the organic matter of the bone passes more and more into the state of putrefaction. (Wöhler.)

The bone purified as above, is next incinerated in a muffle (p. 418), till it becomes quite white, then moistened with solution of carbonate of ammonium, to restore any carbonic acid that may have been driven off from the lime, and again heated just sufficiently to expel the excess of carbonate of ammonium. The difference between the weight of the dried bone before ignition, and that of the ash, gives the amount of cartilage.

The analysis of the ash is made for the most part by the ordinary methods (p. 419).

The *carbonic acid* must be estimated by one of the methods given under ALKALIMETRY (p. 117), first in the unignited bone-powder, and afterwards in the ash. The first gives the amount of carbonate of calcium in the bone, and from the difference of the two determinations, the quantity of lime which was in combination with organic acids may be found. The amount of carbonate of calcium cannot be correctly estimated by precipitating with carbonate of ammonium the lime which remains in solution after the phosphate of calcium has been precipitated by caustic ammonia. The adoption of this method in the earlier analyses, led to the incorrect conclusion that the calcium-phosphate contained in bone-earth was $8Ca^2O.P^2O^5$, instead of $3Ca^2O.P^2O^5$.

The amount of *fluorine* in bones has seldom been determined quantitatively, the calcium really existing as fluoride being generally reckoned together with the carbonate or phosphate. Marchand, however (J. pr. Chem. xxvii. 83), found in a human thigh-bone 1 per cent., and Heintz (Wien, Akad. Ber. 1849, p. 51), found in a similar bone 2·05 per cent. fluoride of calcium. In fossil bones, the proportion of this salt is often much greater.

As bone-tissue is very hygroscopic, it is necessary, in comparing the quantities of *water* which different bones retain, after drying in the air at ordinary temperatures, to notice the indications of the barometer and thermometer before exposing the bones to the heat of the water-bath or oil-bath.

The most complete investigations that have been made of the composition of bone, are those of v. Bibra and Frémy. The following table exhibits the percentage of inorganic matter in human bones of various ages, as determined by v. Bibra.

Name of Bone.	Percentage of Ash.	Name of Bone.	Percentage of Ash.
Male fœtus, 7 months:		*Woman*, 25 years:	
Femur, tibia, humerus	59·1 to 59·6	Femur, tibia, fibula, ulna, os occipitis	68·4 to 68·8
Female fœtus, 7 months	64·5 to 65·4	Humerus	69·25
Boy, 2 months:		Clavicule	67·51
Tibia	65·32	Rib	64·57
Atlas	64·07	Sternum	51·43
Boy, ¾ year:		Scapula	65·48
Femur	56·43	Vertebræ	54·25
Humerus	58·58	Os innominatum	59·97
Tibia	56·58	*Man*, between 25 and 30 yrs.	
Radius	52·52	Femur, tibia, humerus, ulna	68·0 to 69·4
Ulna	56·51	Os occipitis	68·73
Rib	49·30	Rib	63·99
Scapula	49·71	*Woman*, 78 years:	
Boy, 5 years:		Femur	66·81
Femur	67·80	*Man*, 58 years:	
Tibia	67·71	Femur, dense portion	68·53
Girl, 19 years:		,, spongy portion	64·18
Femur	67·85		
Humerus	67·71		

From these results it appears: 1. That the proportion of inorganic matter in bone is smaller in youth than in age, although no regular gradation can be observed. 2. The proportion of inorganic matter is greater in compact than in spongy bone-tissue; greater also in the bones of the extremities than in those of the trunk; greatest of all in the thigh-bone. It appears, indeed, to be greatest in those bones which are most moved, or have to bear the greatest strain; this observation is corroborated by the composition of the bones of birds (see below).

The different orders of mammiferous animals do not exhibit any essential differences in the proportions of inorganic matter in their bones, the limits being 64 and 75 per cent. The bones of birds contain on the average a larger proportion of inorganic matter than those of mammals, viz. 68·6 to 75·8 per cent.; those of reptiles rather less, 51·7 to 68·9 per cent. The bones of fishes exhibit great variety in the proportion of mineral matter which they contain, *e. g.* Bony fishes: *eel* 51·62 per cent.; *cod* 65·76; *salmon* 64·37; *perch* 59·40 per cent. Cartilaginous fishes: *Shark* 46·82 per cent.; *lamprey* 1·66 per cent.

Frémy's results agree for the most part with those of v. Bibra, excepting in the proportion of organic and inorganic matter in bones of different ages, which, according to Frémy, do not exhibit in this respect any sensible variation. The bone of a fœtus was found to yield the same quantity of ash as that of a woman 97 years of age, and the first bony particles that make their appearance in the midst of the cartilaginous mass, which in the fœtus precedes the formation of true bone, were found to contain the same quantity of mineral matter as the bone of an adult animal (see table, p. 621). The greater brittleness of the bones in age is attributed by Frémy to the increase in the proportion of the spongy tissue, the thickness of the hard and dense portion of the bones continually diminishing as age advances.

Frémy's analyses of the bones of animals belonging to different orders show, in accordance with those of v. Bibra, that the bones of mammifers exhibit the same average composition as those of man, the bones of herbivorous quadrupeds, however, generally containing a larger proportion of lime-salts than those of flesh-eaters. The bones of birds have nearly the same proportion of lime-salts as those of herbivorous mammals, and those of reptiles nearly the same as those of carnivorous mammals. The bones of fishes exhibit great diversity of composition, those of bony fishes being very much like those of mammifers, whereas those of cartilaginous fishes are rich in organic matter, and contain but a small proportion of mineral salts.

Comparative Analyses of Bones belonging to different Orders of the Animal Kingdom.

Diseased Bones.—Bones are subject to several diseases, in nearly all of which the proportion of inorganic matter is found to diminish. In *caries*, the calcareous portion of the bone is destroyed, without alteration of the cartilage, the latter still yielding gelatin when boiled with water. In a carious femur, v. Bibra found the proportion of inorganic salts reduced to 38·3 per cent., and in a portion of astragalus, taken from the centre of the caries, it was only 18·5 per cent.—In *osteomalacia* and *rachitis*, the proportion of mineral matter sometimes diminishes to such an extent, that the bones bend under the weight of the body. Marchand found in the femur of a rachitic child 72·20 per cent, cartilage, 7·20 fat, 14·78 phosphate of calcium, 3·0 carbonate of calcium, 0·80 phosphate of magnesium, and 2·02 sulphate of calcium, chloride of sodium, iron (and loss). In the *osteomalacia* of adults, the tribasic phosphate of calcium is converted into $\frac{8}{3}$-phosphate, $8Ca^2O.3P^2O^5$ (Weber), and the bones sometimes contain a free acid. In this disease, and in the rachitis of children, the cartilage is frequently altered in character, so that it no longer yields gelatin when boiled with water. *Exostosis* is the formation of osseous tumours on the surface of bones; these tumours likewise contain an excess of cartilage. *Sclerosis* is the formation of cartilage, and ultimately of true bony tissue within the medullary cavities and canals of the bones, which thus become denser and almost like ivory. Here also the organic matter is generally in excess, and the carbonate of calcium is increased in proportion to the phosphate. In *osteoporosis*, which is a dilatation of the medullary cavities, &c., either from the excessive development of the medulla, or from the solvent action of fluids infused into the cavities, the mineral matter is also found to disappear more quickly than the organic matter.

Fossil Bones.—When a bone is exposed to the air or buried in the earth, the organic tissue gradually disappears, while the calcareous salts remain. In buried bones, the tissue likewise becomes incrusted with various substances derived from the surrounding soil, so that fossil bones often contain considerable quantities of carbonate, sulphate, and fluoride of calcium, silica, &c., according to the nature of the formation in which they are embedded. The proportion of carbonate of calcium sometimes amounts to 67 per cent. The silica is in the form of quartz, that is, in the modification which is insoluble in acids and in dilute alkalis. In some cases, the proportion of tricalcic phosphate remains nearly the same as in the original bone, whereas in others it is greatly diminished. The proportion of phosphate of magnesium does not vary greatly; it diminishes, however, to a certain extent when the phosphate of calcium is replaced by carbonate of calcium or by siliceous compounds. Many fossil bones still retain a portion of their cartilage, which is sometimes also converted into true gelatin.

BONE-BLACK. *Animal black, Animal charcoal, Beinschwarz.*—A product obtained by heating bones to redness in close vessels. Large quantities of stinking gas, empyreumatic oil, and volatile alkaloïds, are then evolved, and there remains a black mass consisting of an intimate mixture of charcoal containing nitrogen, with the mineral matter of the bone, chiefly phosphate and carbonate of calcium. It possesses the power of abstracting many solid substances from their solutions, and is used on a very large scale as a decolorising agent in the refining of sugar. That it may possess this property in the highest degree, the preparation must be so conducted as to leave the largest possible quantity of carbon in the product, and at the same time to render it very porous. The air must therefore be carefully excluded during the ignition, and the heat must be regulated so as not to cause the mass to cake together or become agglutinated by the fusion of organic substances. The bones should be fresh; those which have lost much of their organic matter by putrefaction, either in the air or underground, do not yield a sufficient quantity of charcoal. They should be coarsely comminuted and boiled to free them from fat, which would melt and yield a very compact charcoal.

The yield of bone-black varies from 30 to 60 per cent. according to the composition of the bones. The long cylindrical bones of the extremities are best adapted for the purpose; they yield about 60 per cent of bone-black, containing 1 to 1¼ carbon to 9 pts. phosphate of calcium. Ribs, skulls, and vertebræ yield a smaller quantity, and not of good quality: hence it is better to use them for the preparation of gelatin.

The carbonisation of bones is performed either in iron cylinders, like those used in the distillation of coal, or in covered pots of cast-iron or crucible-ware, heated in a reverberatory furnace; the latter method yields the best charcoal, but the former is adopted when it is desired to collect the volatile products which are given off. (See BONE-OIL.) (For details and figures of machinery, see *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 369; *Muspratt's Chemistry*, i. 315; *Handwörterbuch d. Chem.* 2te Aufl. ii. 767).

Bone-black is extensively used both as a decolorising and deodorising agent; it likewise removes lime and its salts from their aqueous solutions, and is accordingly used for the purification of highly calcareous waters. In the refining of sugar, it serves to free the syrup both from colouring matter and from lime. It decomposes many metallic salts, sometimes absorbing the oxides or metallic acids, sometimes reducing them. It abstracts iodine, not only from solution, but even from its salts. It likewise removes bitter principles and organic alkaloïds from their solutions, and has been recommended as an antidote in case of poisoning by such substances.

Bone-black which has been used for removing colouring matter and lime from syrup or other liquids, may be *revivified*, that is, restored to its original state, by the following processes:—1. Treating it with acids to remove the lime.—2. Leaving it to ferment or putrefy, in order to render soluble the organic substances which it has absorbed.—3. Washing.—4. Ignition. (For details, see the works above cited.)

Bone-black is sometimes used as a pigment; for which purpose it is made into a paste with water, and finely pulverised in a colour-mill. The finest pigment of this kind is *ivory-black*, which is obtained by the carbonisation of ivory.

Lastly bone-black is used as a manure, especially for cereal crops, being well adapted for this purpose, both by the phosphoric acid and the nitrogen which it contains. It is chiefly efficacious on soils which still retain a considerable quantity of decayed vegetable matter.

BONE-OIL. *Dippel's oil, Animal oil, Oleum animale Dippelii.*—This oil is obtained in large quantity in the preparation of bone-black, by igniting charcoal in cylinders. Similar products are obtained by the dry distillation of other animal substances. The original *Dippel's oil* known in Pharmacy was produced from stag's horn; but all the animal oil now met with in commerce, is obtained from bones in the manner abovementioned. It has been made the subject of a series of elaborate investigations by Professor Anderson of Glasgow. (Transactions of the Royal Society of Edinburgh, xvi. 4; xx. Part II. 247; xxi. Part I. 219, and Part IV. 571. Ann. Ch. Pharm. lxx. 32; lxxx. 44; xciv. 358; cv. 335. Jahresber. f. Chem. 1847–8, p. 651; 1851, p. 475; 1854, p. 488; 1867, p. 392.)

Bone-oil is mainly a product of the decomposition of gelatinous tissue, inasmuch as the bones used for the preparation of animal charcoal are boiled, before ignition, with a large quantity of water, to deprive them of their fat (p. 624). The crude oil is dark brown or nearly black, and has a specific gravity of 0·970. It consists chiefly of a mixture of volatile organic bases, together with smaller quantities of acids and neutral hydrocarbons.

On subjecting a large quantity of the crude oil to fractional distillation, the first $\frac{2}{5}$ of the distillate consists of about equal parts of a yellow oil and a watery liquid holding in solution sulphide, cyanide, and carbonate of ammonium, together with small quantities of very volatile organic bases. On supersaturating this watery liquid with sulphuric acid, boiling for a while, then distilling with slaked lime, and immersing sticks of potash in the watery distillate, ammonia is given off with brisk effervescence, and a small quantity of oily bases separates on the surface of the potash-solution.

The remaining $\frac{3}{5}$ of the distillate consists of oily bases of various degrees of volatility. On mixing them (together with the small portion of oily bases separated from the watery liquid just mentioned) with excess of dilute sulphuric acid, setting the mixture aside for some days, and frequently shaking it, then separating the strongly acid liquid from the portion of oil still unacted on, and boiling it for some time in a still, an alkaline liquid passes over containing *pyrrhol*, C^4H^5N, a weak base first noticed by Runge (Pogg. Ann. xxxi. 65) in bone-oil and in coal-tar, and distinguished by the property of imparting a deep purple-red colour to fir wood moistened with hydrochloric acid.

The remaining acid liquid, after cooling, is mixed with excess of slaked lime and distilled, and the distillate is treated with solid caustic potash, which separates a quantity of oily bases, while the watery liquid retains in solution *ammonia* and *methylamine*, which are given off on simply distilling the liquid, and may be condensed in dilute hydrochloric acid.

On submitting to fractional distillation the mixture of oily bases separated by the potash, a number of bases are obtained from 65° to 100° C. belonging to the series $C^nH^{2n+3}N$, viz. ethylamine C^2H^7N, tritylamine C^3H^9N, tetrylamine $C^4H^{11}N$, and amylamine $C^5H^{13}H$; and above 115° C. another series of bases are given off belonging to the series $C^nH^{2n-5}N$, and isomeric with phenylamine and its homologues, viz.:

Pyridine, C^5H^5N, boiling at 116·7° C.
Picoline, C^6H^7N, „ „ 135
Lutidine, C^7H^9N, „ „ 154·5
Collidine, $C^8H^{11}N$, „ „ 180

The non-basic portion of bone-oil yields by repeated rectification, a liquid boiling at 65·5° C., which, when exposed to a freezing mixture, separates into two distinct layers. The portions boiling at a higher temperature do not exhibit this property. They contain *benzene*, and probably also homologues thereof, also *alcohol-radicles*, and *nitrogenous compounds* which are decomposed by sodium.

BONSDORFFITE. A variety of hydrous dichroïte (ii. 422).

BORACITE. *Borazite. Borate of Magnesia.*—A mineral occurring in crystals imbedded in gypsum and anhydrite at Lüneberg in Hanover, Segeberg in Holstein, and Luneville, La Meurthe, in France. The crystals are monometric; cubes, rhomboïdal dodecahedrons or tetrahedrons, generally hemihedral combinations with a great number of faces. Cleavage octahedral in traces. Specific gravity = 2·974. Hardness = 7. Lustre vitreous, inclining to adamantine. Colour white, inclining to grey, yellow, and green. Streak white. Subtransparent to subtranslucent. Fracture conchoïdal, uneven. Pyro-electric, even when massive. (Dana, ii. 393.)

Boracite was formerly regarded as a borate of magnesium, $3Mg^2O.B^2O^3$, containing a small quantity of iron; but recent analyses have shown that it likewise contains chlorine. The mean results are as follows:

Mg^2O	Fe^2O	B^2O^3	Cl	H^2O	
30·67	1·62	62·55	7·96	0·75	(Potyka.)
30·48	1·38	—	8·50	—	(Siewert and Geist.)

If now the ferrous oxide be reckoned as magnesia ($Fe^2O : Mg^2O = 72 : 40$) these analyses give respectively 31·57 and 31·25 magnesia; and the results agree nearly with the formula $MgCl.(3Mg^2O.4B^2O^3)$, which requires 31·35 per cent. Mg^2O, 62·50 B^2O^3, and 7·94 Cl. (Rammelsberg's Mineralchemie, p. 254.)

BORAX. Acid borate of sodium. See Borates, under Boron, Oxide of (p. 645).

BORIDES. Compounds of boron with metals. See Boron.

BORNEENE. *Valerene.* $C^{10}H^{16}$.—A liquid hydrocarbon, isomeric with oil of turpentine, secreted by the *Dryabalanops camphora,* and holding in solution a solid substance, borneol, or camphor of Borneo. It is also obtained from essential oil of valerian, by submitting that oil to fractional distillation, and heating the first portions of the distillate with hydrate of potassium, which takes up valerol, while borneene passes as a distillate. Solid Bornean camphor distilled with phosphoric anhydride also yields a liquid hydrocarbon having the composition $C^{10}H^{16}$. (See Valerian, Oil of.)

Borneene is lighter than water, almost insoluble in that liquid, and smells like oil of turpentine. It turns the plane of polarisation of a luminous ray to the left, but less strongly than oil of turpentine. The product obtained from oil of valerian boils at 160° C., that from Borneo camphor at 165°. Vapour-density 4·60. It absorbs hydrochloric acid gas, forming a cyrstalline compound. It appears to oxidise when left in badly closed vessels, and when immersed in water, especially in presence of alkalis, it appears to be converted into borneol (Gerhardt, Traité, iii. 628, 641). (See Dryabalanops.)

Borneene from Madder Fusel-oil.—The fusel-oil contained in the alcohol produced by the distillation of madder-sugar, yields liquid products when distilled at temperatures rising to 230° C., while at higher temperatures lævo-rotatory borneol sublimes. The former, by digestion with caustic potash, then with chloride of calcium, and repeated fractional distillation, yields a liquid which boils at 160° C., contains 88·23 per cent. carbon and 11·81 hydrogen, has a vapour-density = 4·85, and is therefore probably borneene. Lævo-rotatory borneol (*vid. inf.*) distilled with phosphoric anhydride also yields a liquid which appears to be borneene. (Jeanjean, Ann. Ch. Pharm. ci. 94.)

BORNEOL. *Borneol Alcohol, Solid Camphor of Borneo.* $C^{10}H^{18}O$.—This substance is extracted from the *Dryabalanops camphora,* being found in cavities in the trunks of old trees. It is also found in small quantity in moist oil of valerian, being probably formed by hydration of borneene.

According to Pierlot (Ann. Ch. Phys. ix. 291) the crystals found in oil of valerian are not borneol, but valerian-camphor, $C^{12}H^{20}$.

Borneol is produced artificially by heating common camphor with alcoholic potash, its formation being attended, either with evolution of oxygen:

$$\underset{\text{Camphor.}}{C^{10}H^{16}O} + H^2O = \underset{\text{Borneol.}}{C^{10}H^{18}O} + O;$$

or with simultaneous production of camphic acid:

$$\underset{\text{Camphor.}}{2C^{10}H^{16}O} + H^2O = \underset{\text{Borneol.}}{C^{10}H^{18}O} + \underset{\text{Camphic acid.}}{C^{10}H^{16}O^2}.$$

The action takes place slowly at 100° C., more quickly at higher temperatures in sealed tubes. (Berthelot, Ann. Ch. Phys. [3] lvi. 78.)

Borneol forms small transparent, colourless, very friable crystals or crystalline fragments, having an odour like that of common camphor and of pepper, and a hot burning taste. The crystals appear to be regular six-sided prisms belonging to the hexagonal system. Their alcoholic solution possesses dextro-rotatory power, like that of common camphor. Dextro-rotatory power of natural borneol = 33·40 (Biot), of the artificial = 44·9°. Borneol is lighter than water, and insoluble in that liquid, but very soluble in alcohol and ether. Melts at 198° C., and boils at 212°, distilling without alteration. Gently heated with phosphoric anhydride, it yields borneene, $C^{10}H^{16}$. Boiled with strong nitric acid, it gives off H^2, and is converted into common camphor, $C^{10}H^{16}O$. With hydrochloric acid it unites without liquefying: the compound is destroyed by heat.

Lævo-rotatory Borneol.—This substance, which is isomeric with ordinary borneol, but differs from it in possessing equal but opposite rotatory power, is found in the alcohol produced by the fermentation of madder-sugar, and is obtained by collecting the laminæ which crystallise out on standing, or during fractional distillation. It forms crystalline laminæ, or a white powder smelling like pepper and common camphor. It dissolves sparingly in water, and when thrown on the surface of water, spins like common camphor. It dissolves easily in acetic acid, alcohol, and ether. Boiling nitric acid converts it into lævo-rotatory camphor. Distilled with phosphoric anhydride or chloride of zinc, it yields a hydrocarbon resembling oil of lemon or bergamot. (Jeanjean, Ann. Ch. Pharm. ci. 94.)

BORNITE. Syn. with ERUBESCITE and with TETRADYMITE.

BOROCALCITE. Native borate of calcium (p. 643).

BORON. *Atomic Weight* 11. *Symbol* B.—This element occurs in nature as *boric* or *boracic acid*, and in a few minerals, viz. *native borax* or *tincal*, *boracite*, *hydroboracite*, *datolite*, and *botryolite*, and in small quantities in *schorl*, *apyrite*, *axinite*, and *rhodizite*. It never occurs in the free state. Homberg, in 1702, first obtained boric acid from borax, and anhydrous boric acid was decomposed by Gay-Lussac and Thènard in 1808, and immediately afterwards, by Sir H. Davy, into oxygen and boron.

Boron may be obtained in three different states, viz. *amorphous*, *graphitoïdal*, and *adamantine*. (Wöhler and Deville, Ann. Ch. Phys. [3] lii. 63.)

1. *Amorphous Boron.*—This is the form in which boron was first obtained. Gay-Lussac and Thénard prepared it by igniting boric anhydride (vitrefied boric acid) in a tube with an equal weight of potassium in small pieces, then boiling the fused mass with very dilute hydrochloric acid, washing with water, and drying. This process yields, however, but a small product, as it is difficult to deprive the boric acid of all its water, and the remaining quantity oxidises part of the potassium, with violent combustion, causing part of the mass to be projected. According to R. D. Thomson (Phil. Mag. [3] x. 419), this inconvenience may be obviated by drying the boric anhydride as completely as possible, mixing it in the state of coarse powder, with twice its weight of potassium, freed as completely as possible from the crust of hydrate which generally adheres to it, and gradually heating the mixture to redness in a glass tube over a lamp. Wöhler and Deville mix 60 grammes of sodium in small pieces with 100 grammes of finely powdered boric anhydride in an iron crucible, and cover the mixture with about 30 grammes of pulverised and previously ignited chloride of sodium. The crucible is then quickly heated to redness, whereupon a violent reaction takes place, and the whole becomes liquid. It is carefully stirred with an iron rod till no more free sodium or unfused chloride of sodium can be seen, then carefully poured into water acidulated with hydrochloric acid, and washed and dried as above. As the amorphous boron is very apt to run through the filter when washed with pure water, it is best to wash with water containing sal-ammoniac, and then remove that salt by means of alcohol.—Another mode of preparing amorphous boron is that of Berzelius, which consists in decomposing perfectly dry borofluoride of potassium by heating it with an equal weight of metallic potassium in an iron tube closed at both ends. The mixture is first heated merely to the melting point of potassium, then well stirred with an iron rod, and afterwards heated to redness. The decomposition takes place without explosion, and the boron is afterwards separated from the fluoride of potassium, with which it is mixed, by digestion and washing with water containing sal-ammoniac, the latter being finally removed by alcohol. If too little potassium has been taken to produce complete decomposition, the washing is rendered difficult by the remaining borofluoride of potassium, which has but little solubility. Amorphous boron is also formed, together with the other two varieties, in the modes of preparation presently to be described.

Amorphous boron is a dark-brown or greenish-brown powder, opaque, destitute of taste and smell, and stains the fingers strongly. It is a non-conductor of electricity. In vacuo, or in gases with which it does not unite, it may be raised even to a white heat without melting, or subliming, or undergoing any alteration, excepting that it becomes so dense that it sinks rapidly in oil of vitriol. In the unignited state, it dissolves, to a very slight extent, in pure water, imparting its colour; in water containing acids or salts it is insoluble, and indeed such substances precipitate it from its aqueous solution.

Amorphous boron does not oxidise in the air or in oxygen gas at ordinary temperatures, but at about 300° C. it burns in the air with a reddish light, and in oxygen gas with dazzling brightness; the combustion is in both cases attended with vivid emission of sparks, and in oxygen gas, according to Berzelius, a faint greenish flame is observed. The product is boric oxide or anhydride, B^2O^3, the only known oxide of boron, which melts on the surface of the boron and partly protects it from further action. In atmospheric air, according to Wöhler and Deville, a small quantity of nitride of boron is formed at the same time.

Amorphous boron does not decompose water, even at the boiling heat, but it readily decomposes strong sulphuric acid when heated with it, and nitric acid, even when but slightly concentrated, in the cold, the product in each case being boric acid. At a red heat, it decomposes the carbonates, sulphites, sulphates, nitrites, and nitrates of the alkali-metals, an alkaline borate being formed, and carbon, sulphur, or nitrogen set free. The decomposition is sometimes attended with incandescence and, in the case of nitre, with explosion. It also decomposes many metallic oxides at a red heat, forming a borate, if the oxide is in excess. Heated with hydrate of potassium, it eliminates hydrogen, and forms borate of potassium. It likewise reduces many metallic chlorides and sulphides, *e.g.* chloride of lead, chloride of silver, and sulphide of lead at a red heat, chloride of boron being formed and escaping as gas (Wöhler and Deville). It precipitates metallic gold from a solution of the chloride. When strongly ignited in a current of nitrogen gas, it is converted into white nitride of boron. Heated nearly to redness in a current of nitric oxide gas, it burns brilliantly, forming boric anhydride and nitride of boron. It does not decompose nitrous oxide. (Wöhler and Deville).

By ignition with aluminium, amorphous boron may be converted into the two other modifications, which remain behind on dissolving out the aluminium by hydrochloric acid.

Graphitoïdal Boron.—This variety of boron is obtained:—1. By passing gaseous chloride of boron for some time over aluminium in the state of fusion. The metal takes up but a small quantity of boron; but on breaking it, the boron is found on the fractured surface in copper-coloured crystalline laminæ, like graphite in cast-iron; they may be separated by dissolving out the aluminium with hydrochloric acid.—2. By heating 8 pts. of borofluoride of potassium and 5 pts. of aluminium with a flux of 9 pts. chloride of potassium and 7 pts. chloride of sodium to the melting point of silver, in a porcelain crucible, and treating the half fused metallic mass found in the midst of the slag, first with hydrochloric then with hydrofluoric acid. Boron then remains in small blackish-grey crystalline scales.—3. By fusing a mixture of 15 pts. boric anhydride, 10 pts. fluor-spar, and 2 pts. aluminium; or by fusing aluminium with boric anhydride, or better with fused borax and cryolite, and a flux of chloride of potassium and chloride of sodium. A large excess of aluminium, however, is required to obtain but a small quantity of boron.

Graphitoïdal boron has a semi-metallic lustre, like graphite or crystalline ferric oxide, but with a distinct tinge of copper-red. When well crystallised, it forms thin six-sided tablets belonging to the hexagonal system; but it is more generally obtained as a reddish-grey, micaceous powder composed of fine crystalline laminæ. It is perfectly opaque. When heated to redness in the air, it does not burn or undergo any apparent alteration. It does not dissolve in acids or in alkalis, but appears to be converted into boric acid by the long-continued action of nitric acid. (Wöhler and Deville.)

Adamantine or *Diamond Boron.*—This is not, strictly speaking, a form of pure boron; at least, as hitherto obtained, it always contains carbon and sometimes aluminium. To prepare it, 80 grammes of aluminium in lumps are heated with 100 grammes of boric anhydride to a temperature at which nickel fuses readily. The mixture is introduced into a crucible of compact charcoal fitted with a charcoal cover and placed within a hessian or black-lead crucible, the intermediate space being filled with charcoal-powder, and the cover fastened on with refractory luting; and the whole is exposed for five or six hours to the strongest heat of an air-furnace, having a tall chimney and fed with a mixture of coke and coal. On breaking the crucible after cooling, two layers are found, one glassy, consisting of boric anhydride and alumina, the other a metallic iron-grey mass of aluminium, penetrated throughout with crystalline boron. The aluminium is dissolved out by strong soda-ley, iron by hot hydrochloric acid, and the residue is treated with a hot mixture of nitric and hydrofluoric acid, to remove silicium. The crystals of diamond boron thus far purified are still mixed with graphitoïdal boron and crystalline laminæ of alumina; the former, being light, may be separated by levigation; the latter only by careful mechanical selection.

Adamantine boron forms quadratic octahedrons, in which the principal axis is to the secondary axes as 0·577 : 1. The crystals vary in colour, from a scarcely perceptible honey-yellow to deep garnet-red; sometimes they are so deeply coloured, probably by amorphous boron, that they appear black. In lustre and refracting power, they are nearly equal to the diamond. Their specific gravity is 2·63. They are extremely hard, always sufficiently so to scratch corundum with facility, and some crystals are nearly as hard as diamond itself. The hardest are obtained by repeatedly exposing aluminium to the action of boric anhydride at a temperature high enough to cause the anhydride to volatilise very quickly.

Adamantine boron does not fuse, even at the heat of the oxyhydrogen blowpipe, and withstands the action of oxygen even when very strongly heated; but it is slightly oxidised at the temperature at which the diamond burns, a film of boric anhydride being then formed, which stops further oxidation. Heated on platinum-foil before the blowpipe, it forms a fusible boride of platinum. It is not attacked by acids at any temperature, but when heated to redness with acid sulphate of potassium, it is converted into boric acid. It is not attacked by a strong boiling solution of caustic soda, but is slowly dissolved by hydrate or carbonate of sodium at a red heat. Nitre does not appear to act upon it at any temperature.

Boron unites, as already observed, with oxygen and with nitrogen, also with chlorine, bromine, fluorine, and sulphur. With metals it does not, for the most part, unite readily; but borides of palladium and platinum are known. The platinum compound is very fusible, so that boron, in either of its modifications, if ignited on platinum-foil before the blowpipe, instantly perforates the platinum. (Wöhler and Deville.)

Boron in all its combinations appears to be triatomic; the chloride being BCl^3, the oxide B^2O^3, the hydrate (boric acid) H^3BO^3, &c.

BORON, BROMIDE OF. BBr^3.—Discovered by Poggiale in 1846 (Compt. rend. xxii. 124), but first obtained pure by Wöhler and Deville (Ann. Ch. Phys. [3] lii. 89.) It is produced by the action of bromine on amorphous boron, or on boric anhydride in presence of charcoal. The best way of preparing it is to pass bromine-vapour over heated amorphous boron, previously well dried in a current of hydrogen; then digest the product for some time with metallic mercury, to remove excess of bromine, and distil.

Pure bromide of boron is a colourless mobile liquid, of specific gravity 2·69, volatilising readily at ordinary temperatures, in colourless, pungent vapours, and boiling under the ordinary atmospheric pressure, at 90° C. Vapour-density (referred to air), by experiment, 8·78; by calculation (2 vol.) = 8·7. It fumes in moist air, and is instantly decomposed by water, with formation of boric and hydrobromic acids. With dry ammonia-gas, it forms a white pulverulent substance, which is converted by water into bromide and borate of ammonium: possibly thus:

$$BBr^3.4NH^3 + 2H^2O = 3NH^4Br + NH^4BO^2.$$

BORON, CHLORIDE OF. BCl^3.—First prepared by Berzelius (Pogg. Ann. ii. 147), afterwards by Dumas (Ann. Ch. Phys. [2] xxxi. 436; xxxiii. 376), more exactly investigated by Wöhler and Deville (*ibid.* [3] lii. 88). It is formed by the direct combination of chlorine and boron, which takes place at ordinary temperatures, or at a gentle heat; also by heating boron in hydrochloric acid gas, or a mixture of boric anhydride and charcoal in chlorine gas, and by the action of boron at a red heat on chloride of mercury, lead, or silver.

To prepare it, amorphous boron, loosely packed in a glass tube, is first freed from moisture by passing dry hydrogen over it at a gentle heat; the tube is then left open for a few seconds, to allow the hydrogen to escape; after which, dry chlorine gas is passed through the tube, the action being assisted if necessary, by gently heating the tube in a combustion furnace. Combination then takes place, attended with evolution of light and heat; and the vapours of chloride of boron are passed through a caoutchouc connecting-tube into a Y-shaped tube, the two upper arms of which are surrounded with ice and salt, while the lower arm conveys the condensed liquid into a receiver placed below. The product may be freed from excess of chlorine by digestion with mercury. A small quantity of oxychloride of boron is generally formed at the same time, by the action of a little air or moisture left in the apparatus; but it condenses in the cooler part of the combustion-tube. The chloride of boron may be freed from excess of chlorine by digestion with mercury.

When the vapour of chloride of boron is mixed with hydrogen, as when it is produced by heating boron in hydrochloric acid gas, or with carbonic oxide, as when produced by the action of chlorine on a hot mixture of boric anhydride and charcoal, it is very difficult to condense; indeed, chloride of boron was originally regarded as a gas at ordinary temperatures, until Wöhler and Deville obtained it in a state of purity by the process above described.

Pure chloride of boron is a colourless, mobile, strongly refracting liquid, having a specific gravity of 1·35 at 17° C. (? 7°); it expands very perceptibly by a rise of 1° or 2° of temperature. It boils at 17° C. Vapour-density, by experiment = 4·06—4·08; by calculation (2 vol.) = 4·07. It fumes in damp air, and is quickly decomposed by water, yielding boric and hydrochloric acids. With alcohol, it forms, with great rise of temperature, hydrochloric acid and borate of ethyl: similar reactions with methylic and amylic alcohols.

Ammonio-chloride of Boron, $3NH^3.2BCl^3$, is formed, with great evolution of heat, when dry ammonia-gas is passed over chloride of boron. It is a white, finely crystalline powder, which sublimes unaltered when heated alone, though not so easily as sal-ammoniac. It does not fume in the air, but is decomposed by water, yielding boric acid, chloride of ammonium, and hydrochloric acid:

$$2BCl^3.3NH^3 + 6H^2O = 2H^3BO^3 + 3NH^4Cl + 3HCl.$$

When the vapour of this compound, mixed with ammonia-gas, is passed through a red-hot tube, nitride of boron is produced.

BORON, CHLOROCYANIDE OF. See CYANOGEN, CHLORIDE OF.

BORON, DETECTION AND ESTIMATION OF. Boron almost always occurs in the form of boric acid, and therefore the reactions by which it is detected are best considered in detail in connection with that acid (see page 639). When the acid is in the free state, it is easily recognised by the green colour which it imparts to flame, especially to an alcohol flame, and by its peculiar action on turmeric paper. If the acid is in combination with a base, the compound must first be decomposed in the state of powder by sulphuric acid, and the boric acid extracted with alcohol. Native borates not decomposible by sulphuric acid, must be fused with potash, and then digested with alcohol and sulphuric acid. Another method of detecting boron in minerals is to mix the pulverised substance with 4 pts. of a flux containing 1 pt. pounded fluorspar and 4½ pts. acid sulphate of potassium, made into a paste with a little water, and heat the mixture on a platinum wire in the inner blowpipe flame. As the mass melts, fluoride of boron is given off, and imparts a yellow-green colour to the outer flame. If the quantity of boron present is small, this appearance lasts only for a few seconds, ceasing, in fact, as soon as the fluoride of boron is completely volatilised.

The green colour imparted to flame is a very delicate test for boron. Before applying it, however, care must be taken to ensure the complete absence of copper, as the salts of this metal impart a very bright green colour to flame. Certain chlorine-compounds also colour flames green, as when hydrochloric acid is dropped into an alcohol flame; but the green colour thus produced has a decided bluish tinge, which distinguishes it from that produced by boron. Lastly, phosphates moistened with sulphuric acid, also give a faint green colour to the outer blowpipe flame.

Quantitative Estimation.—The exact estimation of boron presents considerable difficulties, as all borates are more or less soluble in water or in alcohol, and boric acid cannot be heated without loss in contact with water. The best mode of direct estimation, originally proposed by Berzelius, and perfected by Stromeyer (Ann. Ch. Pharm. c. 82), is to precipitate the boron as borofluoride of potassium, which is quite insoluble in alcohol of a certain strength. This mode of precipitation, however, is directly applicable only when the boron exists in solution as borate of potassium: any other bases present must first be separated. Borates of the alkaline-earth-metals, earth-metals, or heavy metals, are fused with carbonate of potassium; and the mass is digested in water, which takes up nothing but borate of potassium, except perhaps a trace of magnesia. Borate of sodium is treated with alcohol and sulphuric acid; the alcoholic liquid filtered from the sulphate of sodium, is mixed with excess of potash free from silicic and carbonic acids; and the alcohol is evaporated. The alkaline borate of potassium obtained in either case, is now to be saturated with pure hydrofluoric acid, and the liquid evaporated to dryness in a silver or platinum vessel; the dry saline mass is macerated with a solution of acetate of potassium (1 pt. of the salt to 4 pts. water); the undissolved borofluoride of potassium is collected on a weighed filter supported on a gutta-percha funnel, and washed, first with the solution of acetate of potassium, which removes chloride, phosphate, and sulphate of potassium, likewise sodium-salts though slowly, and afterwards with alcohol of 84 per cent. Tralles (specific gravity 0·8526), then dried at 100° C. and weighed. 100 parts of the borofluoride correspond to 27·78 boric anhydride, or 9·06 boron.

To ascertain whether the precipitate is pure, it is dissolved in boiling water, which leaves behind any traces of magnesia that may be present, and the solution is treated with ammonia, which precipitates silica if present: the precipitate may then be washed, first with acetate of potassium, then with alcohol, and its weight ascertained.

The quantity of free boric acid in an aqueous or alcoholic solution, cannot be determined by evaporation to dryness, because a considerable quantity of the acid goes off with the aqueous or alcoholic vapours: even the presence of excess of lead-oxide, baryta, or basic phosphate of sodium, does not completely prevent this evaporation. Ammonia prevents the volatilisation to a greater extent than either of these substances, but it does not quite prevent loss. The only exact mode of determining boric acid by evaporation, is to supersaturate the liquid with a known weight of pure fused carbonate of sodium (about 2 pts. of the carbonate to 1 pt. of acid supposed to be present); then evaporate to dryness, and ignite the residue in a covered crucible. The amount of carbonic anhydride in the residue is then to be determined by the method given under ALKALIMETRY (p. 149), and deducting this, together with the known weight of soda contained in the carbonate added, from the total weight of the residue, the remainder is the quantity of boric anhydride present.

Boron in borates may be estimated *indirectly* in several ways. The best method is to digest a weighed quantity of the pulverised compound in a capacious platinum crucible, with hydrofluoric acid, then gradually add strong sulphuric acid, and heat the mixture, gently at first, and afterwards to redness, till the excess of sulphuric acid is expelled. The boron is then completely driven off as fluoride, and the bases remain in the form of sulphates. If only one base is present, its quantity is easily calculated from the weight of the residue. If two bases are present, *e.g.* potash and soda, the amount of sulphuric acid in the residue must be ascertained; the quantities of the two bases may then be found by the method given under INDIRECT ANALYSIS (p. 224). If more than two bases are present, they must be separated by the usual methods. The weight of the bases deducted from that of the original substance, gives the amount of boric anhydride.

Instead of driving off the boron as fluoride, it may be volatilised as borate of ethyl, by treating the pulverised borate with strong sulphuric acid and alcohol. Or the boric acid set free by the action of sulphuric acid, may be dissolved out by alcohol and separated by filtration; but this last method is applicable only when the resulting sulphates are completely insoluble in alcohol.

Boric acid combined with potash or with soda, may be estimated volumetrically by means of a standard solution of sulphuric acid. The solution is coloured with tincture of litmus, and the sulphuric acid is cautiously added from a burette, till the wine-red colour first produced by the liberation of the boric acid, changes to the bright red which indicates the presence of free sulphuric acid: this takes place as soon as the quantity of sulphuric acid (H^2SO^4) amounts to 1 at. for 2 at. of potash or soda (KHO or NaHO). Hence the amount of the base is found, and this deducted from the total weight of the dry salt, gives the boric acid.

Separation of Boron from other Elements.—When boric acid is in combination with several bases, it is best to estimate the amount of these bases at once, and determine the boric acid (or anhydride) by difference. From the metals of the first group, *copper*, for example, boron is easily separated by sulphuretted hydrogen; from *iron*, and others of the second group, by sulphide of ammonium. From *barium* it is separated by sulphuric acid; from *strontium* and *calcium*, by sulphuric acid and alcohol; from *magnesium*, by ammonia and phosphate of sodium: the precipitate in this last case generally contains a small quantity of boric acid.

The separation of boric acid from all these bases may likewise be effected by fusion with alkaline carbonates; in the case of magnesia, carbonate of potassium must be used, because soda forms with magnesia an insoluble compound.

Sulphuric acid is easily separated from boric acid by precipitation with chloride of barium; *hydrochloric, hydrobromic,* and *hydriodic* acids, by adding nitrate of silver to the solution acidulated with nitric acid; *phosphoric acid*, by ammonia and sulphate of magnesium.

The estimation of boron in presence of *fluorine* is difficult. Metallic borofluorides are analysed by heating them with sulphuric acid, whereby fluoride of boron and hydrofluoric acid are driven off, and the metal remains as sulphate, from the weight of which its quantity may be determined, and hence the amount of the boron and fluorine together. If the compound contains water of crystallisation, it must be determined by mixing the compound with 6 pts. of oxide of lead, covering the mixture in a retort with a layer of oxide of lead, and exposing it to a heat short of redness. The loss of weight gives the water.

In a mixture of a borate with a fluoride, it is impossible to determine either the boron or the fluorine exactly. By dissolving the compound in excess of nitric acid, and adding excess of carbonate of calcium, the fluorine is precipitated as fluoride of calcium, but not completely, probably because a borofluoride is formed.

The estimation of boron in *silicates* is likewise difficult. If the silicate is decomposed by acids, like datolite or botryolite, it is finely pulverised, heated in a corked flask with hydrochloric acid, at last nearly to boiling; the thick jelly is then diluted with water and filtered; the filtrate supersaturated with ammonia, which separates alumina; oxalic acid is added to precipitate lime; and the filtrate, which now contains nothing but boric acid in combination with ammonia, is evaporated in a platinum capsule over the water-bath, with frequent addition of ammonia. The dry residue is then gradually heated to redness in a covered platinum crucible, whereupon boric anhydride remains mixed with a little silica. The boric anhydride is afterwards dissolved out by water, and the residual silica weighed. The result is not quite exact, as a little boric acid goes off even in presence of excess of ammonia, but the loss is not considerable.

In silicates not decomposible by acids, boron is estimated by heating the pulverised mineral, first with hydrofluoric and then with sulphuric acid, whereby the boron and silicium are expelled as fluorides. The bases then remain as sulphates, and are determined by the ordinary methods. In another portion of the mineral, the silica is determined by fusion with a mixture of the carbonates of potassium and sodium, treatment of the residue with hydrochloric acid, evaporation to dryness, digestion of the residue in acidulated water, filtration, and washing,—whereupon the silica remains on the filter in a state of purity, and may be ignited and weighed. The bases and the silica having been thus determined, the boric anhydride is found by difference, the result being of course affected by all the errors in the several determinations. (H. Rose, Analyt. Chem. ii. 734.)

The estimation of boron in *organic compounds*, is generally effected by mixing the compound with ammonia in a capacious platinum crucible, then evaporating and igniting the residue. This method, according to Ebelmen, always involves a loss of at least 2 per cent. of boron, and that loss may even amount to 4 per cent. A better method might perhaps be to heat the compound with nitric acid in a sealed tube, according to Carius's method (p. 247): the boron would thereby be converted into boric acid, and might then be estimated by any of the methods above given.

Atomic Weight of Boron.—The earlier experiments of Gay-Lussac and Thénard, Davy, and Berzelius, in which the atomic weight of boron was estimated by the amount of oxygen absorbed in its combustion, did not lead to concordant results. Berzelius afterwards determined its value from the amount of water in crystallised borax, which in three experiments, he found to be 47·1 per cent. Now supposing the formula of the salt to be $Na^2O.2B^2O^3 + 10H^2O$, and that the atomic weight of sodium is 23, this result makes the atomic weight of boron equal to 11. Experiments by Deville, reported by Dumas (Ann. Ch. Phys. [3] lv. 129), on the proportion of chlorine in chloride of boron, gave, on the supposition that the formula of the chloride is BCl^3, the two results $B = 11·0$ and $B = 10·6$. Similar experiments with bromide of boron BBr^3, gave $B = 11·0$. This number appears therefore to have the greatest weight of evidence in its favour. If the formula of chloride of boron were BCl^2, the atomic weight of boron would be 7·3.

BORON, FLUORIDE OF. BF^3.—Discovered by Gay-Lussac and Thénard, in 1810. It is obtained: 1. By the action of boric anhydride on fluoride of calcium at high temperatures:

$$6CaF + 7B^2O^3 = 3(Ca^2O.2B^2O^3) + 2BF^3.$$

An intimate mixture of 2 pts. fluorspar and 1 pt. vitreous boric anhydride, is introduced into a gun-barrel closed at one end, and heated to whiteness in a furnace with good draught, and the gas which escapes is received over mercury: borate of calcium then remains behind.—2. By the action of hydrofluoric acid on boric acid or anhydride, viz. by heating a mixture of 1 pt. boric anhydride (or 2 pts. fused borax), and 2 pts. fluor spar, with 12 pts. oil of vitriol, in a glass vessel:

$$6CaF + B^2O^3 + 3H^2SO^4 = 3Ca^2SO^4 + 3H^2O + 2BF^3.$$

This method is easier than the former, but the gas which it yields is not quite pure, as it contains a little fluoride of silicium, resulting from decomposition of the glass; moreover part of the fluoride of boron is converted by the water into boric and hydrofluoric acids.

Fluoride of boron is a colourless gas, of pungent suffocating odour, like that of fluoride of silicium. Specific gravity = 2·37 (Davy); 2·31 (Dumas); and by calculation:

$$\frac{11 + 3\ .\ 18·7}{2} \times 0·0693 = 2·29$$

It reddens litmus, fumes in damp air, and chars organic bodies like sulphuric acid. It does not corrode glass. It is not decomposed by a red heat, or by the electric spark.

Water absorbs about 700 times its volume of this gas, with great evolution of heat and increase of bulk, forming an oily liquid of specific gravity 1·77, which when boiled, gives off $\frac{1}{5}$ of the dissolved gas, and leaves a residue consisting of $B^2O^3.6HF$, or $2BF^3.3H^2O$, which may be distilled without alteration. Water incompletely saturated with fluoride of boron, deposits boric acid on cooling, or after standing for some time, while fluoride of boron and hydrogen $HF.BF^3$, remains in solution.

Strong *sulphuric acid* absorbs 50 times its volume of gaseous fluoride of boron, forming a viscid liquid, which deposits boric acid when mixed with water.

Potassium, *sodium*, and the *alkaline earth-metals*, heated in fluoride of boron, become covered with a blackish crust, which bursts at a red heat, the metal then burning with bright incandescence, and forming a metallic borofluoride, with separation of boron. *Iron* does not act upon the gas, even at a bright-red heat. *Quick lime* absorbs fluoride of boron readily when heated, forming a fusible mixture of fluoride and borate of calcium.

Dry *ammonia gas* forms with an equal volume of fluoride of boron, a white, opaque, solid compound, $NH^3.BF^3$, which volatilises undecomposed, and is converted by water into borofluoride and borate of ammonium. By the further action of ammonia on this body, two liquid compounds, $2NH^3.BF^3$, and $3NH^3.BF^3$, are formed; when exposed to the air or heated, they give off ammonia and reproduce the solid compound.

According to Kuhlmann, fluoride of boron unites with nitric oxide, nitrous acid, peroxide of nitrogen, and nitric acid.

Fluoboric Acid. $HBO^2.3HF$.—This compound, discovered by Gay-Lussac and Thénard, is obtained by saturating water with gaseous fluoride of boron, the vessel being cooled with ice, and the gas-delivery-tube made to dip under mercury below the water, as otherwise the rapid absorption would cause the liquid to run back into the generating vessel. The saturated solution has a specific gravity of 1·77, and is nearly pure fluoboric anhydride, $B^2O^3.6HF$, or hydrate of boric fluoride, $2BF^3.3H^2O$ (Gmelin's tri-hydrofluate of boric acid, $BO^3.3HF$, Handbook, ii. 363). On heating it, one-fifth of the absorbed fluoride of boron goes off, and there remains a liquid of specific gravity 1·584, which is fluoboric acid, $H^2O.B^2O^3.6HF$, or $HBO^2.3HF$.

An easier mode of preparing this acid is to dissolve boric acid or anhydride in hydrofluoric acid contained in a platinum crucible externally cooled, avoiding an excess of boric acid, then evaporate over the water-bath, gently boil the remaining liquid in the covered crucible, till the vapours form a thick fume in the air, and leave the liquid to cool over sulphuric acid. It may also be obtained by fusing an intimate mixture of 10 pts. fluorspar and 8½ crystallised borax, pulverising the fused mass, and distilling it with 16⅔ pts. strong sulphuric acid. The product thus obtained generally contains a little silica derived from the distillation-vessel.

Fluoboric acid is an oily liquid, like oil of vitriol, fumes in the air, boils at a temperature above 100° C., and distils without alteration. It is highly caustic, chars organic bodies, and converts alcohol into ether. By dilution with water, it is decomposed, one-fourth of the boric acid being separated, and a solution of hydrofluoboric acid remaining:

$$4(HBO^2.3HF) - HBO^2 = 3HBF^4 + 6H^2O.$$

Fluoboric acid forms salts, having the general formula $MBO^2.3MF$. They are produced by the direct action of the acid on the bases, or by dissolving the corresponding borates and fluorides in the proper proportions, and leaving the solution to evaporate. But few of them have been examined.

The *sodium-salt*, $NaBO^2.3NaF + \frac{1}{2}$ aq, crystallises in small rectangular prisms, having their terminal faces obliquely truncated; they have an alkaline reaction, give off their water at 40° C., and melt at a higher temperature. The fused salt, if quickly cooled, solidifies to a clear glass; but by slow cooling, it becomes turbid, from separation of fluoride of sodium, which remains undissolved on treating the mass with cold water, whereas boiling water dissolves the whole, reproducing the original salt.

Another *fluoborate of sodium*, $NaHB^2O^4.6NaF + 10$ aq, is produced by slowly evaporating a solution of 1 at. borax and 6 at. fluoride of sodium. It crystallises in small rectangular four-sided prisms, which become turbid at 40° C. from loss of water, and behave like the preceding when melted and slowly cooled. (Handw. d. Chem. 2^{te} Aufl. ii. [2] 279.)

Hydrofluoboric Acid. $HBF^4 = BF^3.HF$.—Obtained by passing gaseous fluoride of boron into water, till the liquid is strongly acid, and exposing it to a low temperature. Boric acid then separates, and hydrofluoboric acid remains in solution:

$$4BF^3 + 2H^2O = 3BHF^4 + HBO^2.$$

A similar solution is obtained by dissolving crystallised boric acid to saturation in moderately strong hydrofluoric acid artificially cooled.

Hydrofluoboric acid is known only in the state of dilute solution. It is decomposed by concentration, yielding hydrofluoric and fluoboric acids:

$$BHF^4 + 2H^2O = HF + HBO^2.3HF.$$

In the dilute state, it does not attack glass; but if it be concentrated in a glass vessel, the glass becomes corroded, from separation of hydrofluoric acid; if, however, boric acid be added during the concentration, so as to form fluoboric acid, no corrosion of the glass takes place.

Borofluorides.—These salts, whose composition is expressed by the general formula, MBF^4 or $MF.BF^3$, are formed by the action of gaseous fluoride of boron or aqueous fluoboric acid on metallic fluorides; by the action of metallic oxides on hydrofluoboric acid; or by dissolving a metallic fluoride, together with boric acid, in aqueous hydrofluoric acid; sometimes also by merely bringing a fluoride in contact with boric acid, the liquid then becoming alkaline if previously neutral, or even if acid.

Most borofluorides are soluble in water, and are obtained in the crystalline state by evaporating their aqueous solutions. At a red heat, they are resolved into fluoride of boron and metallic fluoride. Distilled with sulphuric acid, they give off gaseous fluoride of boron and aqueous hydrofluoboric acid. They are for the most part not decomposed by heating with alkalis or alkaline carbonates.

Borofluoride of Aluminium, crystallises by slow evaporation from a solution of hydrate of aluminium in excess of hydrofluoboric acid; the crystals dissolve in water only when free acid is present. On mixing a solution of chloride of aluminium with borofluoride of sodium, a basic borofluoride of aluminium is precipitated, which, at a red heat, is resolved into fluoboric acid and borate of aluminium.

Borofluoride of Ammonium, $NH^4F.BF^3$, is obtained by subliming a mixture of the potassium-salt with sal-ammoniac, or more easily by dissolving boric acid in aqueous fluoride of ammonium, ammonia being then evolved:

$$4NH^4F + H^3BO^3 = NH^4F.BF^3 + 3H^2O + 3NH^3.$$

It crystallises by evaporation in six-sided prisms with dihedral summits; dissolves readily in water, somewhat less in alcohol; reddens litmus; does not attack glass; dissolves in aqueous ammonia, and crystallises out unaltered; sublimes when heated.

Borofluoride of Barium, $2BaBF^4.H^2O$.—Prepared by saturating hydrofluoboric acid with carbonate of barium, avoiding an excess, otherwise fluoride of barium and boric acid are produced. Crystallises from a warm solution in long needles; by slow evaporation in a warm atmosphere, in smooth rectangular prisms, often arranged in steps like common salt. Has an acid reaction; tastes like barium-salts in general; dissolves readily in water; deliquesces in moist air. Alcohol decomposes it, dissolving an acid salt, and separating a white powder. The crystals effloresce at 40° C. and decompose at a higher temperature.

Borofluoride of Calcium.—A solution of carbonate of calcium in hydrofluoric acid, deposits on evaporation, a gelatinous mass, which dries up to a white powder, reddens litmus, and is decomposed by water, with separation of a basic salt.

Borofluoride of Copper, $CuBF^4$.—Light blue needles obtained by decomposing the barium-salt with sulphate of copper, and evaporating the filtrate.

Borofluoride of Lead, $PbBF^4$.—Prepared like the barium-salt, and crystallises with difficulty by spontaneous evaporation, in four-sided prisms; from the solution evaporated to a syrup, in long prisms. Has a sweetish taste, with sour astringent aftertaste. Partially dissolved by water and by alcohol. Heated with oxide of lead, it is said to yield an easily fusible oxyborofluoride, whose aqueous solution is rendered turbid by the carbonic acid in the air.

Borofluoride of Lithium, $LiBF^4$.—Prepared like the copper-salt, and separates by evaporation at 40° C. in large prismatic crystals, which have a rather bitter and acid taste, and deliquesce in the air, sparingly soluble rhombohedral crystals then separating, which have not been further examined.

Borofluoride of Magnesium. — Easily soluble; crystallises in large prisms; tastes bitter.

Borofluoride of Potassium KBF^4. — Formed like the ammonium-salt, by adding boric acid to aqueous fluoride of potassium. It may be prepared by dissolving 2 at. (124 pts.), of crystallised boric acid, and 1 at. (138 pts.) carbonate of potassium in excess of hydrofluoric acid, or by adding a soluble potassium-salt to hydrofluoric acid; it then separates as a transparent gelatinous precipitate, which appears iridescent by reflected light while suspended in the liquid, and dries up to a white powder. It dissolves in 70 pts. of cold, and in a smaller quantity of hot water, and crystallises from the solution in anhydrous, shining, six-sided prisms. It has a bitterish taste, and does not redden litmus. Alkalis do not dissolve it more readily than pure water. Ammonia does not alter it, unless the solution contains silica, in which case a precipitate is formed. It dissolves in boiling alcohol. When heated, it first melts, then gives off fluoride of boron, and if not quite dry, likewise fluoboric acid; and after prolonged exposure to a strong heat, leaves fluoride of potassium. Strong sulphuric acid decomposes it but slowly, even with the aid of heat.

Borofluoride of Sodium, $NaBF^4$, forms short four-sided rectangular prisms, very soluble in water, less in alcohol; has a rather bitter and acid taste, and reddens litmus. The crystals are anhydrous, melt below a red heat, but require strong and prolonged ignition to decompose them completely into fluoride of boron and fluoride of sodium.

Borofluoride of Yittrum dissolves only in water containing free acid. It is obtained in crystals by dissolving yttria in excess of hydrofluoboric acid, and evaporating.

Borofluoride of Zinc, $ZnBF^4$.—Zinc dissolves in hydrofluoboric acid with evolution of hydrogen. The solution evaporated to a syrup, solidifies at low temperatures to a deliquescent mass.

BORON, IODIDE OF. Not yet obtained in the pure state. Iodine and boron strongly heated together, form a product which appears to be an oxyiodide (Wöhler and Deville). Boron does not decompose iodide of silver, even at temperatures above the melting point of the metal.

According to Inglis, a mixture of boric anhydride and charcoal heated in iodine-vapour, yields a yellow sublimate, which has not been examined.

BORON, NITRIDE OF. BN. — This compound was discovered by Balmain (Phil. Mag. [3] xxi. 170: xxii. 467; xxiii. 71; xxiv. 191), who at first regarded it as capable of uniting with metals and forming compounds analogous to the cyanides; but afterwards found that all these supposed metallic compounds were one and the same substance, viz. nitride of boron without any appreciable amount of metal. This conclusion has been confirmed by Marignac (Ann. Ch. Pharm. lxxix. 247). Balmain obtained this substance by heating boric anhydride with cyanide of potassium or cyanide of zinc, or with cyanide of mercury and sulphur. It has since been more completely investigated by Wöhler (Ann. Ch. Pharm. lxxiv. 70), who prepares it by heating to bright redness in a porcelain or platinum crucible a mixture of 2 pts. dried sal-ammoniac and 1 pt. pure anhydrous borax:

$$Na^2O.2B^2O^3 + 2NH^4Cl = 2BN + 2NaCl + B^2O^3 + 4H^2O.$$

The product is a white porous mass, which is pulverised and washed with water to free it from chloride of sodium and boric anhydride, the final washings being made with boiling water acidulated with hydrochloric acid. The boric anhydride is, however, so completely incorporated with the nitride of boron, that it cannot be wholly removed by washing. A purer product might perhaps be obtained by using neutral borate of sodium instead of borax, in which case, no excess of boric anhydride would be present:

$$Na^2O.B^2O^3 + 2NH^4Cl = 2BN + 2NaCl + 4H^2O.$$

Wöhler formerly prepared nitride of boron by igniting anhydrous borax with ferrocyanide of potassium. It is likewise produced when amorphous boron is heated to whiteness in a stream of pure nitrogen; more easily, but with simultaneous formation of boric anhydride, when boron is ignited in a current of air, or of nitrous or nitric oxide gas; also, with incandescence and evolution of hydrogen, when boron is heated in gaseous ammonia. (Wöhler and Deville, Ann. Ch. Pharm. cv. 69.)

Nitride of boron is a white amorphous powder, tasteless, inodorous, soft to the touch, insoluble in water, infusible, and non-volatile. If very pure, it exhibits when heated at the edge of a flame, a brilliant greenish-white phosphorescence, undergoing at the same time a slow oxidation. Heated in an alcohol-flame fed with oxygen gas, it burns rapidly, with faint greenish-white flame, giving off fumes of boric anhydride. It easily reduces the oxides of copper and lead, giving off nitrous fumes. Heated in a current of aqueous vapour, it yields ammonia and boric anhydride:

$$2BN + 3H^2O = B^2O^3 + 2NH^3.$$

Alkalis, and the greater number of acids, even in the state of concentrated solution, have no action on nitride of boron; strong sulphuric acid, however, with the aid of heat, ultimately converts it into ammonia and boric acid. Fuming hydrofluoric acid converts it into borofluoride of ammonium. Nitride of boron undergoes no alteration when heated in a current of chlorine. When fused with hydrate of potassium, it gives off a large quantity of ammonia. With anhydrous carbonate of potassium, it yields borate and cyanate of potassium:

$$BN + 2(K^2CO^3) = KBO^2 + KCNO.$$

It does not decompose carbonic anhydride, even at the highest temperatures.

BORON, OXIDE OF. *Boric Oxide* or *Anhydride. Anhydrous boric acid*, B^2O^3. —This the only known oxide of boron. It is formed when boron burns in oxygen gas, in the air, or in nitric oxide gas (p. 626); but it is more easily obtained by exposing boric acid, which is its hydrate, to a strong heat. Water then goes off, and the anhydride melts to a viscid mass, which, on cooling, solidifies to a colourless brittle glass (*vitrified boric* or *boracic acid*) of specific gravity 1·83. It cracks spontaneously in cooling, and the formation of each crack is attended with a flash of light (Dumas). It is perfectly fixed in the fire when alone, but in presence of water, and still more of alcohol, it volatilises to a considerable amount. It is perfectly inodorous; has a slightly bitter but not sour taste; dissolves readily in water, forming boric acid, also in alcohol. The alcoholic solution burns with a green flame; so likewise does a mixture of boric anhydride and sulphur.

Potassium heated with boric anhydride decomposes it with visible combustion; sodium decomposes it quietly. It is not decomposed by phosphorus-vapour at a red heat, or by charcoal even at a white heat (Gmelin). It unites with metallic oxides when fused with them, forming borates. From its fixity in the fire, it is capable of decomposing at high temperatures, not only carbonates, but likewise nitrates, sulphates, and indeed the salts of all acids which are more volatile than itself.

Boric Acid.

Oxide of Boron and Hydrogen. Boracic Acid. Sel sedativum Hombergii. Sel narcoticum vitrioli. H^3BO^3 or $3H^2O.B^2O^3$.—This acid is formed by the oxidation of boron in presence of water, *e. g.* by the action of nitric acid or aqua-regia on boron; also by dissolving the anhydride in water. It occurs native in the free state in many volcanic districts, especially in Tuscany, where it issues from the earth together with vapour of water, and is found, either as an efflorescence in the neighbourhood of hot springs, or dissolved in the water of small lakes or lagoons (*Laguni*), formed by the vapours themselves. It is also found in small quantity in several mineral waters, viz. in the boiling spring of Wiesbaden; in the iodine-water of Krankenheil near Fölz, and of the Kaiser spring in Aachen; in the mother-liquor of the salt-spring at Bex (Baup), and in several hepatic waters. A few borates are also found in nature (p. 626), especially borax, the acid borate of sodium, which exists in the water of certain lakes in Central Asia.

Preparation.—On the small scale, boric acid is prepared from borax. 3 pts. of crystallised borax are dissolved in 12 pts. of boiling water, and to the filtered solution is added 1 pt. of strong sulphuric acid, or so much hydrochloric acid that the liquid strongly reddens litmus. The greater part of the boric acid then separates on cooling in crystalline scales, and a larger quantity may be obtained by evaporating the mother-liquor. The crystals retain a certain portion of sulphuric or hydrochloric acid; from the latter they are easily freed by gentle heating and recrystallisation. To obtain them free from sulphuric acid, they must be fused in a platinum crucible, and then recrystallised.

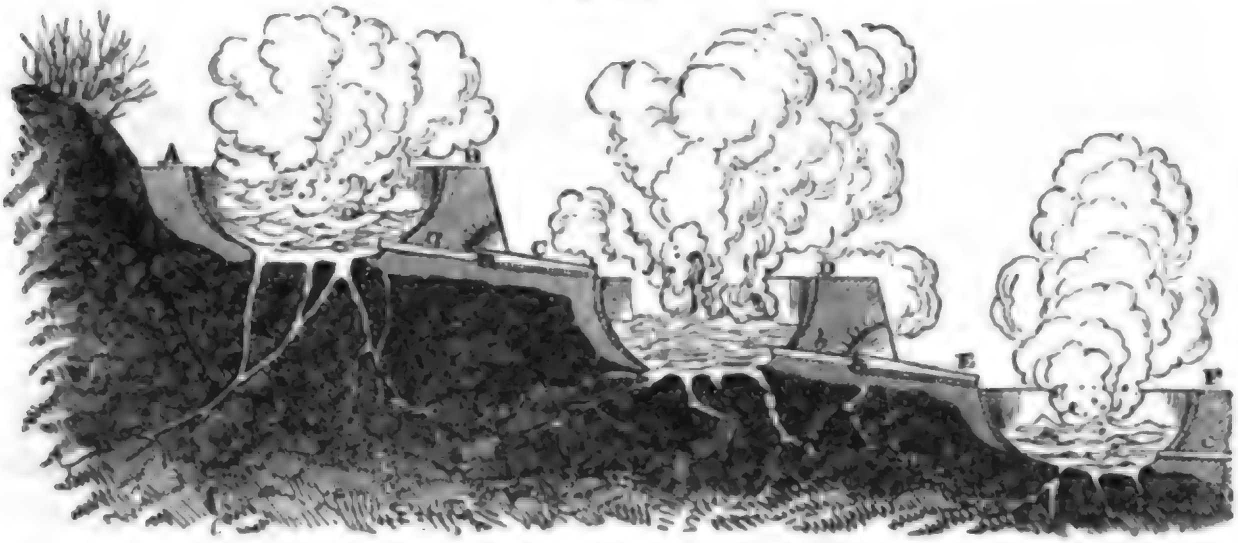
Formerly all the boric acid of commerce was obtained from borax. It was first separated in 1702 by Homberg, who prepared it by heating borax with calcined ferrous sulphate in closed vessels, whereby sodio-ferric sulphate was formed, and boric acid was carried over with the watery vapour which escaped. Boric acid may also be prepared by the decomposition of other native borates, *e. g.* borate of magnesium (*boracite*), and borate of calcium and sodium (*boronatrocalcite*).

Preparation on the large scale (Payen, Précis de Chimie industrielle, 4^{me} éd. 1859, i. 423).—All the boric acid of commerce is now obtained from the volcanic district of Tuscany, where it is discharged from the interior of the earth by numerous jets of vapour called *suffioni*, often rising in thick columns to a considerable height. The entire surface of the district, consisting of chalk and marl, is subject to constant shocks caused by subterranean agencies; and columns of boiling water are frequently projected into the air, which is also strongly impregnated with sulphuretted hydrogen. These vapours contain, besides aqueous vapour, carbonic acid, sulphydric acid, nitrogen, hydrogen, a gaseous hydrocarbon, and sometimes oxygen, together with a small quantity of boric acid and much solid matter carried up mechanically. Ch. Deville and F. Leblanc found, in the vapour of one of the suffioni, about 91 per cent. CO^2, 4 per cent. H^2S, and 5 per cent. nitrogen and combustible gases.

The vapours which issue from the clefts do not contain any appreciable quantity of boric acid, but where pools are formed round the suffioni, either artificially or by natural condensation of the vapours, the water soon becomes charged with boric acid. Probably the greater part of the acid is first deposited on the sides of the clefts before it reaches the surface, and when water penetrates into them, the acid is dissolved and thrown up in the state of solution.

To obtain the boric acid, the suffioni are surrounded with basins of coarse masonry, glazed on the inside, and large enough to enclose two or three suffioni. A series of these basins are constructed on the hill-side, and into the uppermost A B (*fig.* 106), the water of a spring is turned, and after remaining there 24 hours, during which time it is kept in a state of constant agitation by the subterranean vapour, it is made to pass through the tube *a*, into a second basin C D, where it likewise remains 24 hours, and takes up a second quantity of boric acid; thence it passes successively by the pipes *b*, *c*, into the third and fourth basins, the liquid discharged from a lower basin being continually supplied from the one above it. When the liquid has thus traversed six or eight of these lagoons, it is found to have taken up about 0·5 per cent. of boric acid, and to have a specific gravity of 1·007 to 1·010.

Fig. 106.



From the last lagoon G, H (*figs.* 107, 108), the solution passes into a large vessel I, called a *vasco*, where it deposits a quantity of mud, and afterwards into two smaller reservoirs J, K, for further clarification. From K it passes into a series of leaden pans, shown in section in *fig.* 106 and in plan in *fig.* 107, placed one above the other in the manner of terraces on a wooden scaffold. Formerly these pans were heated by wood fires; but this was found too costly, the district being nearly bare of wood; the evaporation is now performed by means of the subterranean heat, one or more of the jets of steam enclosed in pipes being conducted between the foundation and the bottom of the pans. The steam enters beneath the bottom pans, and is carried regularly upwards, so that the lowest pans, which contain the most concentrated liquid, become most heated. This mode of utilising the subterranean heat was introduced in 1817, by Count Larderel, at that time the proprietor of all the lagoons, and had the effect of converting an unprofitable branch of industry into one which is now the source of immense wealth.

Fig. 107.

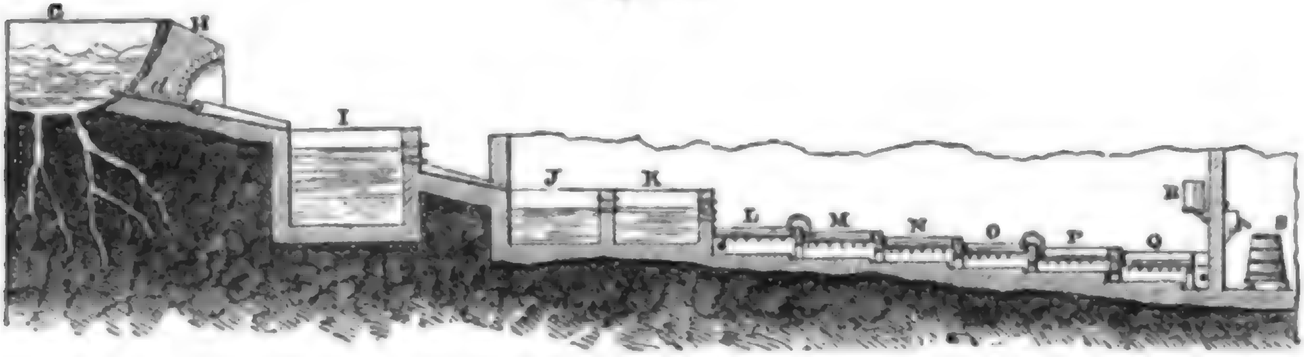


Fig. 108.

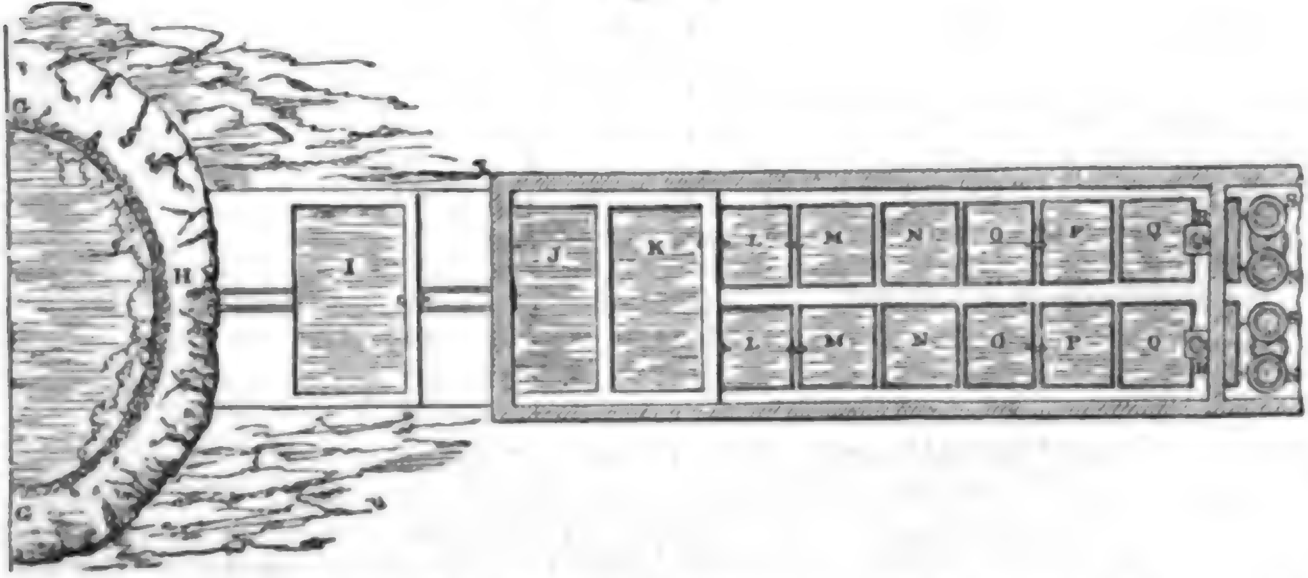
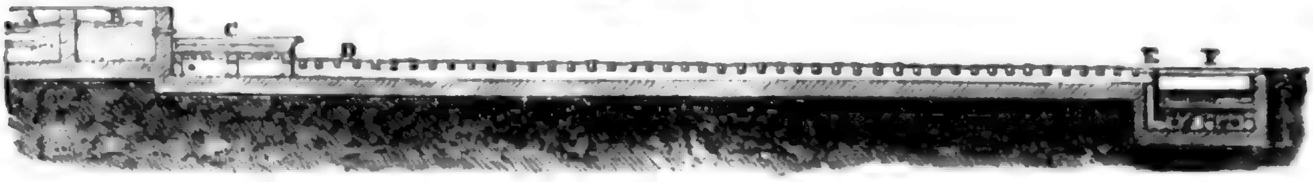


Another form of apparatus for the evaporation is shown in *fig.* 109. The liquid, after leaving the vascos A, B, passes into a shallow boiler C, from which it is made to run slowly over an inclined sheet of lead, D, E, about 150 feet long, and having corrugations on its surface, which form a series of channels. The liquid, in running over this surface, gradually evaporates, and the solution ultimately reaches the basin F, at a degree of concentration fit for crystallisation. Heat is supplied by the vapour of one of the suffioni introduced under the basin F, and carried up under the sheet of lead to C. This method of evaporation is easier than the preceding, and does not introduce so much lead into the solution.

Fig. 109.



The solution of boric acid concentrated by either of these methods, is next mixed with the mother-liquor of a preceding operation, and poured through the funnels R, into the round crystallising tubs S, S, (*figs.* 107 108, 110) which are made of wood lined with lead. The crystals are taken out after a while, and placed to drain in baskets, J, on the top of the tubs, the mother-liquor running into receivers placed under the floor.

Fig. 110.

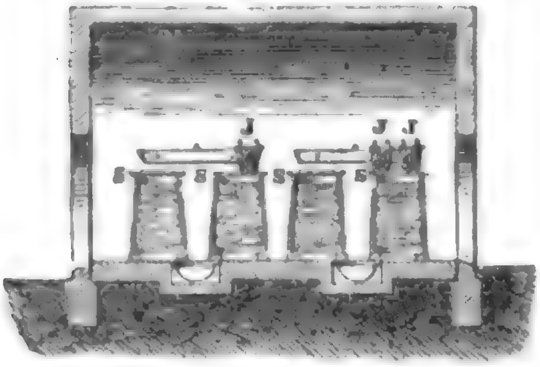


Fig. 111.

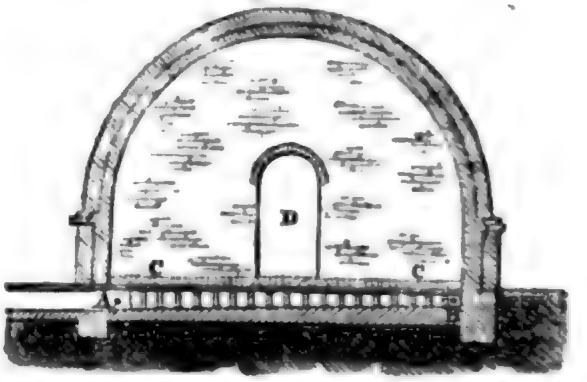

Lastly, the crystals, while still moist, are spread out on the floor C C, of the drying chamber D (*fig.* 111). This chamber has a double floor, and is heated by steam entering at A, and circulating between the two floors.

The product thus obtained is far from pure, not containing more than about 76 per cent. of boric acid. The composition of the crude acid, according to the analyses of Wittstein and Payen, is as follows:

	Wittstein.	Payen.
Crystallised boric acid	76·5	74 to 84°
Ferric sulphate	0·4	
Sulphate of aluminium	0·3	
Sulphate of calcium	1·0	2·4 to 1·2 *
Sulphate of magnesium	2·6	14·0 to 8
Sulphate of ammonium	8·5	
Sulphate of sodium	0·9	
Sulphate of potassium	0·4	
Sulphate of manganese	trace	
Chloride of ammonium	0·2	2·6 to 1·0
Silica	1·2	
Sulphuric acid	1·3	
Water	6·6	7·0 to 5·8 †

Schmidt found, in crude boric acid from Tuscany, 80 per cent. boric acid and 20 per cent. impurities, chiefly the sulphates of ammonium and magnesium. Richardson and Browell found in some samples, not more than 36 to 42 per cent. of the pure acid [? crystallised or anhydrous]. The experience of the French manufacturers of borax, seems to show that the impurities in boric acid from Tuscany become greater year by year, which may perhaps be due to the increasing disintegration of the earthy strata by the aqueous and acid vapours.

Of the origin of the vapours by which the boric acid is brought to the surface, nothing certain is known. Dumas has suggested that they may proceed from a deep-seated bed of sulphide of boron, with which the water of lakes, or of the sea, comes in contact, thereby producing boric and sulphydric acids. Part of the boric acid may thus be supposed to act upon the carbonates of calcium and magnesium in the soil, converting

---

* Including sand, clay, &c.

† Including organic matter.

them into borates, and setting free carbonic anhydride. The sulphuretted hydrogen being oxidised by the air, yields free sulphur, which is deposited on the edges of the suffioni. The ammonia and organic matter are derived from the water, and the saline impurities from the water and the earthy strata, through which the vapours make their way. Bolley supposes that the boric acid and ammonia may result from the action of solution of sal-ammoniac at a boiling-heat, on borates contained in the earth; and according to Warington, the formation of these products may be ascribed to the action of water on nitride of boron. There is, however, nothing positive to indicate the nature of the particular compound or compounds of boron, to which the elimination of the boric acid is really due.

Properties.—Boric acid crystallises from water in white, translucent, nacreous, six-sided laminæ, somewhat unctuous to the touch; it is inodorous, and has a faint, scarcely acid, rather bitterish, cooling taste. Specific gravity = 1·48. It dissolves in 2·57 parts of water at 18° C.; in 14·9 parts at 25°, in 10·7 parts at 50°, in 4·7 parts at 75°, and in 2·97 parts at 100°. (Brandes and Firnhaber.) It is still more soluble in alcohol and in volatile oils.

Boric acid dissolves in warm concentrated sulphuric, nitric, or hydrochloric acid, but separates for the most part on cooling, or on addition of water. Its solubility in water is increased by addition of tartaric acid, tartrate of potassium, Rochelle salt, racemic acid, or alkaline racemates.

The crystallised acid heated to 80°—100° C., gives off 21·8 per cent. water, that is to say, half the quantity which it contains, leaving $H^6B^4O^9$ or $3H^2O.2B^2O^3$ (according to Schaffgotsch, it gives off nearly all its water at 100° C.); by prolonged heating to 160° it is deprived of 2 at. water more, leaving $H^2B^4O^7 = H^2O.2B^2O^3$, and at a stronger heat, the remaining water goes off, leaving the anhydride B^2O^3, as a fused viscid mass, which solidifies to a fissured glass on cooling (p. 635).

Reactions.—A cold saturated aqueous solution of boric acid colours litmus-tincture wine-red (the tint of port wine), like carbonic acid, but a hot saturated solution colours it bright red. Turmeric paper moistened with the alcoholic solution of boric acid acquires a reddish-brown colour, quite different from that produced by alkalis, and becoming distinct only after drying: it is intensified by acids, especially by hydrochloric, sulphuric, nitric, and tartaric acids, and turned black by alkalis.

The alcoholic solution of boric acid burns with a beautiful green-edged flame, a reaction which is quite characteristic of boron, provided copper and certain chlorine-compounds are absent. This green colour is not produced, however, when the acid is in combination with an alkali or other base; and its production is partly prevented by the presence of chloride of sodium or calcium, and even by small quantities of tartrate of potassium or Rochelle salt (doubtless because these salts are partly decomposed by the boric acid, and neutralise it), also by free tartaric acid or phosphoric acid. In either of these cases, the green colour appears on addition of sulphuric acid, or of a considerable quantity of hydrochloric acid (H. Rose, Pogg. Ann. cii. 545). It must be observed, however, that a green flame, though of a more bluish tint, is produced when hydrochloric acid itself is dropped into burning alcohol. (See p. 630.)

For the reactions with metallic salts see p. 640.

Borates. (Berzelius, Traité, vol. i—iv. Gm. vol. i—vi. Handw. d. Chem. 2te Aufl. ii. [2] 303. H. Rose, Pogg. Ann. ix. 76; lxxxvi. 581; lxxxvii. 1, 470 and 587; lxxxviii. 299, 482; xci. 452. Wöhler, *ibid.* xxviii. 525. Rammelsberg, *ibid.* lxix. 445. Ebelmen, Ann Ch. Phys. [3] xxxiii. 34. Herapath, Ann. Ch. Pharm. lxxii. 254. Bolley, *ibid.* lxviii. 122. Laurent, Ann. Ch. Phys. [2] lxvii. 215. Tissier, Compt. rend. xxxix. 192; xlv. 411. Bloxam, Chem. Soc. Qu. J. xii. 177; xiv. 143.)—Boric acid forms salts in which the proportion of anhydrous base (M^2O) to anhydrous acid (B^2O^3), or of metal to boron, ranges between the limits 9 : 1 and 1 : 6. Those which contain equal proportions of base and acid are usually regarded as neutral or normal borates, the rest as basic or acid. The following proportions have been observed:

Basic.	Neutral.	Acid.
$9M^2O.B^2O^3$	$M^2O.B^2O^3$	$2M^2O.3B^2O^3$
$6M^2O.B^2O^3$		$M^2O.2B^2O^3$
$9M^2O.2B^2O^3$		$M^2O.3B^2O^3$
$3M^2O.B^2O^3$		$M^2O.4B^2O^3$
$5M^2O.2B^2O^3$		$M^2O.5B^2O^3$
$2M^2O.B^2O^3$		$M^2O.6B^2O^3$
$3M^2O.2B^2O^3$		

Most of the so-called acid borates, however, contain several atoms of water; and if the whole or part of this water be regarded as basic, we shall find that nearly all borates may be arranged in two classes, orthoborates and metaborates (so called from their analogy with the ortho- and meta-phosphates and silicates), the composition of which may be represented by the following general formulæ, the symbol M denoting either a single metal, or two, or three metals, including hydrogen:

$$\text{Orthoborates } 3M^2O.B^2O^3, \text{ or } M^3BO^3 = \left.\begin{matrix} M^3 \\ B''' \end{matrix}\right\} O^3$$

$$\text{Metaborates } n(M^2O.B^2O^3), \text{ or } M^nB^nO^{2n} = \left.\begin{matrix} M^n \\ (B''')^n \end{matrix}\right\} O^{2n}$$

The latter formula, which, when $n = 1$, becomes that of the so-called neutral borates, MBO^2, includes the greater number of the salts of boric acid. Nevertheless it appears probable that boric acid is essentially tribasic, and that the borates containing 3 at. metal to 1 at. boron are its normal salts (hence called orthoborates): for crystallised boric acid contains H^3BO^3; and there are boric ethers containing 3 at. alcohol-radicle to 1 at. boron, whereas none are known of the form RBO^2. Moreover it appears from the experiments of Bloxam, that boric acid, when ignited with metallic hydrates, mostly drives out 3 at. of water, forming a trimetallic borate, except in the case of hydrate of potassium, in which the water is retained with peculiar force; and when heated to bright redness with carbonates, it expels a quantity of carbonic anhydride approaching more nearly to 3 atoms as the base is weaker, that limit being actually reached in the case of strontia. (See BORATES OF BARIUM, LITHIUM, POTASSIUM and SODIUM.) There appear also to be a few borates intermediate in composition between ortho- and metaborates, viz. $M^4B^2O^5 = M^3BO^3.MBO^2$.

Borates containing more than 3 at. metal to 1 at. boron may be regarded as compounds of orthoborates with metallic oxides or hydrates (see BORATES OF ALUMINUM); and those anhydrous borates which contain more than 1 at. boron to 1 at. metal may be regarded as metaborates combined with boric anhydride; *e.g.* anhydrous borax, $Na^2O.2B^2O^3 = 2NaBO^2.B^2O^3$.

Borates are formed by the action of boric acid on metallic oxides or their salts, either in the wet or in the dry way. At high temperatures, boric acid or anhydride decomposes carbonates, sulphates, chlorides, and indeed the salts of all volatile acids. Acid borates, borax for example, take up additional quantities of base when ignited with metallic oxides, and likewise decompose the salts of volatile acids. In the wet way, on the contrary, boric acid acts as a very weak acid, being separated from its combinations completely by most acids, and partially, under certain circumstances, even by carbonic acid, sulphydric acid, and water. In concentrated solution, however, it decomposes carbonates, especially at the boiling heat; also soluble sulphides and precipitated sulphide of manganese. It has but little power of neutralising the alkaline reaction of the stronger bases, so that even the solutions of many of the polyacid borates exhibit a strong alkaline reaction to litmus, which is not neutralised till the base is combined with 5 or 6 atoms of boric acid, and even then the liquid does not exhibit an acid reaction.

The borates of the alkali-metals dissolve readily in water, but are precipitated by alcohol. All other borates dissolve but sparingly soluble in water; but none are perfectly insoluble. The sparingly soluble borates may be obtained by precipitation. Many of these precipitates are soluble in excess of the soluble metallic salt from which they have been formed, but not in excess of alkaline borate; *e.g.* the precipitate formed by borax dissolves in solution of chloride of barium, but not of borax: they are often likewise soluble in chloride of ammonium and in free boric acid. The sparingly soluble borates are easily decomposed by water, especially when boiled with it, the boric acid being sometimes almost completely removed. Hence it is very difficult to obtain these salts in the pure state. H. Rose, in his elaborate investigation of the borates, purified the precipitates as completely as possible by repeated pressure between paper without washing, and afterwards estimated the quantity of foreign salts still attached to the precipitate. The soluble borates are likewise decomposed by water. If a strong solution of borax be mixed with slightly reddened tincture of litmus, the liquid retains its faint red colour, but on dilution with water becomes distinctly blue, behaving indeed like a dilute solution of free alkali mixed with boric acid. Neutral borates of alkali-metal exhibit a similar reaction.

When a solution of an alkaline borate coloured with tincture of litmus is gradually mixed with sulphuric acid, the liquid exhibits a wine-red colour till all the alkali is saturated with sulphuric acid; after that, a single drop of sulphuric acid produces the bright red colour.

Solutions of alkaline borates absorb carbonic and sulphydric acid gases; expel ammonia from its salts when boiled with them, like dilute alkalis; their dilute solutions also react like alkalis with mercury and silver-salts, and with many organic substances. (See BORAX, p. 648.)

The soluble borates, both neutral and acid, give white precipitates with solutions of chloride of barium, chloride of *calcium*, *alum*, sulphate of *zinc* and nitrate of *lead*; reddish with sulphate of *cobalt*; greenish with sulphate of *nickel*; yellowish with *ferric* sulphate in the cold, brown on boiling. These precipitates dissolve easily in sal-ammoniac; and if they have been produced by an acid borate of alkali-metal, borax for example, they dissolve pretty readily in an excess of the salt from which they have been obtained; The precipitates formed by neutral borates of alkali-metal in the same solutions exhibit similar characters, excepting that they are less soluble in excess of the earth-metal or heavy metal salt.

Solution of borax or of monoborate of sodium, does not precipitate sulphate of *magnesium* in the cold; but on heating, a precipitate forms which disappears again on cooling; completely; if formed by the acid borate; nearly, if by the neutral borate. Both neutral and acid borates of alkali-metal form with manganous salts, a precipitate insoluble in excess of the latter, easily soluble in sal-ammoniac.

Dilute solutions of neutral borates of alkali-metal form with nitrate of *silver*, a brown precipitate of nearly pure oxide of silver, insoluble in excess of water, easily soluble in ammonia or nitric acid. A concentrated solution of neutral borate forms with silver-salts, a brown precipitate which dissolves in a large quantity of water, leaving only a slight residue of oxide of silver. Concentrated solutions of acid borates of alkali-metal form with nitrate of silver a white precipitate of borate of silver, completely soluble in a large quantity of water. Borate of ammonium forms a white precipitate in concentrated silver-solutions, none in dilute solutions.

Soluble borates, whether neutral or acid, give with *mercuric chloride*, a brown precipitate of oxychloride, insoluble in excess of the mercury-salt. Concentrated solutions give with neutral *mercurous nitrate*, a yellow-brown precipitate, soluble in much water: dilute solutions, a blackish-grey precipitate which remains long suspended. Basic mercurous nitrate forms with a strong solution of borax, a dingy, yellow-brown precipitate which dissolves in a large quantity of water, leaving black mercurous oxide.

If the solution of a calcium or magnesium salt be mixed with excess of boric acid, and to the boiling solution borax be added in quantity just sufficient to neutralise the acid of the calcium or magnesium salt, no precipitate is formed; similarly with salts of manganous, ferrous, cobalt, nickel, cadmium and zinc salts; but solutions of aluminium, chromicum, ferricum, stannicum, lead and copper, yield precipitates when thus treated. (Tissier.)

For the reactions of borates with fluorspar and acid sulphate of potassium before the blowpipe (see p. 630).

Borates of Aluminium.—A solution of alum mixed with alkaline borates yields precipitates which, according to H. Rose, are double salts of borate of aluminium and borate of the alkali-metal mixed with sulphate of potassium; water abstracts the greater part of the latter and of the alkaline borate, leaving a basic borate of aluminium. In this manner, the precipitate produced by monosodic borate yields sexbasic borate of aluminium, $2(Al^4O^3)'''.B^2O^3 + 3\,aq. = 6al^2O.B^2O^3 + 3\,aq.$, which may also be regarded as an orthoborate combined with 3 at. hydrate of aluminium $= al^3BO^3.3alHO$.—By adding acid borate of sodium (borax) to solution of alum, a precipitate is formed containing $3(Al^4O^3)'''.2B^2O^3 + 7\,aq. = 9al^2O.2B^2O^3 + 7\,aq.$ or $2al^3BO^3.3alHO + 2\,aq.$

Ebelmen, by heating a mixture of alumina and borax for a long time in a porcelain furnace, obtained a nonobasic salt $3(Al^4O^3)'''.B^2O^3 = 9al^2O.B^2O^3$ or $al^3BO^3.3al^2O$.

Borates of Ammonium.—Boric acid forms with ammonia, several salts which may all be regarded as metaborates, expressed by the general formula $M^nB^nO^{2n}$, the *n* at. M being made up partly of ammonium, partly of hydrogen.

a. $(NH^4)^3HB^4O^8$ is obtained by saturating crystallised boric acid with dry ammonia gas, or by dissolving one of the following salts in warm concentrated aqueous ammonia. The salt obtained by the former process contains 4 at., that by the latter 1 at. water of crystallisation.

b. $(NH^4)HB^2O^4 + \frac{3}{2}aq.$ crystallises from a solution of boric acid in excess of ammonia, in very efflorescent crystals of the dimetric system, soluble in 12 pts. of water. It effloresces like the preceding, giving off part of its ammonia.

c. $(NH^4)H^3B^4O^8 + 2\,aq.$ is obtained, according to Arfvedson, by dissolving boric acid in warm caustic ammonia, till the alkaline reaction is nearly neutralised. The liquid, if slowly cooled, deposits rhombic crystals, exhibiting, according to Schabus, the faces $oP . P . \infty P . \infty P \infty$, and often assuming a prismatic form from the predominance of oP and of four P-faces situated in the same zone; sometimes twin crystals occur. It is permanent in the air, dissolves in 8 pts. of cold water, gives off ammonia on boiling, and leaves boric anhydride when ignited. A salt called *Larderellite*, of similar constitution, but containing less water of crystallisation, viz. $(NH^4)HB^2O^4 + \frac{1}{2}aq.$ was found by Bechi in the boric acid formations of Tuscany, in yellowish-white, transparent, tasteless crystals, exhibiting under the microscope, the form of rectangular tablets, and by polarised light the optical appearances of gypsum. It dissolves in water, but the solution when evaporated deposits the salt $(NH^4)H^5B^6O^{12} + 2aq$.

d. $(NH^4)H^4B^5O^{10} + \frac{3}{2}aq.$ (Laurent) $+ 2aq.$ (Rammelsberg). First prepared by L. Gmelin, who, however, supposed it to contain 4 at. boric acid to 1 at. ammonia (Handbook ii. 436). According to Rammelsberg, however, it has the composition above given, and is isomorphous with the corresponding potassium-salt. According to Laurent, it is obtained by dissolving excess of boric acid in aqueous ammonia and recrystallising. It forms small shining prisms of the monoclinic system, generally in cruciform groups. It is permanent in the air, dissolves in about 8 pts. of cold water, and, like the preceding salts, has an alkaline reaction. The solution gives off ammonia when boiled, and the residue solidifies to a granular crystalline mass, which is permanent in the air, and appears to contain 6 at. boric acid to 1 at. ammonia.

e. $(NH^4)^2H^3B^5O^{10} + aq.$ is obtained by dissolving boric acid in aqueous ammonia. (Arfvedson.)

A solution of borate of ammonium has been successfully used for rendering muslin and other light fabrics non-inflammable. When tissues thus impregnated are held in the flame of a candle, they are merely carbonised, the water and ammonia which escape preventing the communication of the flame. If the contact with the flame be prolonged, the boric acid melts and forms a glassy varnish round the charred tissue, which prevents it from taking fire.

Borate of Amyl. See Boric Ethers (p. 649).

Borates of Barium.—Boric acid ignited with excess of hydrate of barium expels 3 at. water, and forms the *tribarytic orthoborate*, Ba^3BO^3. Heated with excess of carbonate of barium, it expels 2 at. carbonic anhydride at a dull red heat, and $2\frac{1}{2}$ at. at a bright red heat, forming the anhydrous salts, $Ba^4B^2O^5 = 2Ba^2O.B^2O^3$ and $Ba^{10}B^4O^{11} = 5Ba^2O.2B^2O^3$. (Bloxam.)

By precipitating barium-salts with borates of the alkali-metals, borates of barium are obtained, mostly as white crystalline powders, differing in composition according to the composition and relative proportions of the salts employed, the temperature of the solutions, and the duration of the washing. They are probably all metaborates.

a. *Monometaborate*, $BaBO^2 + 5aq.$ (or possibly a monobarytic orthoborate, $BaH^2BO^3 + 4aq.$), was obtained by Berzelius by precipitating chloride of barium with monoborate of potassium. According to H. Rose, when prepared from cold solutions, and dried at 100° C. after pressure between paper, but without washing, it has the composition $BaBO^2 + \frac{1}{2}aq.$, and when precipitated from very hot solutions it contains more than $\frac{1}{2}$ aq., but less than 1 aq. To drive off all the water requires a strong heat. The salt dissolves in cold, and more readily in hot water, especially in presence of ammoniacal salts, and therefore cannot be completely washed.

b. *Sesquimetaborate.* $Ba^2HB^3O^6 + 7aq.$—Laurent obtained this salt by mixing a solution of chloride of barium with pentaborate of sodium, under circumstances not particularly specified. According to H. Rose, the precipitate obtained by mixing chloride of barium with an acid borate of alkali-metal, has, when dried at 100° C., the composition $Ba^3H^2B^5O^{10} + \frac{7}{2}aq.$

c. *Dimetaborate*, $BaHB^2O^4 + 2aq$, is precipitated in white flocks when a solution of nitrate of barium is added by drops to excess of solution of borax mixed with ammonia. It dissolves in 100 pts. of water, more easily in ammoniacal salts and in excess of chloride of barium. (Laurent.)

d. *Trimetaborate.* $BaH^2B^3O^6 + 6aq.$—Precipitated as a white crystalline powder, when a warm solution of nitrate of barium is added by drops and with stirring, to excess of pentaborate of sodium.

Borates of Cadmium.—The precipitate formed on mixing the cold solutions of borax and sulphate of cadmium contains, after being merely pressed, the *monoborate*, $CdBO^2$, mixed with a small quantity of an acid salt. The precipitate from boiling solutions consists chiefly of $2CdBO^2.CdHO + aq.$

Borates of Calcium. a. *Orthoborate.* CaH^2BO^3 (dried at 100° C.)—The formula might also be that of a monometaborate, $CaBO^2 + H^2O$, but the first view of its constitution is the more probable, inasmuch as the salt gives off 1 at. H as water, only at 200° C., and is not completely dehydrated even at 300°. It is produced by precipitating chloride of calcium with monoborate of sodium, probably also when solution of borax is precipitated by lime-water. It is somewhat soluble in water, and is decomposed by hot water.

b. *Sesquimetaborate*, $Ca^2HB^3O^6$, appears to be precipitated, together with variable quantities of the dimetaborate, when calcium-salts are mixed with solution of borax (H. Rose). A similar composition appears to belong to *rhodicite*, a mineral found in the Ural, in small, hard, shining, yellowish-white crystals of tetrahedral habit. It has not been exactly analysed, but appears to contain 4B to 3Ca. (G. Rose.)

c. *Dimetaborate*, $CaHB^2O^4$.—Obtained, according to Tünnermann, when borax is precipitated by nitrate of calcium. It occurs also as a white efflorescence composed of crystalline needles containing $\frac{5}{2}$ at. water, on the plain of Iquique in Ecuador, South America, forming the mineral called *borocalcite*, *hydroborocalcite*, or *hayesite* (Ulex). Bechi found a calcic diborate with $\frac{3}{2}$ aq. in an old lagoon-crater in Tuscany.

d. *Tetrametaborate*. $CaH^3B^4O^8 + \frac{3}{2}$ aq.—Precipitated on boiling milk of lime with excess of boric acid.

Borate of calcium occurs associated with silicate of calcium in *botryolite* and *datolite* (*q. v.*), and with magnesia in *hydroboracite* (*q. v.*)

Borate of Cobalt is probably contained in the glass fluxes formed with cobalt-compounds and borax. Cold solutions of a cobalt-salt and borax yield a reddish precipitate, which, after drying at 100° C., consists chiefly of $2CoBO^2.CoHO + \frac{3}{2}$aq. It is soluble in water, and melts to a blue glass when strongly heated.

Borates of Copper.—It is difficult to obtain these salts in a definite state. Sulphate of copper mixed with solutions of alkaline borates, yields precipitates consisting of compounds of borate and oxide of copper mixed with sulphate of soda and basic sulphate of copper, which are decomposed by water, leaving a residue composed of oxide and borate of copper, but with less boric acid than the original precipitate. Cold concentrated solutions of cupric sulphate and monoborate of sodium yield a precipitate which, after washing, consists of $CuHO.2CuBO^2$ + aq. The precipitate from the same solutions mixed hot is, after washing, $CuHO.2CuBO^2$. That obtained in like manner from cold concentrated solutions of cupric sulphate and borax is an orthoborate containing 2 at. copper, viz. $(Cu^2H)BO^3 + \frac{1}{2}$aq. The same precipitate is obtained from hot concentrated solutions of cupric sulphate and borax, especially if the copper-salt is in excess. It is a loose blue-green powder, sparingly soluble in water, but decomposed by water, leaving the compound $CuBO^2.3CuHO + \frac{1}{2}$aq. Cold *dilute* solutions of the same salts yield a precipitate containing 5Cu to 2B and 5H, while the precipitate from hot dilute solutions contains 10 or 12 at. Cu to 1 at. B.

Bolley has suggested the use of the green precipitate, obtained from cold solutions of 2 pts. cupric sulphate (blue vitriol), and 3 pts. borax, as a substitute for the arsenical greens used in painting, paper-staining, and calico-printing.

Borate of Ethyl. See **Boric Ethers** (p. 650).

Borates of Iron.—*Ferric monometaborate*, $Fe^2O^3.3B^2O^3$ + 3 aq. or $\mathit{fe}BO^2 + \frac{3}{2}$ aq. has not been prepared artificially, but has been found by Bechi in an old lagoon-crater in Tuscany: hence called *Lagunite*.

Ferric orthoborate, $Fe^4O^3.B^2O^3$ or fe^3BO^3, is not known in the separate state, but only in combination with borate of sodium or with ferric oxide. On mixing a solution of ammonioferric sulphate (ammonia-iron-alum) with monometaborate of sodium, a bulky precipitate is formed, which, after being pressed between paper, but not washed, is a sodio-ferric borate containing $NaBO^2.4\mathit{fe}^3BO^3$ + 3 aq. Cold water abstracts boric acid and borate of sodium, leaving an oxyborate, which, after drying at 100° C., is $6Fe^4O^3.B^2O^3$ + 6 aq. or $15\mathit{fe}^2O.2\mathit{fe}^3BO^3$ + 6 aq. By precipitating ammonioferric sulphate with borax, a light brown bulky precipitate is formed containing $NaH^3B^4O^8.4\mathit{fe}^3BO^3$ + aq., and reduced by washing with water to $24\mathit{fe}^2O.2\mathit{fe}^3BO^3$ + 9 aq. or $9Fe^4O^3.B^2O^3$ + 9 aq.

Borates of Lead.—*a.* The *monometaborate*, $PbBO^2 + \frac{1}{2}$ aq. is obtained, according to Herapath, when the precipitate formed by borax in a neutral lead-salt, is digested for some hours with strong ammonia. It is said also to be produced when a solution of basic acetate of lead is partially precipitated by borax, and, according to H. Rose, by washing with cold water the precipitate formed on mixing the cold solutions of borax and nitrate of lead. It is a white, amorphous, heavy powder, insoluble in water and in alcohol, soluble in dilute nitric and in warm acetic acid, from which solutions it is precipitated by ammonia. It gives off some of its water at 120° C., the whole at 160°, and at a red heat, melts to a colourless glass, of specific gravity 5·598.

b. The *sesquimetaborate*, $Pb^2HB^3O^6 + \frac{3}{2}$aq. formed by adding a large excess of borax to a boiling solution of a lead-salt, resembles the preceding, gives off 1 at. water between 170° and 200° C., and melts to a colourless glass, of specific gravity 5·235. (Herapath.)

c. Dimetaborate, $PbHB^2O^4 + \frac{3}{2}$aq. obtained by boiling the salt *b* with borax. Light amorphous powder, which gives off its water between 200° and 230° C., and at a red heat melts to a vitreous mass (Herapath). When 100 pts. lead-oxide are fused with 64 pts. boric anhydride (1 : 2 at.), a nearly colourless glass is obtained as hard as flint-glass, and possessing much higher refractive power.

Basic borates.—According to H. Rose, the precipitates formed with nitrate of lead and either mono- or di-borate of sodium, are frequently basic salts, probably mixtures of monoborate and hydrate of lead, varying in composition according to the strength of the solutions and the duration of the washing. Hot, very dilute solutions, give a precipitate to which Rose assigns the formula $3(PbO.BO^3) + PbO.HO + aq.$, or $2(3PbBO^2.PbHO) + aq.$

Borochloride of Lead, $PbBO^2.PbCl + \frac{1}{2}aq.$ is obtained by mixing hot solutions of borax and chloride of lead, and crystallises in very small, irregular, nacreous needles, which are not decomposed by cold water, but gradually by boiling water. It gives off all its water between 120° and 150° C.

Boronitrate of Lead, $PbBO^2.PbNO^3$, is deposited in irregular shining crystals, from a solution of borate of lead in nitric acid, evaporated till a film forms on the surface, At 120° C. the crystals give off water and a little nitric acid, and at a higher temperature evolve nitrous acid and melt to a colourless glass.

Borate of Lithium.—Boric acid heated to bright redness with carbonate of lithium, expels 2½ at. carbonic anhydride, forming the salt $5Li^2O.2B^2O^3$. (Bloxam.)

Borates of Magnesium. *a. Orthoborate.* Mg^3BO^3.—Ebelmen obtained this salt by fusing magnesia with boric anhydride, and exposing the vitreous mass, in a platinum dish, to the strongest heat of a porcelain furnace for several days, till the excess of boric anhydride was volatilised. It formed radiating nacreous crystals, of specific gravity 2·987. It is also obtained as a hydrate, $Mg^3BO^3 + 5aq.$ by boiling a mixture of borax and sulphate of magnesium, and washing the precipitate (which contains borate of sodium, magnesia, and hydrate of magnesium) with cold water. When boiled with water, it gives up part of its acid, and leaves a basic salt which absorbs carbonic acid from the air. The precipitate formed by boiling sulphate of magnesium with borax, redissolves completely on cooling.

b. *Monometaborate*, $MgBO^2$.—Obtained as an amorphous precipitate, containing 2 at. water, on mixing the hot solutions of borax and nitrate of magnesium (Laurent). The same salt, but with 4 at. water, was obtained, according to Wöhler, when a mixed solution of borax and sulphate of magnesium, which had been heated, and had afterwards become clear by cooling, was left to itself for several months in winter in a place where the temperature often fell below 0° C. It formed slender radiating needles, insoluble in water, soluble in dilute acids, reprecipitated in needles by ammonia, giving off water and becoming turbid when heated. *Boracite*, from Segeberg in Holstein, appears to be a monoborate of magnesium, while that from Luneburg is a mixture or compound of $3Mg^2O.4B^2O^3$, or $6MgBO^2.B^2O^3$, with MgCl.

c. *Trimetaborate*, $MgH^2B^3O^6 + 3aq.$ separates, according to Rammelsberg, in crystalline crusts, when a concentrated solution of boric acid is boiled with carbonate or hydrate of magnesium and the filtrate is evaporated.

d. *Tetrametaborate*, $MgH^3B^4O^8 + aq.$—This, according to Laurent, is the composition of the last crops of crystals deposited when a solution obtained by boiling boric acid with magnesium is left to evaporate spontaneously.

e. *Hexmetaborate*, $MgH^5B^6O^{12} + \frac{13}{3}aq.$—Granular salt obtained by heating hydrate of magnesium with excess of boric acid; melts to a porcelain-like mass (Rammelsberg). Perhaps a mixture of one of the preceding salts with free boric acid.

Magnesio-chromic Borate.—A salt containing $6Mg^2O.3Cr^4O^3.2B^2O^3$, is obtained by heating for five days in the porcelain furnace a mixture of 20 grm. chromic oxide, 15 grm. magnesia, and 20 grm. boric anhydride, being deposited in the cavities of the fused mass in grass-green microscopic crystals, of specific gravity 3·82. (Ebelmen.)

Magnesio-ferric Borate, $6Mg^2O.3Fe^4O^3.2B^2O^3$, is obtained by fusing in like manner a mixture of 25 grm. ferric oxide, 20 grm. magnesia, and 25 grm. boric anhydride, in small, black, prismatic crystals, of specific gravity 3·85.

Borate of Methyl. See Boric Ethers (p. 650).

Borate of Nickel.—Cold solutions of borax and sulphate of nickel yield a precipitate of $NiBO^2 + aq.$ or NiH^2BO^3, from which cold water abstracts boric acid, leaving a salt containing $2NiBO^2.NiHO + 2aq.$ By boiling for some time with borax, this precipitate is converted into the dimetaborate, $NiHB^2O^4$.

Borates of Potassium.—a. The *monometaborate*, KBO^2, is formed by melting together 70 pts. (1 at.) boric anhydride, and 138 pts. (1 at.) carbonate of potassium. It melts at a white heat, has a caustic alkaline taste, dissolves in water, and separates slowly from the solution in ill-defined crystals which, according to Schabus, are monoclinic. The solution should be evaporated out of contact with the air, as it absorbs carbonic acid. Boric anhydride, heated to redness with excess of hydrate of potassium, expels 2 at. carbonic anhydride, forming the salt $K^4B^2O^5 = 2K^2O.B^2O^3$. (Bloxam.)

b. The *dimetaborate*, KHB^2O^4, is prepared by supersaturating a boiling solution of carbonate of potassium with boric acid, and then adding pure potash in sufficient quantity to produce a strong alkaline reaction. It crystallises sometimes with 2aq. sometimes with 2½aq. The hydrate, $KHB^2O^4. + 2aq.$, forms regular six-sided prisms, which dissolve readily in water with strong alkaline reaction, and swell up considerably when heated. The other hydrate, $KHB^2O^4 + \frac{5}{3}aq.$: forms right rhombic prisms of 98° 35′, with basic brachydiagonal end-faces. It behaves like the former hydrate, but when kept in a closed vessel, separates into a liquid and a solid salt, apparently the hydrate with 2 aq.

c. *Trimetaborate*, $KH^2B^3O^6 + 3aq.$ or perhaps, *tri-orthoborate*, $KH^8B^3O^9$.—Obtained like the preceding, but with a smaller quantity of caustic potash. Separates in rectangular prisms, with four-sided pyramidal summits. Permanent in the air; melts without much tumefaction. (Rammelsberg.)

f. *Pentametaborate*, $KH^4B^5O^{10} + 2aq.$—Formed when a boiling solution of carbonate of potassium is mixed with a sufficient quantity of boric acid to produce a strong acid reaction. The solution on cooling deposits small shining prisms, isomorphous with the corresponding ammonium-salt. Permanent in the air, sparingly soluble in cold, easily in hot water; neutral. (Rammelsberg.)

BORATES OF SILVER.—The precipitates formed in solution of nitrate of silver by alkaline borates vary in composition according to the dilution and temperature of the the solutions. Very dilute solutions, especially if hot, yield a precipitate of pure oxide of silver (H. Rose). A moderately dilute silver-solution mixed with a strong solution of borax, yields a flocculent precipitate of the *monometaborate* $AgBO^2$, which when dry is a white powder blackened by light. It dissolves in a large quantity of water; but is decomposed by a small quantity; melts at a gentle heat. The same salt is obtained as a curdy dirty yellow hydrate, $AgBO^2 + \frac{1}{2}aq.$, on mixing concentrated solutions of nitrate of silver and monoborate of sodium, or boiling concentrated solutions of silver-salt and borax. It is decomposed by washing with water, especially if hot, which ultimately leaves nothing but oxide of silver.

Acid borates of silver have not yet been obtained pure. Rose states that cold concentrated solutions of nitrate of silver and borax yield a white precipitate containing $3Ag^2O$ to $4B^2O^3$, and after washing with a little cold water, which turns it brown, $4Ag^2O$ to $5B^2O^3$. According to Laurent, nitrate of silver yields with pentaborate of potassium, an acid borate of silver which decomposes partially in washing.

BORATES OF SODIUM.—Boric anhydride fused with excess of hydrate of sodium expels 3 at. water and forms *trisodic orthoborate*, Na^3BO^3.

$$B^2O^3 + 6NaHO = 3H^2O + 2Na^3BO^3$$

(Bloxam, Chem. Soc. Qu. J. xiv. 143). Fused with excess of carbonate of sodium at a bright red heat, it expels $1\frac{1}{2}$ at. carbonic anhydride and forms: $Na^6B^4O^9$ or $3Na^2O.2B^2O^3$.

$$2B^2O^3 + 3Na^2CO^3 = Na^6B^4O^9 + 3CO^2.$$

(Arfvedson, Gmelin's Handbook, iii. 87; compare Bloxam, Chem. Soc Qu. J. xii. 186). By fusing borax with excess of carbonate of sodium, Arfvedson found that 1 at. anhydrous borax expelled 3 at. carbonic anhydride producing a dibasic borate of sodium or tetrasodic borate: $Na^4B^2O^5$ or $2Na^2O.B^2O^3$:

$$Na^2O.2B^2O^3 + 3(Na^2O.CO^2) = 3CO^2 + 2(2Na^2O.B^2O^3),$$

1 at. carbonate of sodium fused with 1 at. boric anhydride yields *anhydrous monometaborate of sodium*, $NaBO^2$ or $Na^2O.B^2O^3$, and with 2 at. boric acid anhydride, it yields anhydrous acid borate of sodium, $Na^2B^4O^7 = Na^2O.2B^2O^3 = 2NaBO^2.B^2O^3$. The aqueous solutions of both these salts yield crystalline hydrates which might be regarded either as orthoborates or metaborates, but are most probably the latter. Respecting the behaviour of the tri- and tetrasodic borates in the hydrated state, nothing appears to be known.

Monometaborate or *Neutral Borate of Sodium*, $NaBO^2$, is produced by heating 62 pts. of crystallised boric acid, or 191 pts. crystallised borax, with 53 pts. of anhydrous carbonate of sodium at a heat near the melting point of silver. The unfused mass thus obtained dissolves in water, with rise of temperature; and by cooling the hot but not saturated solution, the hydrated salt $NaBO^2 + 4aq.$ (or possibly $Na^3BO^3 + 3aq.$) crystallises in large oblique rhombic prisms with lateral angles of 130° and 70°. It has a caustic alkaline taste, and quickly absorbs carbonic acid from the air, both in the solid state and in solution; but on boiling the solutions, the carbonic acid escapes. At 57° C. it melts in its water of crystallisation, and after the liquid has cooled for some time, the hydrate $NaBO^2 + 3aq.$ separate in indistinct crystals. At a stronger heat, it gives off all its water, and forms a friable tumefied mass, which absorbs carbonic acid from the air.

Dimetaborate or *Acid Metaborate of Sodium.* $Na^2B^4O^7 = 2NaBO^2.B^2O^3$, or *$NaO.2BO^3$*. *Biborate of Soda. Borax.*—This salt is obtained in the anhydrous state by fusing 124 pts. crystallised boric acid with 53 pts. anhydrous carbonate of sodium, or by heating crystallised borax. (A process for obtaining borax on the large scale by heating boric anhydride with carbonate of sodium has been patented by Sautter Nov. 20th, 1843). In contact with water, it passes into the hydrated state, and crystallises from its aqueous solution, either with 5 or with 10 at. water, according to the temperature. The former hydrate is octahedral borax; the latter, prismatic or ordinary borax.

Borax is found native in several localities, viz. at Halberstadt in Transylvania, at Viquintizoa and Escapa in Peru, in the mineral springs of Chambly, St. Ours, &c. Canada West, but more particularly in certain salt lakes of India, Thibet, and other parts of Asia, whence the greater part of the borax of commerce was formerly obtained. The salt separated from these waters by evaporation, either natural or assisted by artificial contrivances, is sent to Europe as crude borax or tincal, sometimes in large regular crystals, but more frequently as a white or yellowish-white mass, which is very impure, containing lime, magnesia, and alumina, and likewise covered over with a greasy substance (said to be added to diminish the risk of breakage during transport). According to analyses by Richardson and Browell, crude Indian borax contains:

Boric acid (anhydrous)	22·88	40·24	24·41
Soda ,,	12·59	11·11	11·71
Chloride of sodium	0·92	0·11	0·21
Sulphate of sodium	0·13	0·49	2·84
Sulphate of calcium	1·36	0·68	1·36
Insoluble matter	17·62	1·37	20·02
Water	44·50	46·00	39·45
	100·00	100·00	100·00

The purification or refining of this crude Asiatic borax has been carried on from very early times in various seaport towns of Europe, especially at Venice, and more lately at Amsterdam. Great pains have always been taken to keep the process secret, but two methods, one with *lime* and the other with *soda*, have become known:—1. The tincal is macerated in a small quantity of cold water, and stirred about, with gradual addition of 1 per cent. of slaked lime, the turbid lime-water being poured off from time to time, and when it has clarified, again poured upon the crystals. This treatment removes the greater part of the soapy compound, and the rest is decomposed by adding 2 per cent. of chloride of calcium to the solution of the crystals in hot water. The insoluble lime-soap thus formed, is removed by straining, and the clear liquid is evaporated to the density of 21° Beaumé.—2. The powdered tincal is placed in a tub with holes in the bottom, and washed with a solution of caustic soda of specific gravity 1·034, then drained and dissolved in water, and 12 per cent. of soda added to precipitate the earths, after which the solution is strained and evaporated. The crystallisation is effected in wooden vessels lined with lead, having the form of short inverted cones.

The greater part of the borax used in the arts, is now prepared in France by treating the native boric acid of Tuscany with carbonate of sodium, according to a method first practised by Payen and Cartier. 1300 kilogrammes of crystallised carbonate of sodium are dissolved in 1500 litres of water in a wooden vessel lined with lead; the liquid is heated to the boiling point by a jet of steam, and 1200 kilogrammes of crystallised boric acid are added. The density of the solution varies according to the degree of purity and dryness of the boric acid used; it is brought to a certain strength by adding borax or water as required, then left at rest till the insoluble matters have settled down, and finally transferred to the crystallising vessels, which are rectangular wooden boxes lined with lead, 6 metres long, 1·7 met. wide, and 0·5 met. deep. The formation of prismatic or of octahedral borax, depends upon the density of the solution, and the temperature at which the crystallisation takes place.

a. Prismatic or *Ordinary Borax*, $NaHB^2O^4 + \frac{9}{2}aq.$ or $2NaHB^2O^4 + 9aq.$ or $NaO.2BO^3 + 10aq.$—To obtain this hydrate, the solution, after all the carbonic acid has escaped, should have a density of 21° or 22° B. (specific gravity 1·14 to 1·15), and should boil at 104° C. (220° F.) It is left to crystallise for two or three days, the crystallisation being finished when the thermometer in the interior of the vessels stands at 25° to 30° C. (77° to 86° F.) The crystals thus obtained, are freed from mother-liquor, then dissolved in boiling water together with $\frac{1}{20}$ of their weight of crystallised carbonate of sodium, to separate any remaining earths, and the strained liquid is concentrated to 21° or 22° B. and left to crystallise as before. The mother-liquor is then drawn off as rapidly as possible with wide syphons, and that which remains amongst the angles of the crystals is soaked up with sponges, so that no small crystals may deposit upon the larger ones. The whole is then covered and left at rest for several hours, to avoid the formation of cracks in the crystals, which would be occasioned by the access of cold air.

The mother-liquor is diluted with water and used in a subsequent operation for dissolving the boric acid and carbonate of sodium. After three or four operations, it contains a considerable quantity of sulphate of sodium; but on cooling it to 30° C. (86° F.), borax crystallises out alone, the sulphate remaining in solution. The last mother-liquors yield by evaporation an impure borax, which is used in glass-making.

Considerable quantities of borax are also prepared from the native borate of calcium and sodium (*Boronatro-calcite*), from South America, by decomposing it with carbonate of sodium, either in the wet or in the dry way.

Artificial borax is for the most part purer than that obtained from native tincal by the refining process, but the crystals often contain cracks, and split when heated, in the direction of their natural cleavage, which is a great inconvenience when the borax is used for soldering, as it causes the crystals to fly off from the surface of the metal. This fault is partially corrected by slow recrystallisation from a rather concentrated solution; but it is more effectually remedied by the addition of a small quantity of tincal before recrystallisation. (For further details of the manufacture of borax, see *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 379; *Handwörterbuch der Chemie*, 2^{te} Aufl. ii. [2] 320; *Précis de Chimie industrielle par A. Payen*, 4^{me} ed. i. 436.)

The impurities generally found in artificial borax, are carbonate of sodium, small quantities of sulphates, chlorides, and salts of calcium and magnesium. It is sometimes purposely adulterated with alum and common salt. It should dissolve in about 2 pts. of hot water, and exhibit no effervescence when treated with acids. The aqueous solution should remain perfectly clear on addition of alkali, and when acidulated with nitric acid, should not be clouded either by chloride of barium or nitrate of silver.

The proportion of soda in borax may be estimated by colouring the solution with litmus, and adding a standard solution of sulphuric acid, till a bright red colour is produced (p. 631), and from the amount of alkali thus determined, the quantity of boric acid may be calculated.

Prismatic borax forms large transparent prisms, of the monoclinic system, generally combinations of a nearly rectangular prism, having the acute and obtuse lateral edges truncated. The crystals effloresce in the air (according to Sims, only when they contain carbonate of sodium). When heated, they melt in their water of crystallisation, swelling up considerably, and solidifying to a loose spongy mass called burnt or calcined borax (*Borax usta*); at a red heat, the salt fuses to a colourless anhydrous glass of specfiic gravity 2·36, called vitrified borax. This, if pulverised and exposed to the air, gradually absorbs 10 at. water, reproducing ordinary prismatic borax.

β. *Borax with 6 at. water*, $Na^2O.2B^2O^3 + 6aq.$ or $NaHB^2O^4 + \frac{5}{2}aq.$ — Found by Bechi in an old lagoon crater; not yet obtained artificially.

γ. *Borax with 5 at. water. Octahedral Borax*, $Na^2O.B^2O^3 + 5aq.$ or $NaHB^2O^4 + 2aq.$ (or possibly $NaH^5B^2O^6$). — To obtain this salt, the solution (p. 646), is concentrated to a strength of 30° B (specific gravity 1·246), and left to cool very slowly in a warm place. The crystallisation begins at 79° C. (174° F.), and as soon as the temperature of the liquid has fallen to 56° C. the mother-liquor must be quickly withdrawn, because at that temperature prismatic borax begins to crystallise out. After a few hours, the crusts of the octahedral salt are removed and dried in the air. The crystals are regular, transparent octahedrons, harder and less fragile than ordinary borax; they have a conchoïdal fracture, and specific gravity = 1·8. They are unalterable in dry air, but in a moist atmosphere, they absorb water, and are converted into prismatic borax. When heated, they fuse to an anhydrous glass with less intumescence than common borax, and without splitting. On this account, octahedral borax is better adapted than common borax for many purposes, as for soldering and as a flux; its smaller proportion of water (30 per cent., that of common borax being 47 per cent.) also diminishes the cost of transport. Nevertheless, prismatic borax is generally preferred by consumers, probably because they are used to it, and it is sold at a lower price, weight for weight.

δ. *Amorphous Borax*, $NaHB^2O^4 + aq.$—Obtained by evaporating a solution of borax at 100° C.

Borax is easily soluble in water, but insoluble in alcohol. Poggiale found that 100 parts of water at various temperatures, dissolve the following quantities of prismatic borax:

at 0° C.	2·8 pts.	at 50° C.	27·4 pts.
10	4·6	60	40·4
20	7·9	70	57·8
30	11·9	80	76·2
40	17·9	90	119·7

and at the boiling heat, 201·4 parts.

The aqueous solution has a slight alkaline reaction, and changes the light yellow colour of an alcoholic solution of turmeric to brown: on adding a small quantity of sulphuric acid, the yellow colour is restored; but a larger addition of sulphuric acid sets the boric acid free, which then produces the peculiar red-brown colouring already mentioned (p. 639).

Borax is easily decomposed by acids. Even water, when present in considerable quantity, abstracts part of the base, so that a dilute solution of acid borate of sodium reacts like a mixture of boric and the neutral borate, or even free soda, giving, for example, a brown precipitate with silver-salts (p. 641). A solution of borax evaporated with excess of hydrochloric acid leaves a mixture of chloride of sodium and free boric acid. It also absorbs carbonic acid when exposed to the air, or when the gas is passed into it, and on adding alcohol to the liquid, when saturated with carbonic acid, no borax separates from it. A solution of borax saturated with sulphuretted hydrogen, and mixed with alcohol, separates, on addition of ether, into two layers, the lower containing sulphide of sodium, the upper free boric acid.

Borax forms with many of the weaker acids, double salts in which the boric acid appears to act as a base to the other acid. Thus, with *arsenious acid* it forms a compound whose empirical formula is $3Na^2O.6B^2O^3.5As^2O^3 + 10aq$. It unites also with fluoride of sodium (see p. 633). When 1 at. *tartaric acid* is mixed in solution with 2 at. borax, boric acid separates out on cooling; if the quantity of tartaric acid be gradually increased, the quantity of boric acid separated likewise increases up to a certain point; but beyond that it diminishes, and at last no further separation of boric acid takes place. Here also the boric acid seems to play the part of base towards the tartaric acid (see TARTRATES). *Acid tartrate of potassium* also forms a double salt with borax. Of silicic acid, a solution of borax dissolves but a mere trace.

Benzoic, *tannic*, and *gallic acids* dissolve in borax-solution more readily than in water. Many insoluble substances, *e.g. stearic* and other fatty acids, *colophony*, *shellac*, and other *resins*, dissolve in borax-solution as readily as in weak alkaline leys, the solution acting in fact just like a mixture of boric acid and free alkali.

At a red heat, on the other hand, the boric acid in borax readily unites with and dissolves metallic oxides, forming fusible double salts: hence the great use of borax in metallurgic and assaying operations, and for soldering. The compounds thus formed often take the form of transparent glasses of various colours, affording very characteristic and delicate tests for the several metals: hence the use of borax in blowpipe analysis. It is also used in the formation of easily fusible glass fluxes for enamels and glazes. An enamelled coating for cast-iron vessels is made by first fusing on the surface of the metal, a mixture of quartz, felspar, clay, and borax, and then covering it with a glaze containing borax. A glazing of 1 pt. clay, 1 pt. felspar, and 2 pts. borax is also used instead of lead-glazing for stone-ware.

Borax is likewise used, though not to any great extent, in medicine, either directly as a remedy, external or internal, or for the formation of pharmaceutical preparations, such as tartarised borax.

c. Tetrametaborate of Sodium. $NaH^3B^4O^8 + \frac{7}{2}aq.$—Produced by boiling 2 at. borax with 1 at. chloride of ammonium, as long as ammonia continues to escape:

$$2NaHB^2O^4 + NH^4Cl = NaH^3B^4O^8 + NaCl + NH^3.$$

It separates from the filtrate by slow evaporation in milk-white, transparent, shining, hard crystalline crusts; dissolves in 5 to 6 pts. water of mean temperature, forming an alkaline solution; yields a precipitate of boric acid on addition of a *dilute* acid, whereby it is distinguished from borax; melts when heated, with less tumefaction than ordinary borax. (Bolley, Ann. Ch. Pharm. lxviii, 122.)

d. Pentametaborate. $NaH^4B^5O^{10} + \frac{7}{2}aq.$—Prepared by dissolving 1 at. borax and 3 at. boric acid in hot water, and separates from the solution in small crystals aggregated in roundish masses; they do not suffer any loss of weight at 100° C., and give off their water of crystallisation but slowly at higher temperatures. The salt to which Laurent assigned the empirical formula $Na^{10}B^{48}O^{77} + 55aq.$ is perhaps this pentaborate.

e. Hexmetaborate. $NaH^5B^6O^{12}$.—Not yet obtained in the solid form, but perhaps contained in the solution produced by mixing 3 at. borax dissolved in water with 1 at. sulphuric acid:

$$3NaHB^2O^4 + H^2SO^4 = Na^2SO^4 + NaH^5B^6O^{12}.$$

This liquid thus formed does not redden litmus; but if 1 at. more of sulphuric acid be added, all the boric acid is set free, and the mixture exhibits the wine-red colour thereby produced, which, however, another drop of sulphuric acid immediately changes to bright-red (Laurent, Ann. Ch. Phys. [2] lxvii. 218). The hexborate is perhaps also formed when aqueous borax is mixed with boric acid till the liquid no longer exhibits a basic reaction. This solution is said to yield by evaporation tabular crystals, having a cooling taste like nitre, a neutral reaction, and giving off 30 per cent. water when melted. (Tünnermann.)

Borate of Sodium and Calcium. $NaCaH^2B^4O^8$ + 9 aq.—Such, with addition of 1·9 per cent. chloride of calcium, is, according to Helbig (Chem. Centr. 1858, p. 494), the composition of a mineral from South America, known in commerce as "borate of lime," and forming irregular nodules, mainly composed of a net-work of translucent crystals. Stein regards it as identical with the hydroborocalcite of Hayes and the boronatrocalcite (*q.v.*) of Ulex.

Borate of Sodium and Magnesium. $NaMg^2H^2B^6O^{10}$ + 14 aq. (Rammelsberg).—Separates by spontaneous evaporation, from a mixture of the cold aqueous solutions of borax and sulphate of magnesium, in large, shining, efflorescent, monoclinic crystals. It dissolves in cold water, forming an alkaline solution which is not precipitated by ammonia, but becomes turbid when boiled, clear again on cooling. If the liquid, after boiling for some time, be quickly filtered, the residue consists of basic borate of magnesium.

BORATES OF STRONTIUM. 1. *Orthoborate,* Sr^3BO^3.—Obtained by heating boric anhydride to redness with excess of hydrate or carbonate of strontium. (Bloxam, Chem. Soc. Qu. J. xii. xiv. 142.)

2. *Metaborates.*—The monoborate has not been obtained. Strontium-salts, precipitated by borax in the cold, yield a precipitate, which when pressed between paper and dried at 100° C., has the composition $Sr^3H^2B^5O^{10} + \frac{5}{2}$aq, gives off 2 at. water at 200°, and the rest at 300°, and is partially decomposed by hot water, the residue probably consisting of the sesquiborate, $Sr^2HB^3O^6$.

The *dimetaborate,* $SrHB^2O^4 + \frac{3}{2}$aq. (at 100° C.), is said to be precipitated from boiling solutions of borax and chloride of strontium. It has an alkaline reaction; dissolves in 130 pts. of pure water, more easily in presence of ammoniacal salts; gives off 3 at. H as water at 280°, the remaining atom at a red heat, leaving the anhydrous salt $Sr^2Br^4O^7 = Sr^2O.2B^2O^3$ ($= 2SrHB^2O^4 - H^2O$).

The *tetrametaborate,* $SrH^3B^4O^8 + \frac{3}{2}$ aq. is obtained, according to Laurent, by boiling the preceding with excess of boric acid, and evaporating the filtrate. Pentaborate of potassium also precipitates strontium-salts, but the precipitate has not been examined.

BORATE OF ZINC.—Sulphate of zinc, precipitated by borax in the cold, yields a precipitate consisting chiefly of *monoborate* of zinc, $ZnBO^2$, which, however, is decomposed by washing with cold water, leaving a basic salt $= 4ZnBO^2.5ZnHO + 2$ aq. (at 100° C.) A solution of a zinc-salt, mixed at the boiling heat with borax and boiled for some time, yields a precipitate consisting of a similar basic borate, mixed with basic sulphate of zinc.

Boric Ethers.

BORATES OF AMYL. a. *Orthoborate.* $(C^5H^{11})^3BO^3$ (Ebelmen and Bouquet, Ann. Ch. Phys. [3] xvii. 61).—Produced by the action of chloride of boron on amylic alcohol:

$$3(C^5H^{11}.H.O) + BCl^3 = 3HCl + (C^5H^{11})^3BO^3.$$

When vapour of chloride of boron is passed into amylic alcohol, hydrochloric acid is evolved, and the liquid quickly separates into two layers, the upper of which, when decanted and distilled, passes over almost wholly between 260° and 280° C., and when again rectified, yields pure tri-amylic borate. It is a colourless, oily liquid, having a specific gravity of 0·87 at 0° C., and a faint odour like that of amylic alcohol; it burns with a green-edged flame, and boils between 270° and 275° C. Vapour-density, by experiment, = 10·55; by calculation (2 vol.) = 9·45. Water decomposes it, yielding boric acid and amylic alcohol.

b. The *metaborate of amyl,* $C^5H^{11}BO^2$, has not yet been obtained.

c. *Acid borate,* $2C^5H^{11}BO^2.B^2O^3$ or $(C^5H^{11})^2O.2B^2O^3$ (Ebelmen, Ann. Ch. Phys. [3] xvi. 139), is obtained by pouring 2 pts. of amylic alcohol on 1 pt. of boric anhydride, heating the mixture to about 180° C., exhausting it with anhydrous ether, distilling off the ether from the decanted ethereal solution, and heating the residual liquid to 250—270° C., to free it from fusel-oil. The acid amylic borate thus obtained, is a clear, slightly yellowish liquid, having an odour like that of fusel-oil. It may be heated to 300° C. without alteration, but is decomposed at higher temperatures. It burns with a green flame.

When fusel-oil is heated to 300° C. with excess of boric anhydride, a colourless liquid passes over, which smells like amylic alcohol, and begins to boil below 100°; but the boiling point rises quickly, and there remains a vitreous mass, resembling the acid ether. As acid borate of methyl gives off oxide of methyl by dry distillation, it is probable that the lighter products of the distillation just mentioned contain oxide of amyl.

BORATES OF ETHYL. *a. Orthoborate.* $(C^2H^5)^3BO^3$. (Ebelmen and Bouquet, Ann. Ch. Phys. xvii. 55; Bowman, Phil. Mag. [3] xxix. 546.)—Prepared like the corresponding amyl-compound. Vapour of chloride of boron is rapidly absorbed by absolute alcohol, the liquid becoming hot and separating after a while into two layers, the lower of which is merely alcohol containing hydrochloric acid, while the upper contains the tri-ethylic borate, which may be separated by distilling the decanted liquid, with addition of a little alcohol, collecting that which passes over between 115° and 125° C., and rectifying. It is likewise produced by distilling a mixture of dry ethylsulphate of potassium and anhydrous borax. (H. Rose, Pogg. Ann. xcviii. 245.) See also vol. ii. p. 628.

It is a colourless, mobile liquid, having a peculiar, agreeable odour, and burning bitter taste. Specific gravity 0·885. It dissolves in all proportions in alcohol and ether, mixes with water, but is decomposed thereby in a few minutes, with separation of boric acid. Boiling point 119° C. Vapour-density (by experiment) = 5·14; by calculation (2 vol.) = 5·07. Burns with green flame, giving off white fumes of boric acid, and leaving no residue.

Metaborate, or *Neutral Borate*, $C^2H^5BO^2$.—Produced, with separation of boric acid, by the action of alcohol on the acid borate:

$$\underset{\text{Acid borate of ethyl.}}{2C^2H^5BO^2.B^2O^3} + \underset{\text{Alcohol.}}{C^2H^5.H.O} = \underset{\text{Metaborate of ethyl.}}{3C^2H^5.BO^2} + \underset{\text{Boric acid.}}{HBO^2}.$$

When the syrupy acid ether is mixed with absolute alcohol, boric acid separates, with considerable evolution of heat, and on separating the liquid therefrom by decantation and pressure, and heating it for a while to 100° C., boric acid is again deposited, and there remains a colourless mobile liquid, which resembles the orthoborate, and yields by analysis 32·93 per cent. carbon and 6·97 hydrogen, the formula requiring 33·38 C, and 6·96 H. (Handw. ii. [2] 309.)

Acid Borate. $2C^2H^5BO^2.B^2O^3 = (C^2H^5)^2O.2B^2O^3$. *Biborate of Ethyl* (Ebelmen, Ann. Ch. Phys. [3] xvi. 129.)—Produced by the action of boric anhydride on alcohol. When finely pulverised boric anhydride is mixed with an equal quantity of absolute alcohol at 18° C. the mixture becomes hot, quickly attaining the temperature of 50°, and begins to boil when heated to 95°. If the distillation be interrupted as soon as the boiling-point rises to 110°, the distilled portion poured back, and the distillation repeated till the boiling-point again rises to 110°, acid borate of ethyl remains in the retort, mixed with boric acid, from which it may be separated by digesting the residue for twenty-four hours with anhydrous ether, decanting from the undissolved portion, and distilling till the heat in the retort rises to 200°. Acid borate of ethyl then remains in the form of a thick yellowish liquid, which gives off white fumes in the air at 200°, and solidifies on cooling to a transparent glass. This glass is rather soft, even at mean temperatures, and at 40° or 50° may be drawn out into long threads. It has a faint ethereal odour, a burning taste, and blisters the skin, being at the same time converted into a white powder of boric acid. It gave by analysis, 19·8 per cent. C, 4·4 H, and 66·7 B^2O^3, the formula requiring 22·5 C, 4·7 H, and 65·3 B^2O^3.

Acid borate of ethyl begins to decompose at 300° C. with fusion, intumescence, and thickening, the products being ethylene-gas, alcohol-vapour, vapour of the undecomposed ether, vapour of water, and fused boric anhydride free from charcoal. The ethylene-gas burns with a green flame, the colour arising from admixed boric ether, which, however, may be removed by washing the gas with water.

The acid ether becomes very hot by trituration with *water*, being resolved into alcohol, and boric acid. Exposed to moist air, it becomes white on the surface from slow decomposition. It dissolves in *alcohol* and in *ether*, but gives off these liquids completely at 200° C., a portion of the undecomposed boric ether then passing over with the alcohol so that the distillate burns with a green flame, and when mixed with water solidifies from separation of boric acid. The syrupy acid ether treated with absolute alcohol in the manner above described, yields the neutral borate of ethyl.

BORATES OF METHYL.—a. *Orthoborate.* $(CH^3)^3BO^3$ (Ebelmen and Bouquet, Ann. Ch. Phys. [3] xvii. 59.)—Produced by the action of chloride of boron on anhydrous methylic alcohol; purified by rectifying the upper of the two resulting layers of liquid. It is a colourless mobile liquid of specific gravity 0·955; has a pungent odour somewhat like that of wood-spirit; boils at 72° C. Vapour-density = 3·66. Dissolves in alcohol and ether, is quickly decomposed by water, and burns with a green flame.

b. *Acid Borate* $2CH^3BO^2.B^2O^3 = (CH^3)^2O.2B^2O^3$ (Ebelmen, Ann. Ch. Phys. [3] xvi. 137.)—Obtained, like the acid ethylic borate, by treating boric anhydride with anhydrous methylic alcohol. The mass is repeatedly heated to 110° C., the distillate being each time poured back, the residue is treated with ether, and the decanted solution heated to 200°. Acid borate of methyl is thus obtained as a vitreous mass, soft and tenacious at ordinary temperatures. It burns in the air with a beautiful green flame; is decomposed by distillation into boric anhydride and oxide of methyl; and by water, into boric acid and methylic alcohol.

BORON, SULPHIDE OF. B^2S^3.—This compound, which is the analogue of boric anhydride, is formed by igniting boron in vapour of sulphur (Berzelius, Pogg. Ann. ii. 145) or in sulphuretted hydrogen; also by heating boron with sulphide of lead (Wöhler and Deville, Ann. Ch. Pharm. cv. 72), or by heating a mixture of boric anhydride and charcoal in vapour of sulphide of carbon (Frémy, Ann. Ch. Phys. [3] xxxviii. 819), or by strongly heating a borate in vapour of sulphide of carbon (Skoblikoff and Rudloff, Petersb. Acad. Bull. xii. 319). To obtain a pure product, boron is heated in sulphur vapour as long as that vapour continues to be absorbed by it. The action is slow, because the sulphide forms a crust round the boron.

Pure sulphide of boron is a white solid body, sometimes amorphous, sometimes crystalline. It has a pungent sulphurous odour, like that of chloride of cyanogen, or chloride of sulphur. Its vapour attacks the eyes. By itself it does not appear to be volatile, but it volatalises in sulphuretted hydrogen, like boric acid in vapour of water. Heated in a stream of hydrogen, it melts, and gives off a little sulphur, perhaps however, only when not quite pure. It decomposes water with great energy, forming boric and sulphydric acids, a decomposition to which, as already observed, the formation of boric acid in the Tuscan lagoons has been ascribed.

There appears also to be a persulphide of boron, produced by heating boron in sulphur-vapour till it takes fire, and then leaving it to cool in the vapour. When the product thus obtained is thrown into water, boric and sulphydric acids are formed, and milk of sulphur is deposited. (Berzelius.)

BORONATROCALCITE. $NaCa^2H^3B^6O^{12} + \frac{15}{2}$ aq.—Native borate of calcium and sodium, called also *Hydroboracite*, *Hayesin*, and *Tiza*. (See BORATES OF SODIUM, p. 649.)

BOTRYOGEN. *Red vitriol.*—A native ferroso-ferric sulphate from Fahlun in Sweden, occurring rarely in small oblique rhombic prisms, having the lateral faces inclined to each other at an angle of 119° 56′, and to the terminal faces at 113° 37′; more frequently massive and as a deposit on gypsum, sulphate of magnesium, ferrous sulphate, and iron pyrites. Translucent, with vitreous lustre. Dark hyacinth-red to ochre-yellow, Harder than gypsum. Specific gravity 2·039. Swells up before the blowpipe, giving off water and leaving ferric oxide. According to Berzelius, its formula is $3Fe^2O.2SO^3 + 3(Fe^4O^3.2SO^3) + 36H^2O$.

BOTRYOLITE. *Chaux boratée silicieuse concrétionée.* $2CaBO^2.Ca^2Si^2O^5 + 2$ aq. —A kidney-shaped mineral of delicate fibrous texture, found in the veins of magnetic iron ore at Arendal in Norway; generally as a deposit on crystals of calcspar. Its formula is the same as that of datolite, but with twice the amount of water.

BOULANGERITE. A tribasic sulphantimonite of lead, $3Pb^2S.Sb^2S^3$ or $\overset{\prime\prime\prime}{Sb}Pb^3S^3$, found at Molières in France, in Lapland, and other localities. Crystallo-laminar or fine-grained. Dark lead-grey. Specific gravity 5·59 to 5·97.

BOURNONITE. *Schwarzspiessglanzerz. Antimoine plombo-cuprifère:* $2Pb^2S.Cu^2S.Sb^2S^3 = \overset{\prime\prime\prime}{Sb}Pb^2CuS^3$.—Crystallises in right rectangular prisms of dark steel-grey colour, with metallic lustre, and yielding a black powder. Hardness equal to that of calcspar. Specific gravity 5·7 to 5·8. Melts before the blowpipe, giving off white fumes, covering the charcoal with oxide of lead, and changing to a slag containing a large quantity of copper. It is found in the copper mines of Cornwall, at Neudorf and Andreasberg in the Harz, at Kapnik and Offenbanya in Transylvania, &c., but is not very abundant. Some varieties found near Freiberg contain silver to the amount of about 0·12 per cent. (Gm. v. 486.)

BOVEY COAL. A kind of coal of a brown or brownish-black colour and lamellar texture, the laminæ being often flexible when first dug out, but generally hardening by exposure to the air. It consists of wood penetrated with petroleum or bitumen, and frequently contains pyrites, alum, and protosulphate of iron. By distillation, it yields a fetid liquor mixed with ammonia and an oil partly soluble in alcohol. It is found in England, France, Italy, Switzerland, Germany, Iceland, &c.

BOWENITE. See SERPENTINE.

BOYLE'S FUMING LIQUOR. *Monosulphide of Ammonium* (p. 193.)

BRAGITE. A mineral found at Arendal in Norway, but not yet sufficiently examined to establish its separate identity. (Forbes and Dahll, J. pr. Chem. lxvi. 446.)

BRAIN. See Nervous Tissue.

BRAN. *Son. Kleie.* (Millon, Ann. Ch. Phys. [3] xxvi. 5. Péligot, *ibid.* xxix. 5. Kékulé, Liebig's chem. Briefe, 3 Aufl. i. 595. Wetzel and Van Hees, Arch. Pharm. [2] lxvii. 284. Poggiale, Compt. rend. xxxvii. 171; xlix. 128. Sigle, Dingl. pol. J. cxxxi. 298. Mouriès, Compt. rend. xxxvii. 351; xlvii. 505; xlviii. 431. Oudemans, Rep. chim. app. i. 585.)—The husky portion of ground corn, separated by the boulter from the flour. The analyses which have been made of it, even from the same kind of corn, differ widely in the proportion of some of the essential constituents, as the following table will show.

	Rye-bran.	*Wheat-bran.*					
	Oudemans.	Oudemans.			Poggiale.	Kékulé.	Millon.
Ash	3·35	6·52	6·26	4·99	5·5	5·6	5·7
Water	14·55	14·07	14·27	14·40	12·7	13·8	13·9
Fat	1·86	2·46	2·88	3·88	2·9	4·1	3·6
Nitrogenous matter (gluten, &c.) .	14·50	13·46	12·68	15·41	13·0	67·3	14·9
Dextrin	7·79	5·52	5·24	5·71	7·9	4·1	51·0
Starch	38·19	26·11	29·74	29·31	21·7		
Sugar					1·9		
Cellulose	21·35	30·80	27·11	25·98	34·6	9·2	9·7
Resinous and odoriferous matter .							1·2
	101·59	98·94	98·28	99·68	100·0	104·1	100·0
Nitrogen	2·23	2·07	1·95	2·37			

Kékulé's determination of the nitrogenous matter is probably too high. The 13·0 per cent. nitrogenous matter found by Poggiale was made up of 5·6 soluble matter (albumin), 3·9 insoluble, but capable of assimilation, and 3·5 insoluble and incapable of assimilation. Poggiale isolated the cellulose by rendering the starch soluble with diastase; he finds that the usual process of determination by the successive use of acids and alkalis, always gives the amount of cellulose too low, part of it being converted by those reagents into sugar and dextrin.

Bran, though rich in nitrogen, appears to possess but little nutritive power. Animals fed upon it quickly lose flesh (Poggiale). It contains a nitrogenous principle called cerealin, analogous to diastase, and perhaps identical therewith, which possesses the power of quickly converting starch into dextrin and sugar. Mouriès found that 130 pts. of wheaten bread containing bran easily diffused through 520 parts of water when triturated therewith, and yielded 59·35 pts. of soluble and 69·75 pts. of insoluble matter, whereas the same quantity of bread not containing bran, was converted by trituration with water into a semisolid mass, and yielded only 9·03 per cent. soluble matter to 120·25 insoluble. This action of the bran on the flour commences in the kneading and baking, but is completed only in the stomach. (See Bread.)

Bran is used by calico-printers in the clearing process, for removing the colouring matters adhering to the non-mordanted parts of the maddered goods, as well as the dun matters which cloud the mordanted portions. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 383.)

BRANCHITE. C^9H^{16}.—A fossil hydrocarbon from the lignite of Mount Vaso in Tuscany. It is colourless and translucent, like Scheererite; melts at 75° C. but does not crystallise on cooling. It dissolves in alcohol. Specific gravity = 1·00. (Savi, Leonhard and Bronn's Jahrbuch, 1842, p. 459.)

BRANDISITE. See Clintonite.

BRANDY. This well known liquor is the spirit distilled from wine, and forms an extensive article of trade in the south of Europe. It is generally manufactured from white or pale-red wines, but often from inferior articles, such as the refuse wine and the marcs of the wine-press. Distillation of the wines is the only process necessary for procuring brandy: hence the richer the wine in alcohol, the greater will be the yield of brandy. Many circumstances, however, independent of the manufacture, influence the quality of the product. Thus, white wines do not always afford more alcohol than the red, but they yield a spirit of finer quality, because they contain more of the essential oil of grapes. Wines which have a certain taste of the soil, communicate it to the brandy derived from them by distillation; thus, the wines of Selleul in Dauphiné give a brandy which has the odour and taste of the Florentine iris; those of St. Pierre in Vivarais, give a spirit which smells of the violet, and so of many other varieties.

Real Cognac is obtained from the distillation of choice wines, every attention being paid to the proper degree of cleanliness in the various utensils employed. In the improved form of still, a very superior article is obtained from inferior wines, but the small proportion of essential oils in such wines divests the brandy of that aromatic flavour which belongs to the better sorts of wine, and is communicated to the brandies procured from them. An inferior brandy called *eau-de-vie de marcs* is obtained by distilling the dark red wines of Portugal, Spain, and other wine-growing countries, also the lees deposited by wine in keeping, the marc or refuse of the grapes from the wine-press, the scrapings of wine-casks, &c.

Brandy, as sold in France, is generally of two strengths, designated as *à preuve de Hollande*, and *à preuve d'huile*, the former varying from 18° to 20° Beaumé. The stronger liquors are valued according to the quantity of *eau de vie à preuve de Hollande* that a given quantity will furnish on the addition of the proper quantity of water. These strengths are usually twelve, viz. of *five-six*, *four-five*, *three-four*, *two-three*, *three-five*, *four-seven*, *five-nine*, *six-eleven*, *three-six*, *three-seven*, *three-eight*, and *three-nine*, but the last is rarely made. The meaning of these strengths is as follows: — If a spirit be *five-six*, 5 pts. of the spirit will give a liquor *à preuve de Hollande*, when added to six measures of water. The spirit five-six has a specific gravity of 0·9237 or 22° Bm.; but all the other strengths are variable, on account of the uncertainty of the strength of the spirit *à preuve de Holland*.

The following is an average of the yield of brandy which some wines afford by distillation:

1000 litres of wine of St. Gilles, in the environs of Montpellier, afford

of three-six brandy	150 litres
„ of good wine of calcareous soils	140 „
„ of wines of fertile soils near Montpellier	100 „
„ of wines of soils producing much grapes	100 „

Wines of the countries nearest the Mediterranean furnish the largest proportion of brandy, which diminishes as the grapes grow in more northern countries.

British brandy is an artificial product fabricated by the rectifying distiller. The following receipt is given by Ure: — "Dilute the pure alcohol to the proof pitch, and add to every hundred pounds weight of it from half a pound to a pound of argol—crude tartar—dissolved in water, some bruised French plums, and a quart of good cognac. Distil this mixture over a gentle fire in an alembic provided with an agitator. The addition of brandy and argol introduces œnanthic ether, and if a little acetic ether be added to the distillate, the whole imparts the peculiar taste of genuine Cognac brandy. Colour with burnt sugar if necessary, and add a little tannic acid to impart astringency." (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 389; also *Muspratt's Chemistry*, i. 103.)

BRASS. An alloy of copper and zinc. (See COPPER; also *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 399.)

BRASSICA. A genus of cruciferous plants, including some of the most important fodder plants and culinary vegetables, viz. the cabbage, rape, and turnip.

1. *Brassica oleracea.* Cabbage.—Of this species, many varieties are cultivated for their leaves, *e.g.* the common red or white cabbage (*Br. ol. capitata*), the Savoy cabbage (*Br. ol. bullata*), curled kale (*Br. ol. acephala*), &c. The turnip-stemmed cabbage, or kohl-rabi (*Br. ol. caulorapa* or *napobrassica*), is much cultivated in France and Germany for its fleshy turnip-like stem or bulb, which makes an excellent vegetable dish. Cauliflower and broccoli are also varieties of *Brassica oleracea*.

Fresh white cabbage-leaves contain 0·2 per cent. nitrogen; the dried leaves 3·7 per cent. (Boussingault, Ann. Ch. Phys. [2] lxviii. 337). Table A exhibits the composition of cabbage leaves as determined by Anderson (Chem. Centr. 1856, p. 232).—*a.* Of the young plant before the heart-leaves are formed. *b.* The outer leaves of perfectly ripe cabbage. *c.* The heart-leaves of the same.

TABLE A.—*Composition of Cabbage-leaves.*

	a	*b*	*c*
Albuminous substances	2·1	1·6	0·9
Woody fibre, gum, and sugar	4·5	5·0	4·1
Ash	1·6	2·2	0·6
Water	91·8	91·1	94·4

According to Sprengel (J. techn. Chem. xiii. 485), white cabbage contains, in the air-dried state, 52·5 per cent. water, 19·3 per cent. matter soluble in potash-ley, 25·6 per cent. woody fibre, besides wax, chlorophyll, &c. The ash of cabbage has been analysed by Way and Ogston (Journ. Roy. Agr. Soc. vii. [2] 593; xi. [2] 512), by Sprengel and by Stammer (Ann. Ch. Pharm. lxx. 294).

The fleshy stem or bulb of the kohl-rabi contains, according to Sprengel (*loc. cit.*) 91 per cent. water, the leaves 86 per cent. water. 100 pts. of the dried substance contain 41·4 pts. soluble in water, 38·2 soluble in potash-ley, 18·5 woody fibre, besides wax, fat, &c. The ash of the corms and leaves has been analysed by **Sprengel**, and by **Way** and **Ogston** (*loc. cit.*)

The ashes of the heart of cauliflower (*Br. ol.* var. *botrytis cauliflora*), and of the root and leaves of broccoli (*Br. ol.* var. *botrytis asparagoïdes*) have been analysed by **Th. Richardson**, Ann. Ch. Pharm. lvii.; Anhang zum dritten Heft).

2. *Brassica Napus.*—Winter rape, Coleseed, and *Br. campestris* var. *oleifera*, Summer rape, Colzat or Colza, are cultivated chiefly for their seeds, which yield a large quantity of oil, and for the succulent food which their thick fleshy stems and leaves supply to sheep when other fodder is scarce. The cake which remains after the oil has been pressed from the seed, is used on the continent as food for cows and pigs, and also as a manure, for which purpose large quantities of it are imported into England. Colza or summer rape yields the largest quantity of oil, but winter rape is said to be hardier, and is therefore more generally cultivated in this country. **Way** (Journ. Roy. Agr. Soc. x. part 2) found, in 100 pts. of the dry seed of dwarf rape, 4·2 per cent. nitrogen, 37·8 fat, 3·3 ash, and 6·5 water. Of the ash of the seed and straw of rape, numerous analyses are given in Liebig and Kopp's *Jahresbericht für Chemie* for 1849, tables D and E to page 656. From these we extract the following:

BRASSIC ACID. Colza oil is, according to Websky (J. pr. Chem. lviii. 449), a mixture of two glycerides, which yield by saponification, brassic acid, which is solid at ordinary temperatures, melts between 32 and 33° C., and crystallises from alcohol in long needles; and another acid, which is liquid at ordinary temperatures and resembles oleic acid. The two acids are easily separable by means of their lead-salts, the salt of the oily acid being soluble in ether, while brassate of lead is insoluble. Websky assigns to brassic acid the formula $C^{46}H^{44}O^4$. Städeler (Ann. Ch. Pharm. lxxxvii. 133) proposes $C^{44}H^{42}O^4$, or $C^{22}H^{42}O^2$, which agrees quite as well with the analyses, and is the same as that of erucic acid, extracted by Darby from oil of mustard. Brassate of sodium gives by analysis 8·5 per cent. soda; the formula $C^{22}H^{41}NaO^2$ requires 8·6 per cent.

BRAUNITE. Native sesquioxide of manganese. See MANGANESE.

BRAUNSTEIN. The German name of peroxide of manganese.

BRAYERA ANTHELMINTICA (Kunth), or *Hagenia abyssinica* (Lamarck). —The flowers of this plant, called *Kusso* or *Kosso*, contain, according to Viale and Latini (Correspond. Scient. in Roma, Nov. 1852), a peculiar acid, *hagenic acid*, in combination with ammonia.

Harms (Arch. Pharm. [2] lxxxviii. 165) found in 100 pts. of the ash of kusso, after deducting sand and charcoal:

BRAZIL WOOD. The tree which yields this wood, the *Cæsalpina crispa*, grows in Brazil, and also in the Isle of France, Japan, and elsewhere. There are several varieties, distinguished by the names of the localities from which they are obtained, as Pernambuco, Lima, Santa Martha, Sapan (from Japan), &c. Pernambuco wood and Lima wood contain the largest amount of colouring matter; viz. about 2·7 per cent.; Sapan wood, only about 1·5 per cent. Peach or Nicaragua wood, sometimes called Santa Martha wood, is still inferior in point of quantity, but is preferred for some purposes.

Brazil wood is heavier than water, very hard, and susceptible of a good polish. Its colour is pale when newly cut, but becomes deeper by exposure to the air. The heaviest specimens generally yield the best colour. It has a sweetish taste when chewed, and is distinguished from red sanders or sandal wood by giving out its colour to water, which sandal wood does not. The colouring matter may also be extracted by alcohol or ammonia, and with greater facility than by water. The spirituous tincture, according to Dufay, stains warm marble of a purplish red, which, on increasing the heat, becomes violet; and, if the stained marble be covered with wax and

---

* In the calculation of Herapath's analysis, the carbonic acid is deducted.

† Mixed with sand.

‡ And 1·5 basic ferric phosphate.

considerably heated, it changes through all the shades of brown, and at last becomes fixed of a chocolate colour.

According to Chevreul (Ann. Chim. lxvi. 226), the red colouring matter of Brazil wood, to which he gives the name *Brazilin*, exists ready formed in the wood, and is simply dissolved out by water or other solvents. To prepare it, the wood is exhausted with warm water; the solution evaporated to expel free *acetic acid*; the dry residue is dissolved in water; the liquid shaken up with oxide of lead, to remove any remaining free acids; the filtrate again evaporated to dryness; the residue dissolved in alcohol, the alcoholic solution likewise evaporated; the residue dissolved in water, and the solution treated with gelatin to precipitate tannic acid: lastly the evaporation and solution in alcohol must be repeated to remove the excess of gelatin. (Chevreul.)

Brazilin crystallises by spontaneous evaporation in reddish yellow needles. It is soluble in water, alcohol, and ether. The solutions have a fine red colour, if they do not contain free acid; but the addition of sulphuric, nitric, or hydrochloric acid changes the colour to dirty yellow; hydrofluoric acid turns it first yellow then greenish grey; phosphoric and citric acids give it a fine and permanent yellow colour, whereas with acetic acid a yellowish-red solution is formed, which when evaporated in contact with the air, leaves a residue of a fine red colour. The yellow produced by citric acid is well adapted for dyeing wood or silk.

By sulphydric, sulphurous, hyposulphuric, and boric acids, the colouring matter is bleached and destroyed; a similar action is exerted upon brazilin by zinc and dilute acids.

Alkalis change the red colour of a solution of brazilin to violet or blue: hence infusion of Brazil wood may be used as a test for these bases; with hydrate of alumina it forms a crimson lake; with tin- and lead-salts, purple precipitates. (Chevreul.)

According to Bolley (Zeitschr. Ch. Pharm. viii. 192), brazilin is identical with sapan-red, the colouring matter of Sapan-wood (*Cæsalpinia echinata* or *C. Sapan*), and is obtained therefrom with much greater facility than from Brazil wood. (See SAPAN RED, vol. v. p. 191.)

The precipitates obtained with an aqueous decoction of Brazil wood, are extensively used for dyeing and for staining paper for walls. The solubility of the colouring matter of Brazil wood, and its strong affinity for mordants, give it a very extensive range of application both in dyeing and in calico-printing. (For details respecting the mode of dyeing with Brazil wood, see *Muspratt's Chemistry*, vol. i. p. 573, and *Ure's Dictionary of Arts, Manufactures, and Mines*, vol. i. p. 397.)

BREAD. Bread consists of the flour of wheat or other cereal grain, kneaded with water into a paste or dough, which is rendered porous by the interpenetration of carbonic acid gas, either generated within the mass of the dough by fermentation, or forced into it by mechanical means. The dough having thus acquired the proper degree of porosity, is exposed to the heat of an oven, whereby the enclosed gas is further expanded, its escape being prevented by the simultaneous formation of the crust. The crumb of the bread thus produced is a soft porous mass of swollen, but otherwise unaltered starch, mixed with vegetable fibrin; in the crust, the starch is mainly converted into dextrin and empyreumatic products.

It is the rising of the dough, produced by the carbonic acid, which gives to well made bread its peculiar lightness, and distinguishes it from the close, heavy cake, produced by merely mixing flour with water and baking it. The usual method of generating the carbonic acid is by fermentation, and the manner in which this process is conducted has great influence on the quality of the bread; as, if it be not carried far enough, the dough will not rise sufficiently, and if allowed to go too far, it gives rise to the formation of acid and other objectionable products. To facilitate the understanding of it, we must give some account of the composition of flour.

The flour of all cereal grains consists of an azotised portion, chiefly vegetable fibrin; a non-azotised portion, chiefly starch, with variable quantities of dextrin and sugar; and inorganic salts, chiefly phosphates.

If moistened wheat flour be kneaded into a stiff paste, and well washed with water, a milky liquid runs off, and a viscid elastic solid, called gluten, is left behind. The milky liquid, if left to stand, deposits a quantity of starch mixed with minute particles of gluten, and the clear liquid filtered from the deposit, leaves on evaporation, a quantity of extractive matter, consisting of vegetable albumin, dextrin, glucose, or grape-sugar, possibly also gum, and other similar proximate principles, besides soluble inorganic salts. The gluten, which is essentially the flesh-forming constituent of the flour, consists of vegetable fibrin, held together by a very tenacious nitrogenous substance, called *glutin* or *gliadin*, which may be extracted by alcohol; it also contains small quantities of fat, and fine particles of bran mechanically mixed. It is the gliadin which gives to the nitrogenous portion of wheat-flour its peculiar adhesiveness, and causes the dough prepared with it to rise into a spongy mass when penetrated by gases. Other cereal grains, oats and rye for example, though rich in vegetable fibrin, contain scarcely any gliadin, and consequently the dough prepared from them possesses but little tenacity. This is the chief cause of the great superiority of wheat over all other cereals, for the preparation of bread.

When flour in the moist state is exposed to the air, the nitrogenous matter quickly passes into a peculiar state of decomposition, in which it is capable of acting as a ferment, converting the starch into dextrin and glucose, and the glucose into alcohol and carbonic acid (see FERMENTATION). Hence a portion of dough which has been left till it undergoes partial decomposition, and in which state it is called leaven, is capable of inducing the so-called *panary*, but really *alcoholic* fermentation, in a much larger quantity of dough, when well kneaded with it. "A little leaven leaveneth the whole lump." This method of bread-making has been practised from the oldest times, and is still the only one in use for the coarser kinds of bread, such as the *Schwarzbrot*, or black bread of Germany; but for the finer sorts, beer-yeast is now used as a substitute, or rather as a partial substitute of leaven. The process generally adopted in this country is as follows: A certain quantity of flour is mixed with yeast, salt, and tepid water. This constitutes the "sponge," which is covered up and set aside in a warm place, to undergo fermentation. In the course of an hour or so, the mass swells up considerably from the generation of carbonic acid, large bubbles of which rise to the surface and burst. With each successive burst, a sudden falling of the sponge takes place, followed by a gradual rising, and these alternate actions would, if allowed, continue for many hours. Various other modes of making an active sponge are employed, particularly by the use of potatoes. When the sponge, no matter how formed, is in an efficient condition, the baker mixes up with it fresh portions of flour, salt, and water, the quantities so added forming the greater part of the dough. The whole is then subjected to a thorough kneading with the hands, or sometimes with the feet, so that the fermenting dough may permeate and affect the entire substance, and thus cause an equable liberation of carbonic acid in every particle. The dough is set aside for a few hours, during which the fermentation proceeds, then kneaded a second time, and weighed out into loaves, which are allowed to continue fermenting till they have doubled their original bulk. They are then baked in the oven, within which they undergo a further increase of size, due chiefly to the expansion by heat of the confined gases: for the heat of the oven quickly arrests the fermentation.

In Paris, where bread-making has been brought to a high degree of perfection, the fermentation is produced chiefly by the gluten of the dough, yeast being used merely to facilitate the action. A lump of dough remaining from the last batch of bread, and consisting of 8 lbs. flour and 4 lbs. water, is left to itself for ten hours: in this state it is called fresh leaven (*levain de chef*). By kneading this with another quantity of 8 lbs. flour and 4 lbs. water, the once-revived leaven (*levain de première*) is obtained. After another interval of eight hours, 16 lbs. of flour and 8 lbs. water are added, forming the twice-revived leaven (*levain de seconde*); and after three hours more, 100 lbs. flour and 52 lbs. water containing $\frac{1}{4}$ to $\frac{1}{3}$ lb. beer-yeast are added, forming the finished leaven (*levain de tout point*). The 200 lbs. leaven thus obtained are mixed, after two hours, with 132 lbs. flour and 68 lbs. water, containing $\frac{1}{2}$ lb. of yeast in suspension and 2 lbs. common salt dissolved. This quantity of dough serves for five or six bakings. For the first baking, half the dough (200 lbs.) is made into loaves of the required size and form, which are exposed for a while in shallow baskets, to a temperature of 25° C. (77° F.), and then transferred to the oven. The bread thus obtained has a sourish taste and dark colour. The remaining half of the dough is again mixed with 132 lbs. flour, 70 lbs. water, $\frac{1}{2}$ lb. yeast, and the requisite quantity of salt; the half of this quantity of dough is then formed into loaves, left to ferment, and baked. The same operations are repeated three times, one-half of the dough being each time mixed with 130 lbs. flour, $1\frac{1}{3}$ lb. yeast, and the proper quantity of water and salt. The last stage yields the finest and whitest bread.

In the normal process of bread-making, the carbonic acid, whose evolution gives lightness to the bread, is derived principally, if not wholly, from the fermentation of the sugar of the flour, induced by the action of metamorphic gluten. But flour, as already observed, contains other nitrogenised substances than gluten, and other non-nitrogenised substances than sugar. Now these nitrogenous substances, the albumin, for example, readily undergo transformation, and then act as ferments, not only upon sugar and dextrin, but also upon starch, transforming it into dextrin and sugar, and sometimes also into lactic acid. This is the process which takes place in the germination of grain, in malting for example (p. 328), by the action of the albumin in the peculiar state called *diastase*. Now when wheat has been too much exposed to damp during harvesting, or has sprouted from any subsequent cause, or when the flour even of well-harvested wheat is exposed to heat and moisture, the albumin passes into this peculiar state, and the flour becomes incapable of yielding good bread, because, during the process of bread-making, the conversion of starch into dextrin and sugar, which always occurs to a slight extent, then takes place in an exaggerated degree. Bread made from such flour, is sticky, saccharine, and soddened, never light and porous. The conversion of the starch into dextrin and sugar likewise renders the bread darker in colour. In fact, the brown colour of wheaten bread made from flour containing fine bran, is due, not to admixture of particles of bran, but in great part at least to a conversion of the starch into dextrin and sugar by the action of the altered albuminous matter in the bran. According to Mège-Mouriès, bran contains a peculiar nitrogenous body called *cerealin*, which is specially active in inducing this conversion: it appears, however, to be identical or nearly identical, with ordinary diastase. Be this as it may, it is certain that the finest wheat flour obtained from the central portion of the grain, which contains but little nitrogenous matter, has very little tendency to undergo the change under consideration; but coarse flour obtained from the exterior of the grain, is rich in azotised substances, and more ready to undergo the glucosic deterioration. In white bread of good quality, the starch has undergone very little alteration. A small portion of it is rendered soluble in water, but the greater number of the granules are simply swollen, not burst, and may be washed out of the bread, collected, and weighed. Vogel gives the following analysis of a wheat-bread loaf: sugar, 3·6 per cent.; altered starch, 18·0; unaltered starch, 53·5; gluten, with some starch, 20·7 = 95·8.

The injurious action of diastase, &c. on starch in the process of bread-making, may be prevented by the addition of certain mineral substances. Alum has long been employed for this purpose by bakers, and it certainly has the effect of rendering available for bread-making many qualities of flour, which must otherwise be wasted. Dr. Odling says (Journal of the Society of Arts, April 9, 1858): "If we mix a solution of starch with infusion of malt, in the course of a few minutes only, the starch can no longer be detected, being completely converted into dextrin and sugar, but the addition of a very small quantity of alum prevents altogether or greatly retards the transformation. The action of diastase on undissolved starch is very gradual, but here also the interference of the alum is easily recognisable. Bread made with infusion of bran or infusion of malt, is very sweet, sodden, brown-coloured, and so sticky as almost to bind the jaws together during mastication. But the addition of alum to the dough causes the loaves to be white, dry, elastic, crumbly, and unobjectionable, both as to taste and appearance. I have found that flour which is of itself so glucogenic as to yield bread undistinguishable from that made with infusion of malt, could, by the addition of alum, be made to furnish a white, dry, eatable loaf."

Alum is also said to prevent bread from turning sour and mouldy. The sourness often observed in bread of inferior quality, arises from the conversion of part of the starch into lactic acid. Now as alum prevents the transformation of starch, it may be expected also to interfere with the production of lactic acid.

Considerable discussion has taken place as to the probable effects of the habitual use of alumed bread on the digestive functions, some medical men asserting that alum, unless taken in much larger quantity than is likely to occur in bread, is quite harmless, while others attribute to it the most injurious effects. In this, as in many cases, the truth probably lies in the middle. Many of the statements which have been put forth on this, as on other questions relating to the adulteration of food, are doubtless grossly exaggerated; nevertheless, it would be unsafe to assert that the use of alum is quite free from objection. Dr. Dauglish, in a paper to which we shall have again to refer, says: "Its effect on the system is that of a topical astringent on the surface of the alimentary canal, producing constipation, and deranging the process of absorption. But its action in neutralising the efficacy of the digestive solvents, is by far the most important and unquestionable. The very purpose for which it is used by the baker, is the prevention of those early stages of solution which spoil the colour and lightness of the bread whilst it is being prepared, and which it does most effectually: but it does more than needed: for whilst it prevents solution at a time that is not desirable, it also continues its effects when taken into the stomach, and the consequence is, that a large portion of the gluten and other valuable constituents of the flour, are never properly dissolved, but pass through the alimentary canal without affording any nourishment whatever."

Another objection made against the use of alum, viz. that it has the power of causing bread to retain a larger proportion of water than it otherwise would, so that bakers who use alum defraud their customers by selling water instead of bread, does not appear to rest on satisfactory evidence. Odling (*loc. cit.*) examined the new crumb of eighteen alumed and seven non-alumed loaves, and found that the former contained on the average 43·68 per cent., and the latter, 42·78 per cent. water, the difference being quite insignificant as compared with the differences between the individual loaves, whether alumed or not. The detailed results, together with the proportions of nitrogen and ash in the loaves, are given in the following table, the samples marked with an asterisk being the *non*-alumed loaves. They are interesting in a general point of view, independently of the alum question. The loaves were new, that is, obtained during the day on which they were baked.

Percentage of WATER, NITROGEN *and* ASH, *in Bread Alumed and Non-alumed.*

	Price in Pence.	Percentage of Water.	Percentage of Organic Matter.	Percentage of Mineral Matter or Ash.	Percentage of Ash in dry Bread.	Percentage of Nitrogen in new Bread.	Percentage of Nitrogen in dry Bread.

Lime-water has also been recommended to prevent the transformation of starch during panification into dextrin, sugar, and lactic acid. It was first suggested by Liebig, and is said to have been used to a considerable extent by the Glasgow bakers. Odling finds, from laboratory experiments, that lime-water is quite as effective as alum in preventing the action of diastase upon starch, but seems to have scarcely any influence on the fermentation induced by yeast, or, at any rate, a much less action than alum, which certainly retards the process in a perceptible degree. In this respect then lime-water possesses an advantage over alum; it would also doubtless be considered less objectionable in its direct action on the digestive organs. Bread made with it is of agreeable taste, of rather more porous texture than ordinary baker's bread, and quite free from sourness.

There are doubtless many other mineral substances which would act in the same way as alum or lime-water. Thus **sulphate of copper** acts very powerfully in opposing the action of diastase, and is said to have been used for that purpose in Belgium, an ounce of the salt being dissolved in about a quart of water, and a wine-glassful of this solution mixed with the water necessary for fifty quartern or four-pound loaves. This quantity is extremely small; nevertheless the use of so poisonous a substance as sulphate of copper cannot be too strongly condemned: bread containing copper would be sure to act injuriously in the long run.

Mineral substances added to bread may be detected and estimated in the ash by the ordinary processes of inorganic analysis. A few details may, however, be added relating to the detection and estimation of alumina. The bread taken for examination should be crumb, from the middle of the loaf; it should be carefully trimmed from crust and outside crumb, as those portions may be dirty. It is then to be charred on a platinum tray; the charcoal reduced to powder and incinerated in a muffle (p. 418); the ash digested in pure strong hydrochloric acid; the filtered solution evaporated to dryness to render silica insoluble; the dried residue drenched with strong hydrochloric acid, then boiled with water, and the liquid filtered. The acid filtrate must next be nearly neutralised with carbonate of sodium, pure alcoholic potash added in excess, which will precipitate earthy phosphates and retain alumina in solution, and the liquid boiled and filtered; aqueous potash must not be used, as it always contains alumina. The alkaline filtrate is then to be slightly supersaturated with hydrochloric acid and boiled with carbonate of ammonium; this will precipitate all the alumina, which may then be collected, dried, and tested with nitrate of cobalt before the blowpipe. (See p. 155.)

If a quantitative determination is to be made, it must be remembered that the alumina precipitate generally contains phosphoric acid. To estimate the amount of this acid, the precipitate, after being weighed, is to be dissolved in hydrochloric acid, the solution mixed with tartaric acid, excess of ammonia added (which will produce no precipitate), and then sulphate of magnesium. The phosphoric acid will thereby be precipitated as ammonio-magnesian phosphate, which is converted by ignition into pyrophosphate of magnesium, $Mg^4P^2O^7$, whence the quantity of phosphoric anhydride (P^2O^5) may be calculated, and this, deducted from the total weight of the alumina precipitate, gives the quantity of alumina. Or the precipitated alumina containing phosphate may be dissolved in nitric acid, a piece of metallic tin added, and the liquid boiled: the tin is thereby oxidised, and remains as an insoluble powder, consisting of stannic oxide and phosphate, the whole of the phosphoric acid being thus separated from the alumina. The whole is next evaporated to dryness, the residue treated with water and filtered, and the alumina precipitated from the filtrate by carbonate of ammonia.

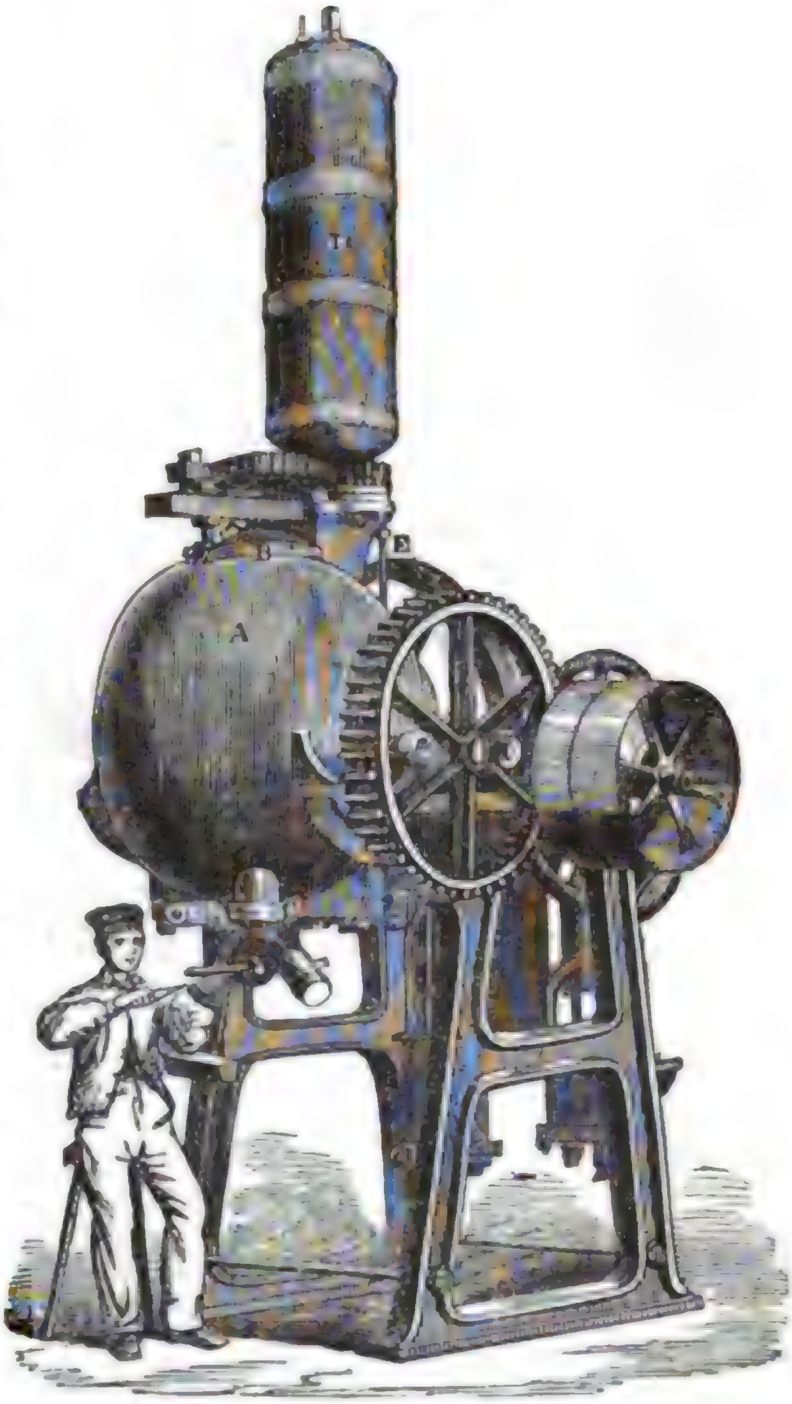
UNFERMENTED BREAD.—Instead of using alum or other mineral substances, as above described, to counteract the injurious secondary actions which take place during the fermentation of dough, methods have been proposed, and to a certain extent carried out, for dispensing with the fermentation altogether, and supplying the carbonic acid which is to give lightness to the dough, from some extraneous source.

1. Instead of mixing salt (chloride of sodium) with the flour and water, hydrochloric acid and carbonate of soda are added in the proportion required to form chloride of sodium, the carbonic acid thereby evolved causing the dough to rise just as if it had been generated by fermentation. Bread thus made is said to be of good quality, though it is never so white as ordinary baker's bread. There is, however, a serious objection to its constant use, namely, that it is liable to be contaminated with arsenic, introduced by the hydrochloric acid. That acid indeed, as found in commerce, always contains arsenic, the complete removal of which can only be effected by a process much too costly and troublesome for the purposes of a bake-house; and though the quantity of arsenic actually present in the bread may be small, still by daily use it might accumulate in the system and ultimately produce injurious effects.

2. *Preparation of* AËRATED BREAD.—Carbonic acid gas produced from chalk, either by the action of dilute sulphuric acid or by ignition, and stored in an ordinary gasholder, is pumped therefrom into a cylindrical vessel containing water, whereby the water becomes charged with the gas. This carbonic acid water is mixed under pressure with the flour, and the resulting dough, which becomes vesicular on the removal of the pressure, is divided into loaves and baked. This process, which was invented and patented by Dr. Dauglish, has been carried out on a large scale in London and other places.

The following is a description of the apparatus:—A (*fig.* 112) is the mixer or vessel in which the flour, water, and salt are mixed together. It consists of a very strong iron spheroïdal vessel, with an internal capacity of from 17 to 20 cubic feet. It has an opening B at the top, to which an air-tight cover is fitted, and the means of closing it to resist considerable pressure. There is also a corresponding opening C at the bottom, large enough for a man-hole, and also closed by a lid, to which is attached the apparatus for drawing off the dough through suitable mouthpieces in a continuous stream, which is cut into pieces by a boy, and received into boxes or baskets to be conveyed to the oven. Through the centre of the mixer, a shaft passes furnished with stuffing boxes, to prevent the escape of compressed gas, and in this shaft suitable mixing arms are fixed: by means of the necessary gearing this shaft is made to rotate by steam power. D is a copper water-vessel, having communication with the mixer from the bottom by means of a valve, and from the top by means of a pipe passing up inside the water-vessel. This water-vessel has also communication with a pair of condensing pumps, which are fixed in the same frame behind the mixer, and are worked by a steam engine. The communication is by means of the pipe E, which terminates within the water-vessel by a rose perforated with minute holes.

Fig. 112.



To work the apparatus, the top cover B of the mixer is opened, and about 560 lbs. of flour are shot into it by means of a hopper and shoot connecting with the floor above; water, to the amount of 30 gallons or so, is drawn into the water-vessel from a cistern above, and the whole is then closed, after adding to the flour the necessary salt. After removing the air from the apparatus by a suitable pump, carbonic acid is pumped by the condensing pump from a gas-holder, in which it is stored until it is condensed to about seven atmospheres. This condensed gas being dispersed by the rose at the bottom of the water-vessel, passes in minute streams through the water, and as the density within increases, the water absorbs the gas in proportion, that which is not absorbed passing down the internal pipe from the top of the water-vessel into the mixer, so that the density within that vessel is kept in equilibrium with that in the water-vessel. When the right density is attained, the valve at the bottom of the water-vessel is opened, when the water falls upon the flour, after which the mixing arms are set to work, and in about six minutes the dough is thoroughly formed. It is allowed to subside for a minute, and is then drawn off through the bottom apparatus, being forced through it by the elastic force of the gas within. On escaping from the condensed atmosphere in the mixer, the dough immediately assumes the vesicular form and texture, and is ready to be baked.

The carbonic acid is obtained by acting on whiting or ground chalk with sulphuric acid; it comes off perfectly pure, and, being kept over water, is thoroughly washed. It takes about 20 cubic feet of carbonic acid at atmospheric density to prepare dough from 280 lbs. of flour, about 11 cubic feet being incorporated with the dough, the remaining 9 cubic feet being wasted in the operation of drawing the dough off, and in other ways: 7 lbs. of sulphuric acid give, in practical working, 21 cubic feet of carbonic acid from 10 lbs. of carbonate of lime, the sulphuric acid being of density of 1·848. The gas which is left in the apparatus after the dough is discharged, is returned to the gas-holder for further use.

The advantages of this process are thus stated by Dr. Odling in a paper read before the Chemical Section of the British Association at Aberdeen in 1859:—1st. Its cleanliness. Instead of the dough being mixed with the naked arms or feet, the bread, from the wetting of the flour to the completion of the baking, is not, and scarcely can be, touched by any one. 2nd. Its rapidity. An hour and a half serves for the entire conversion of a sack of flour into baked loaves; whereas, in the ordinary process, four or five hours are occupied in the formation of the sponge, and a further time in the kneading, raising, and baking of the dough. 3rd. Its preventing the glucogenic deterioration of the flour, which takes place in the ordinary process (p. 657), and thereby obviating the necessity of using alum. 4th. Its certainty and uniformity. Owing to differences in the character and rapidity of the fermentation, dependent on variations of temperature, quality of yeast, &c., the manufacture of fermented bread frequently presents certain vagaries and irregularities from which the new process is entirely free. 5th. The character of the bread. Chemical analysis shows that the flour has undergone less deterioration in bread made by the new than in that made by the fermenting process. In other words, the percentage of extractive matters is smaller. The new bread has been tried dietetically at Guy's Hospital, and by many London physicians, and has been highly approved of. It is well known that, for some years past, the use of fermented bread in dyspeptic cases has been objected to by members of the medical profession, the débris of the yeast being considered unwholesome, and liable to induce acidity. 6th. Its economy. The cost of carbonic acid is alleged to be less than the cost of yeast. Moreover, in making fermented bread, there is a small but necessary waste of the saccharine constituents, which is avoided in the new process. 7th. The saving of labour and health. It substitutes machine labour for manual labour of a very exhausting kind. The sanitary condition of journeymen bakers was investigated some time ago by Dr. Guy, and found to be most lamentable, from their constant night work, and from the fatiguing and unwholesome character of their labour, particularly the kneading. In a politico-economical point of view, the process is also important, as removing bread-making from a domestic manual work to a manufacturing machine work. From the character of the apparatus, the process can only be used profitably on a large scale, and not in small bakeries.

Of all the advantages just noticed, the most important is the prevention of the deterioration of the flour, which is so apt to occur in the ordinary process of bread-making. We have already observed (p. 657) that this deterioration consists in a too great conversion of the starch into dextrin and sugar, and that it takes place to the greatest extent when flour is used which contains the external as well as the central portions of the wheat-grain, because the external portions are rich in nitrogenous matter,—the central consisting almost wholly of starch,—and a portion of this matter passing into a metamorphic state (diastase or cerealin) and acting as a ferment, produces the change just mentioned. Now it is important that this external nitrogenous portion of the grain should be retained—especially for persons who eat but little meat, and to whom bread is essentially the staff of life,—both for its direct nutritive power, and for the part which the metamorphic gluten undoubtedly plays in assisting the solution of the starch and unaltered gluten in the process of digestion. In this country, however, there is an almost universal preference for white bread, and consequently the miller contrives so to grind and dress his flour as to get rid as far as possible of the nitrogenous portion, and thereby prevent the conversion of the starch into dextrin and sugar during fermentation, which, as already observed, is the chief cause of the loss of whiteness. Hence it is, perhaps, as Dr. Dauglish suggests, that wheaten bread has not hitherto entered so extensively into the diet of the poor man in England as oatmeal in Scotland. The latter is prepared for food by simply boiling it in water in the form of a porridge, so that all the elements are presented to the system uninjured by artificial processes, whereas our wheaten bread is generally prepared in such a manner as to rob it of certain of those constituents which not only possess in themselves great nutritive power, but likewise materially facilitate the digestion of the whole. Now the new method of bread-making renders it possible to retain all these matters, and at the same time to produce a light crumbly loaf, without the use of alum or any other mineral ingredient. (See a paper by Dr. Dauglish read before the Society of Arts, 25 April, 1860; also "On Fermented Bread and Aërated Bread," Medical Times and Gazette, 12 May, 1860.)

For further details on the making of bread, and for descriptions and figures of kneading machinery and patent ovens, see the article BREAD in *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 400; *Muspratt's Chemistry*, i. 353; Payen, *Précis de Chimie Industrielle*, 4^{me} éd. ii. 126; *Handwörterbuch d. Chem.* 4^{te} Aufl. ii. [2] 511. On the composition of wheat-grain, flour, and bread, see Lawes and Gilbert. (Chem. Soc. Qu. J. x. 1, 269.)

BREAN. See ICICA RESIN.

BREIDIN and **BREIN.** See ARBOL-A-BREA.

BREISLAKITE. A mineral occurring in cavities of Vesuvian lava, in capillary crystals. Chapman (Phil. Mag. [3] xxxvii. 444) regards it as a variety of augite. The form is that of basaltic augite. Colour brownish or grey with metallic lustre. Melts before the blowpipe to a shining magnetic bead. Not attacked by boiling hydrochloric acid.

BREITHAUPTITE. Native antimonide of nickel, Ni^2Sb (p. 316).

BREMER GREEN. A green pigment consisting chiefly of basic carbonate of copper mixed with alumina and carbonate of calcium. According to Bley, a fine blue-green colour is obtained by dissolving commercial sulphate of copper in 10 pts. of water, adding a little nitric acid, leaving the liquid to itself for a week, then filtering, adding fresh lime-water, precipitating with filtered solution of pearl-ash, and mixing the washed precipitate with gum-water to give it lustre.

BREUNERITE. See MAGNESITE.

BREVICITE. See NATROLITE.

BREWSTERITE. A somewhat rare mineral, occurring in transparent colourless prismatic crystals, of the monoclinic system, with the lateral faces inclined to the terminal faces, at an angle of 93° 40′. Specific gravity 2·12 to 2·2 (Brewster); 2·453 (Mallet). Hardness = 5·0 to 5·5. According to the following analyses by Connell (Ed. N. Phil. J. xiv. 35), Thomson (Mineralogy, i. 348), and Mallet (Sill. Am. J. [2] xxviii. 48), it is of the form $M^2O.Al^4O^3.6SiO^2 + 5H^2O$, the symbol M denoting strontium, barium, and calcium in the atomic proportion Sr : Ba : Ca = 4 : 2 : 1, and by regarding the water as basic and substituting aluminicum ($al = 9·2$) for aluminosum ($Al = 13·7$), the formula may be reduced to $M^2al^6H^{10}Si^6O^{21}$, which is of the form $R^6Si^2O^7$ or $R^4SiO^4.R^2SiO^3$:

SiO^2	Al^4O^3	Ba^2O	Si^2O	Ca^2O	H^2O	Fe^4O^3		
53·67	17·49	6·75	8·32	1·35	12·58	0·29	= 100·45	(Connell)
53·04	16·54	6·02	9·01	0·80	14·73	—	= 100·17	(Thomson)
62·42	15·25	6·80	8·99	1·19	13·22	trace	= 97·87	(Mallet)

Before the blowpipe, it parts with its water and becomes opaque, then froths, and swells up, but melts with difficulty. Leaves a silica skeleton when fused with phosphorus-salt. Dissolves in acids, with separation of silica. It occurs at Strontian in Argyleshire, on the Giant's Causeway, in the lead mines at St. Turpet near Freiburg, in the Breisgau, in the department of Isère in France, and in the Pyrenees.

BREWSTOLIN. A liquid hydrocarbon found in minute cavities in crystals of topaz, chrysoberyl, quartz from Quebec, and amethyst from Siberia, in which it was detected by Sir D. Brewster. It is transparent and colourless, and is nearly thirty-two times as expansible by heat as water, increasing one-fourth of its volume by an increment of 30°, at 50° F. On exposure to the air, it undergoes quick motions and changes, and finally evaporates, leaving a residue of minute solid particles, which, from the moisture of the hand alone, suddenly become fluid again. The residue volatilises by heat, and dissolves in acids without efflorescence. (Dana, ii. 471.)

BRICKS. Common bricks are made with clay mixed with sand or ashes, and baked or burnt at various temperatures. In some southern countries, bricks are merely dried in the sun, but they then remain very friable, and are fit only for light constructions. Nearly all sedimentary or alluvial formations contain clays which may be used for making bricks. Some clays do not require any addition of sand, but with plastic clays an admixture of sand is necessary. In this country, coal-ashes are mixed with the clay, partly to give it the right consistence, partly to facilitate the burning. The clay is dug up and turned over in the winter, and being thus exposed to wet and frost, it breaks up and mixes better with the coal-ashes which are afterwards added. For stiff clays, 50 chaldrons of ashes are added to 240 cubic yards of clay; for clays containing much sand, 40 chaldrons of ashes to 220 cubic yards of clay, and these quantities make 100,000 bricks. The clay and ashes are mixed with water and thoroughly incorporated, first by raking and afterwards in the *pug-mill*, which is an iron-hooped barrel, in the centre of which is a vertical shaft, worked by a horse, and bearing six knives, all of which, except the top one, are furnished with teeth. At the bottom of the barrel, is a small hole, through which the masticated clay is forced by the grinding of the teeth. The clay is next fashioned into bricks in rectangular wooden moulds, previously sanded. The bricks are then dried in the air, and afterwards made up into heaps called *clamps*, having flues or spaces left in them, which are filled with dry wood, on which is put a covering of *breeze*, a coarse kind of coal-ash left from the sifting. The clamp when full is surrounded with old bricks, and on the top of all a thick layer of breeze is laid. The external bricks at the sides are coated with a thin plastering of clay, to exclude the air, and in wet weather protected by hurdles having rushes woven into them. The fire is lighted at the mouths of the flues, which, if it burns well, are then stopped up. In favourable weather, the bricks are burnt in about twenty-five or thirty days. In this mode of burning, the coal-ashes incorporated in the substance of the bricks contribute greatly towards the effect. Sometimes, however, bricks are burned in kilns, and then they have no ashes mixed with them, the firing being wholly external.

Fire-bricks are bricks made of refractory clay, that is of clay which will stand a very strong heat without fusing. Such clays must be free from lime and oxide of iron. The clay of Stourbridge in Worcestershire, and those of Burgundy are celebrated for their fire-resisting qualities, and are therefore used for making bricks for lining furnaces. The clay is mixed with sand or with the fragments of old firebricks ground to powder. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 441.)

BRICKS (FLOATING). Bricks that swim on water were manufactured by the ancients; and Fabbroni discovered some years since, a substance, at Castel del Piano, near Santa Fiora, between Tuscany and the States of the Church, from which similar bricks might be made. It constitutes a brown earthy bed, mixed with the remains of plants. Haüy calls it *talc pulvérulent silicifère*, and Brochant considers it as a variety of *meerschaum*. The Germans name it *Bergmehl* (mountain meal), and the Italians *latte di luna* (moon milk). According to Klaproth's analysis, it consists of 79 silica, 5 alumina, 3 oxide of iron, 12 water, and 1 loss, in 100 pts. It agrees nearly in composition with *Kieselguhr*. U.

BRILLIANT. Diamond cut in such a way as to reflect light most vividly, is called a brilliant. See Diamond.

BRIMSTONE. See Sulphur.

BRINDONIA INDICA. A plant belonging to the order *Guttiferæ*. The pericarp of the fruit is used in Goa as a spice, and the blood-red acid juice as a lemonade. The seeds are convex, red-brown, tasteless, of the size of ordinary beans, and contain 1·72 per cent. nitrogen, or after removal of the fat, 2·58 per cent. In the dry state, they do not yield any fat by pressure, requiring to be previously softened by vapour of water; by the use of solvents, 30 per cent. of fat may be extracted. The crude fat is nearly colourless, melts at 40° C., dissolves sparingly in hot alcohol, and easily saponifies, yielding glycerin, together with oleic and stearic acids, the latter amounting to 50 per cent. From the crude fat, pure stearic is easily obtained by crystallisation and pressing out the mother-liquor. The red-brown cake left after exhausting the fat with ether, contains a fine red colouring matter, soluble in water and alcohol, insoluble in ether and in acids. (J. Bouis and D'Oliveira Pimentel, Compt. rend. xliv. 1355.)

BRITANNIA METAL. An alloy of tin and antimony. (See Tin.)

BRITHYNE. Syn. with Glauberite.—**BRITISH GUM.** See Dextrin.

BRITTLE SILVER ORE. Native sulphide of silver. See Silver.

BROCATELLO. A calcareous stone or marble, composed of fragments of four colours, white, yellow grey, and red.

BROCCOLI. See Brassica.

BROCHANTITE. A basic sulphate of copper, $Cu^2SO^4.6CuHO$, found native, associated with malachite and red copper ore, at Ekatherinenburg in Siberia, and at Rezbanya in Hungary. Small right rhombic prisms of 117°. Emerald-green, transparent, with glassy lustre; harder than calcspar. Specific gravity 3·80—3·87. Melts before the blowpipe, and forms a bead of reduced copper or charcoal.

BRODDBO TANTALITE. See Tantalite.

BROGNIARDITE. A sulphantimonite of lead and silver, $2PbAgS.Sb^2S^3$, from Mexico. It occurs in masses without cleavage. Lustre metallic. Streak greyish-black. It is rapidly attacked by strong nitric acid. An analysis by Damour (Ann. Min. [4] xvi. 227) gave 19·38 per cent. S, 29·95 Sb, 25·03 Ag, 24·74 Pb, 0·54 Cu, and 0·04 Zn.

BROGNIARTIN or **BROGNIARTITE.** Syn. with Glauberite.

BROMACETIC ACID, $C^2H^3BrO^2$.—(W. H. Perkin and B. F. Duppa, Chem. Soc. Qu. J. xi. 22.)

Formation.—By the action of bromine on acetic acid:—

$$C^2H^4O^2 + Br^2 = C^2H^3BrO^2 + HBr.$$

A small quantity of dibromacetic acid is formed at the same time.

Preparation.—A mixture of glacial acetic acid and bromine in equal numbers of atoms (an excess of acetic acid being used to absorb the hydrobromic acid and thereby diminish the pressure) is introduced into a strong sealed tube, and heated in an oil-bath to 150° C., and the bath is then left to cool gradually. When the temperature has fallen to about 146°, the mixture suddenly becomes nearly colourless, or light amber-brown, and at the same time, the tubes are apt to burst, though the temperature of the bath may have risen as high as 155°. The tube when quite cold is opened, torrents of hydrobromic acid gas then escaping; the contents are transferred to a retort provided with proper apparatus for condensing the hydrobromic acid, and heated to 200°; and the retort is left to cool. The whole contents then solidify after a while into a beautifully crystalline mass, consisting of bromacetic and dibromacetic acids, mixed with a little hydrobromic acid, to remove which the mixture is heated to 130°, and carbonic acid gas passed through it till the presence of hydrobromic acid is no longer indicated by nitrate of silver. Carbonate of lead is then added in excess, together with a volume of water about ten times as great as that of the acid; and the whole is heated to 100°, and allowed to stand for some hours. Bromacetate of lead then crystallises out, while dibromacetate remains in solution. The crystals may be freed from the last portions of this salt by washing with a little cold water. Lastly, the crystals of bromacetate of lead are suspended in water and decomposed by sulphuretted hydrogen, and the filtered liquid is evaporated till it crystallises.

Bromacetic acid forms rhombohedral crystals which are very deliquescent. It melts below 100° C., and boils at 208°; attacks the skin powerfully, raising a blister like a burn; when the acid is dilute, this effect takes place after eight or ten hours only. It is very soluble in water.

The acid strongly heated in a sealed tube, is resolved into dibromacetic acid, carbonic oxide, and apparently marsh-gas, together with water and hydrobromic acid, probably as represented by the equation:

$$3C^2H^3BrO^2 = C^2H^2Br^2O^2 + 3CO + CH^4 + HBr + H^2O.$$

On distilling it with acetate of potassium, acetic acid is evolved.—Heated with metallic zinc, it yields acetate and bromide of zinc.—Heated with ammonia, it forms bromide of ammonium and glycocine:

$$C^2H^3BrO^2 + 2NH^3 = NH^4Br + C^2H^5NO^2.$$

The acid is monobasic, the formula of its salts being $C^2H^2BrO^2.M$. Most of them are crystallisable and many of them decompose rapidly.

Bromacetate of Ammonium.—Nearly uncrystallisable; very soluble in water; decomposes when heated, yielding bromide of ammonium.

Bromacetate of Barium crystallises with difficulty in small stars containing water of crystallisation; it is tolerably soluble in alcohol.

Bromacetate of Calcium is a very difficultly crystallisable salt, very soluble in water.

Bromacetate of Copper is a green crystalline salt, very soluble in water. A solution of it appears to decompose when boiled, as the colour becomes paler. The solution, after standing for some days, deposits needle-shaped crystals and small malachite-green tufts of great beauty, which appear to contain a large quantity of water of crystallisation.

Bromacetate of Lead.—Obtained, either by neutralising bromacetic acid with oxide of lead and recrystallising the product from water; or by adding a solution of bromacetic acid to a solution of acetate of lead, washing the resulting crystalline precipitate with cold water, and recrystallising from water. Crystallises in needles, sparingly soluble in cold, but moderately soluble in hot water.

Bromacetate of Potassium.—Obtained by neutralising a solution of carbonate or hydrate of potassium with bromacetic acid, and evaporating the solution in a water-bath. It is a crystalline salt, very soluble in water and alcohol.

Bromacetate of Silver. $C^2H^2BrAgO^2$.—Obtained by treating bromacetic acid with carbonate of silver, or by adding a solution of bromacetic acid to a solution of nitrate of silver. In the latter case, it is thrown down as a beautiful crystalline precipitate, which may be washed with cold water, and dried over sulphuric acid in vacuo. Contains 43·62 per cent. silver (by calculation, 43·9). It is very unstable. The dry salt heated to about 90° C., decomposes with a sort of an explosion. It is rapidly acted upon by light when moist. Boiled with water, it yields bromide of silver and glycollic acid:

$$C^2H^2BrAgO^2 + H^2O = AgBr + C^2H^4O^3.$$

Bromacetate of Sodium is very soluble in water, but insoluble, or nearly so, in alcohol.

BROMACETIC ETHERS.—*Bromacetate of Methyl,* $C^3H^5BrO^2 = C^2H^2BrO^2.CH^3$, is obtained by heating amixture of methylic alcohol and bromacetic acid in a sealed tube for an hour, to a temperature of 100° C., washing the product with water, drying over chloride of calcium, and rectifying. It is a transparent, colourless, mobile liquid, having an aromatic odour highly irritating to the nose and eyes. It is heavier than water; boils at about 144° C., decomposing gradually every time it is distilled. Ammonia acts on it very readily.

Bromacetate of Ethyl. $C^4H^7BrO^2 = C^2H^2BrO^2.C^2H^5$.—Obtained in a similar manner to the preceding. It is a clear colourless liquid, heavier than water, and highly irritating to the eyes and nose. It boils at 159° C. Decomposes partially every time it is distilled, with evolution of hydrobromic acid. It is rapidly acted on by ammonia.

Bromacetate of Amyl. $C^7H^{13}BrO^2 = C^2H^2BrO^2.C^5H^{11}$.—Obtained by heating amylic alcohol with excess of bromacetic acid, washing the product with water, and drying over chloride of calcium. It is an oily liquid which has a pleasant odour when cold, but if heated, acts upon the eyes and nose like the preceding. It boils at 207° C., and decomposes partially every time it is distilled. Ammonia acts but slowly upon it in the cold.

The bromacetates of methyl, ethyl, and amyl, boil at temperatures about 82° to 86°C. higher than the acetates. Thus—

	Boiling-point.		Boiling-point.	Diff.
Bromacetate of Methyl .	144° C.	Acetate of Methyl .	58° C.	86°
„ Ethyl .	159°	„ Ethyl .	74°	85°
„ Amyl .	207°	„ Amyl .	125°	82°

A similar difference exists between the boiling points of bromacetic acid (208°), and acetic acid (120°).

Dibromacetic Acid. $C^2H^2Br^2O^2$. (Perkin and Duppa, Chem. Soc. Qu. J. xii. 1.)—Formed, together with monobromacetic acid, when a mixture of bromine and acetic acid is exposed to light (p. 663). To obtain it in quantity, the monobrominated acid is exposed to the action of bromine-vapour in strong sunshine. The product may be freed from hydrobromic acid by passing a stream of dry carbonic acid gas through it at 120° C.

It is a colourless, inodorous liquid, of specific gravity 2·25; it was once, during very cold weather, obtained in fine needle-shaped crystals. When placed on the skin, it produces painful blisters like burns. It boils between 225° and 230° C., but cannot be distilled without decomposition. It dissolves readily in water, producing cold; also in alcohol and ether. Zinc decomposes it, with evolution of hydrogen.

Dibromacetate of Ammonium. $C^2H^2Br^2O^2.NH^4 + \frac{1}{2}aq.$—Obtained by neutralising the acid with dilute ammonia and leaving the solution to evaporate, either in the air or over sulphuric acid in vacuo. Forms splendid crystals, which give off their water at 100°, becoming white and opaque. Heated to 100° C. with excess of ammonia, it is decomposed, giving off volatile products, which have not yet been examined. It dissolves readily in water, alcohol, and ether.

Dibromacetate of Potassium is a beautifully crystalline salt, shooting out into long and very brilliant crystals, containing water of crystallisation; very soluble in alcohol and water, but not deliquescent.

Dibromacetate of Lead is a very soluble and uncrystallisable substance, drying up to a tough gum-like mass. When added to water in excess, it fuses and runs about like a heavy oil; it is formed by adding the acetate or carbonate of lead to dibromacetic acid.

Mercurous Dibromacetate is precipitated on adding a solution of mercurous nitrate to dibromacetic acid; it much resembles dibromacetate of silver, and like it undergoes decomposition when boiled.

Dibromacetate of Silver is formed by adding the carbonate or nitrate of silver to dibromacetic acid; it crystallises in small needles, often grouped in stars when the acid is dilute. It is easily decomposed at 100° C. yielding bromide of silver and bromoglycollic acid:

$$\underset{\substack{\text{Dibromacetate}\\ \text{of silver.}}}{C^2HBr^2O.Ag.O} + H^2O = \underset{\substack{\text{Bromoglycollic}\\ \text{acid.}}}{C^2HBrO.H^2.O^2} + AgBr.$$

Dibromacetic acid heated with *ethylic* and *amylic alcohols*, yields the corresponding ethers. The ethyl-compound is decomposed by ammonia, yielding alcohol and dibromacetamide:

$$C^2HBr^2.C^2H^5.O^2 + NH^3 = C^2H^5.H.O + N.H^2.C^2HBr^2O.$$

BROMACETINS. See Acetins.

BROMAL. *Hydride of Tribromacetyl. Oxide de Bromèthile.* $C^2HBr^3O = C^2Br^3O.H.$ (Löwig, Ann. Ch. Pharm. iii. 228.)—A compound analogous to chloral, and produced in like manner, by the action of bromine on alcohol. 3 or 4 pts. by weight of bromine are gradually added to 1 pt. of absolute alcohol, cooled by ice; the mixture is left to itself for ten or twelve days, and then distilled; and after three-fourths (consisting of hydrobromic acid, bromide of ethyl, and other products) have passed over, the residue is mixed with water, and exposed to the air for a day or more in a shallow basin. It then deposits large crystals of hydrate of bromal, which yield the anhydrous compound by distillation with sulphuric acid. Or they may be gently heated with six times their weight of strong sulphuric acid, and the anhydrous bromal, which then sinks to the bottom as a colourless oil, may be separated by decantation and distilled, first over slaked and then over quick lime.

Bromal is said to be also produced by the action of bromine on a mixture of alcohol and nitric acid. (Aimé.)

Bromal is a transparent colourless oil, of specific gravity 3·34. It is somewhat greasy to the touch, and makes grease-spots upon paper, which however soon disappear. Its boiling point is above 100° C. and it may be distilled without decomposition. It has a peculiar pungent odour, and excites a copious flow of tears. Its taste is extremely sharp and burning, and very persistent.

Bromal is decomposed by aqueous alkalis in the same manner as chloral, yielding bromoform, $CHBr^3$, and a formate of the alkali-metal. Lime and baryta heated in its vapour become incandescent, and decompose it, yielding carbonic oxide, water, and a bromide of the metal mixed with charcoal. Red-hot iron acts in a similar manner. It is not decomposed by nitric acid, sulphuric acid, or chlorine.

Hydrate of Bromal. $C^2HBr^3O.2H^2O$.—Bromal dissolves in a small quantity of water, and the solution, when left to evaporate, yields the hydrate in large crystals, having the form of sulphate of copper. They melt at the heat of the hand, dissolve readily in water, and yield anhydrous bromal when treated with sulphuric acid. The hydrate is also formed when bromal is exposed to moist air.

Bromal dissolves sulphur and phosphorus, and mixes readily with bromine, also with alcohol and ether.

BROMALOÏN. See Aloin (p. 148).

BROMAMIDE. See Nitrogen, Bromide of.

BROMANIL. Syn. of Perbromoquinone. See Quinone.

BROMANILAMIC ACID. BROMANILIC ACID. BROMANILAMIDE. Syn. with Dibromoquinonamic Acid, Dibromoquinonic Acid, and Dibromoquinonamide. (See Quinonic Acid.)

BROMANILOIDE. See Tribromophenylamine, under Phenylamine.

BROMANISIC ACID. See Anisic Acid.—**BROMANISOL.** See Anisol.

BROMARGYRITE. Native bromide of silver. (See Silver.)

BROMEIN. $C^{10}H^6Br^4$?—A crystalline product, obtained in small quantity by the action of bromine on crude benzene. (Laurent.)

BROMETHERIDE, BROMETHERIN, BROMETHEROIDE. See Vinyl, Bromide of.

BROMETHIONESSIL. A product of the action of bromine on thionessal (*q. v.*) It forms colourless tables, apparently consisting of $C^{28}H^{14}Br^4S$. (Laurent.)

BROMHYDRIC ACID. See Bromide of Hydrogen.

BROMHYDRINS. (Berthelot and De Luca, Ann. Ch Phys. [3] xlviii. 304; lii. 433.)—These compounds are produced by the action of tribromide or pentabromide of phosphorus on glycerin. Their composition is such as might result from the combination of glycerin and hydrobromic acid, with elimination of water, and may be represented empirically by the general formula

$$m\,C^3H^8O^3 + n\,HBr - p\,H^2O.$$

Their names and formulæ are as follows:

Monobromhydrin . .	$C^3H^7BrO^2 = C^3H^8O^3 + HBr - H^2O$
Epibromhydrin . .	$C^3H^5BrO = C^3H^8O^3 + HBr - 2H^2O$
Dibromhydrin . .	$C^3H^6Br^2O = C^3H^8O^3 + 2HBr - 2H^2O$
Tribromhydrin . .	$C^3H^5Br^3 = C^3H^8O^3 + 3HBr - 3H^2O$
Hemibromhydrin . .	$C^6H^9BrO^2 = 2C^3H^8O^3 + HBr - 4H^2O$
Hexaglyceric Bromhydrin	$C^{18}H^{27}BrO^7 = 6C^3H^8O^3 + HBr - 11H^2O$

Mono-, di-, and tribromhydrin, may also be regarded as glycerin, $C^3H^5(HO)^3$, in which 1 or more at. of peroxide of hydrogen has been replaced by bromine.

Besides these compounds, there are formed at the same time others of similar nature, which have not been examined; likewise acrolein, and dibromallylphosphine, $C^6H^9Br^2P = P.H^2.(C^3H^4Br)^2$.

The bromhydrins heated with aqueous potash to 100° C., in closed vessels, all yield bromide of potassium and glycerin.

Preparation of the Bromhydrins.—500 grms. of glycerin are added by small portions to between 500 and 600 grms. of liquid bromide of phosphorus, the liquid being cooled after each addition, and the mixture, after standing for twenty-four hours, is distilled into a well-cooled receiver communicating with a vessel containing potash-ley, to absorb the acrolein vapour. As an additional precaution against the injurious effects of this vapour, the distillation and all the subsequent operations should be performed either in the open air, or under a chimney with a good draught.

The distillate, consisting of an upper watery layer and a lower liquid insoluble in water, may be freed from part of the acrolein by heating it in the water-bath. It is then mixed with potash in sufficient quantity to supersaturate the acid and destroy the acrolein, and the watery layer is separated from the lower liquid.

The watery liquid is then treated with ether, whereby an ethereal solution is obtained, which, when quickly evaporated, leaves a residue chiefly consisting of the most volatile products of the reaction, together with *epibromhydrin.* The lower liquid, which is insoluble in water and requires to be treated for several hours with sticks of potash, consists chiefly of *epibromhydrin* and *dibromhydrin.* The residue which remains in the retort after the distillation, is suspended in water, supersaturated with carbonate of potassium, and shaken up with ether, and the filtered etheral extracts are evaporated: they then leave a mixture of *dibromhydrin, monobromhydrin,* and several other substances.

To separate the individual substances contained in these several mixtures, the mixtures are subjected to repeated fractional distillation, and the portion which does not volatilise at 240° C. under the ordinary atmospheric pressure, is fractionally distilled under diminished pressure (about 10mm. of mercury). The distillate thus obtained between 120° and 160° consists chiefly of dibromhydrin; between 160° and 200°, the compound $C^6H^9Br^2P$ passes over together with monobromhydrin, and between 200° and 300°, syrupy liquids which cannot be further separated, but appear to be bromhydrins. In the retort there remains a thick syrup, together with a black crystalline compound which is *hexaglyceric bromhydrin.*

Monobromhydrin, $C^3H^7BrO^2 = (C^3H^5)'''.(HO)^2.Br$.—This compound, which passes over at 180° C. in the distillation under diminished pressure, is a neutral oily liquid, soluble in ether, and having a sharp aromatic taste.

Dibromhydrin, $C^3H^6Br^2O = (C^3H^5)'''.HO.Br^2$.—This, which is the chief product of the action, is a neutral liquid, of specific gravity 2·11 at 18° C. boiling at 219°, having an ethereal odour, and soluble in ether. Heated with pentabromide of phosphorus, it yields tribromhydrin. Heated to 140° with metallic tin, it is decomposed, yielding bromide of tin and a tin-compound insoluble in water but soluble in ether.

When gaseous ammonia is passed into pure dibromhydrin, the liquid becomes hot, and yields bromide of ammonium, together with an amorphous substance, $C^6H^{12}BrNO^2$, insoluble in water, ether, alcohol, and acetic acid:

$$2C^3H^6Br^2O + 4NH^3 = 3NH^4Br + C^6H^{12}BrNO^2;$$

but if the ammonia gas is passed into a solution of dibromhydrin in absolute alcohol, the products formed are bromide of ammonium and *hydrobromate of glyceramine:*

$$C^3H^6Br^2O + (NH^4)^2O = NH^4Br + C^3H^9NO^2.HBr.$$

Tribromhydrin. $C^3H^5Br^3$.—Obtained by distilling dibromhydrin or epibromhydrin with pentabromide of phosphorus, treating the product with water, distilling, and collecting apart that which passes over between 175° and 180° C. It is a heavy liquid, which fumes slightly in the air, is gradually decomposed by water, and when treated with moist oxide of silver, yields bromide of silver and glycerin. It is isomeric with Wurtz's *tribromide of allyl* (called by Berthelot and De Luca, *isotribromhydrin*), and with *dibromide of bromotritylene,* $C^3H^5Br.Br^2$.

Epibromhydrin or *Oxybromide of Glyceryl.* C^3H^5BrO.—This compound is produced in considerable quantity by the action of the bromides of phosphorus on glycerin. It may be isolated by repeated fractional distillation, the portions which boil at or near 138° C. being each time collected apart. It is a mobile neutral liquid, soluble in ether, with an ethereal odour and pungent taste. Specific gravity 1·615 at 14° C. Boils at 138°. Vapour-density, by experiment, 5·78. (This is considerably above the calculated value, 4·80, probably because the density was taken at a temperature too near the boiling point, viz. at 178°, the compound decomposing rapidly at higher temperatures.)

This compound may be considered as deriving from tribromhydrin, by the substitution of O for Br^2. It is isomeric with *bromide of propionyl,* $C^3H^5O.Br$. Its formula is also that of monobromhydrin *minus* H^2O, or of dibromhydrin *minus* HBr.

Epibromhybrin, heated with aqueous potash to 100° for 112 hours, saponifies, yielding bromide of potassium, glycerin, and a trace of matter soluble in ether. Moist oxide of silver decomposes it rapidly at 100°, forming bromide of silver and glycerrin. Distilled with pentabromide of phosphorus, it is partly converted into tribromhydrin, according to the equation:

$$C^3H^5BrO + PBr^3Br^2 = PBr^3O + C^3H^5Br^3,$$

while the rest undergoes more complete decomposition, yielding a black substance and a gaseous mixture, containing, in 100 volumes, 5·5 carbonic anhydride, 5·5 tritylene, 11·0 hydrogen, and 78·0 carbonic oxide.

Hexaglyceric Bromhydrin. $C^{18}H^{27}BrO^7$.—This compound remains in the retort in the form of a black crystalline mass, impregnated with a syrupy liquid. It is purified by washing with cold ether; boiling ether dissolves it slightly.

Hemibromhydrin. $C^6H^9BrO^2$.—This compound passes over in the fractional distillation between epibromhydrin and dibromhydrin, viz. at 200° C. It is a neutral liquid, soluble in ether, and saponifiable by potash, yielding bromide of potassium, a substance analogous to or identical with glycerin, and a trace of matter soluble in ether. The analyses of the compound are said to agree nearly with the above formula (no analyses are given in Berthelot and De Luca's memoir), according to which it may be regarded as derived from epibromhydrin, in the same manner as the latter from dibromhydrin, viz. by abstraction of half the hydrobromic acid:

$$C^3H^6Br^2O - HBr = C^3H^5BrO:$$

and

$$2C^3H^5BrO - HBr = C^6H^9BrO^2.$$

It is analogous in composition to iodhydrin.

BROMIC ACID. $HBrO^3$ or $H^2O.Br^2O^5$.—This acid is produced: 1. By the action of bromine on alkalis or alkaline earths:

$$6Br + 3K^2O = KBrO^3 + 5KBr.$$

The bromate is separated from the bromide by its inferior solubility. A similar reaction takes place with trioxide of gold, the products being bromate and bromide of gold:

$$18Br + 3Au^2O^3 = \left.\begin{matrix}(BrO^2)^3\\ Au'''\end{matrix}\right\}O^3 + 5AuBr^3.$$

2. In the decomposition of pentachloride of bromine by water or by alkalis:

$$BrCl^5 + 3H^2O = HBrO^3 + 5HCl.$$

To obtain the free acid (bromate of hydrogen) the barium-salt is decomposed with an exactly equivalent quantity of dilute sulphuric acid, and the filtrate concentrated by evaporation at a gentle heat. It cannot, however, be reduced to a syrupy consistence without decomposition. The solution is colourless, acid to the taste, reddens litmus, and then bleaches it. It is decomposed at 100° C., giving off bromine and oxygen. All reducing agents decompose it with facility. With *sulphurous acid* the products are bromine and sulphuric acid; with *sulphydric acid*, water, bromine, and sulphur; with *hydriodic acid*, water and bromide of iodine; with *hydrochloric acid*, water and chloride of bromine; with *hydrobromic acid*, water and bromine, *e.g.*:

$$HBrO^3 + 5HCl = 3H^2O + BrCl^5.$$

Alcohol and *ether* decompose bromic acid, with formation of acetic acid and great rise of temperature.

Bromic acid is monobasic, the formula of the BROMATES being $MBrO^3$ or $M^2O.Br^2O^5$. Most of these salts are soluble in water, though less so than the bromides. They may be prepared by the action of bromic acid on the oxides or carbonates of the metals, or by precipitating bromate of barium with the corresponding sulphates; the bromates of the alkali-metals also by treating the solutions of the alkalis with bromine-water or pentachloride of bromine, and crystallising out the sparingly soluble bromate from the bromide or chloride formed at the same time:

$$\begin{aligned}6KHO + Br^6 &= KBrO^3 + 3H^2O + 5KBr\\ 6KHO + BrCl^5 &= KBrO^3 + 3H^2O + 5KCl.\end{aligned}$$

Bromates are for the most part crystallisable, but many of them decompose when their solutions are heated; hence it is generally best to evaporate the solutions in vacuo or over oil of vitriol. The bromates of mercurosum, silver, and lead are insoluble.

Bromates heated to redness either give off their oxygen and leave bromides (K, Na, Hg, Ag), or they give off bromine and part of their oxygen, and leave oxides, *e.g.*:

$$2ZnBrO^3 = Br^2 + O^5 + Zn^2O.$$

Mixed with charcoal, sulphur, or other combustible substances, they explode by heat or by percussion. Solid bromates heated with *sulphuric acid*, give off bromine and oxygen. A solution of a bromate is coloured red, even by dilute sulphuric acid. By *sulphurous acid* and other reducing agents, they are decomposed in the same manner as the acid. A solution of a bromate, not too dilute, gives with *lead-salts*, a white precipitate; with *mercurous salts*, a yellowish white precipitate, insoluble in cold nitric acid; and with *silver-salts*, a white precipitate almost insoluble in water, sparingly soluble in nitric acid, easily in ammonia. This precipitate is distinguished from chloride of silver by giving off red vapours of bromine when heated with sulphuric acid. The reactions with silver-salts and with sulphuric acid distinguish bromates from chlorates (*q.v.*)

Bromate of Aluminium.—Obtained as a clear, viscid, deliquescent mass, by dissolving hydrate of aluminium in bromic acid, or by precipitating bromate of potassium with silicofluoride of aluminium, and evaporating the filtrate over sulphuric acid.

Bromate of Ammonium. NH^4BrO^3.—White needles or crystalline granules, apparently belonging to the regular system. It cannot be preserved in the solid state, as it decomposes after a while, with violent detonation, even at ordinary temperatures, yielding nitrogen, bromine, oxygen, and water. Hydrochloric acid decomposes it, forming, however, but a small quantity of chloride of ammonium.

Bromate of Barium. $2BaBrO^3 + aq.$—When bromine or chloride of bromine is added to baryta-water till the colour begins to be permanent, bromate of barium crystallises out, while bromide or chloride remains in solution. But a better mode of preparation is to decompose 100 pts. bromate of potassium dissolved in boiling water, with 74 pts. crystallised chloride or 78 pts. anhydrous acetate of barium, and leave the liquid to cool slowly; the bromate of barium then separates out, while chloride or acetate of potassium remains in solution. Acetate of barium is preferable to the chloride for this preparation, on account of the greater solubility of the acetate of potassium.

Bromate of barium forms a crystalline powder or thin prisms of the monoclinic system, with the faces $\infty P . \infty P\infty . (\infty P\infty) . P\infty . oP . +P\infty . -\infty P$. Inclination of faces, $\infty P : \infty P = 82° 10'$; $(P\infty) : (P\infty) = 79° 5'$; $oP : \infty P\infty = 93° 2'$; $\infty P\infty : P\infty = 138°$. The salt is isodimorphous with chlorate of barium (Rammelsberg. Pogg. Ann. xc. 16). It dissolves in 130 pts. of cold and 24 pts. boiling water. It does not give off its water of crystallisation till heated above 200° C. When thrown on red-hot coals, it detonates with a green light. When heated alone, it is resolved, with evolution of light and heat, into bromide of barium and oxygen gas, without forming a perbromate. Hydrochloric or moderately dilute sulphuric acid decomposes it with separation of chloride of bromine or free bromine; very dilute sulphuric acid separates undecomposed bromic acid.

Bromate of Bismuth.—When bromic acid is poured upon hydrate of bismuth, a basic insoluble salt is formed, together with a small quantity of dissolved salt. The basic salt, $3Bi^2O^3.2Br^2O^5 + 6 aq.$, is a white amorphous powder.

Bromate of Cadmium. $2CdBrO^3 + aq.$—Rhombic prisms of 127° and 53°, with four-sided summits and truncation of the acute lateral edges by two narrow faces. Soluble in 0·8 pts. cold water. Decomposed by heat, leaving oxide of cadmium mixed with bromide.

Ammonio-bromide of Cadmium, $3NH^3.CdBrO^3$, is deposited from an ammoniacal solution of bromide of cadmium evaporated over quick lime, as a white crystalline powder, which gives off ammonia when heated, and is decomposed by water.

Bromate of Calcium. $2CaBrO^3 + aq.$—Monoclinic tables or needle-shaped prisms; $\infty P : \infty P$ in the clino-diagonal section $= 79° 56'$; $\infty P2 : \infty P2$ in the same $= 118° 22'$; $+P : +P$ in the same $= 98° 41'$: $-P : -P$ in the same $= 106° 22'$: $(\frac{1}{2}P\infty) : (\frac{1}{2}P\infty)$ in the same $= 123° 33'$ (Rammelsberg). Dissolves at mean temperature in 1·1 pt. water, forming a syrupy solution. The crystals gives off their water at 180° C.; at a stronger heat, oxygen is given off and bromide of calcium remains.

Bromate of Cerium. $2CeBrO^3 + aq.$—Colourless laminæ, which dissolve easily in water, and do not effloresce over sulphuric acid.

Bromate of Chromium.—Chromic sulphate decomposed by bromate of barium yields a green filtrate, which decomposes by evaporation, giving off bromine and leaving a dark red residue, consisting almost wholly of chromic acid.

Bromate of Cobalt. $CoBrO^2 + 3 aq.$—Hyacinth-red, transparent octahedrons, soluble in 2·2 pts. water; the solution is decomposed by heat. The dry salt when heated leaves a residue of oxide of cobalt. The salt dissolves in aqueous ammonia, forming a red liquid which turns brown in the air, and yields, after filtration, dark-brown crystals, probably consisting of the bromate of Fremy's *fuscocobaltia*.

Bromate of Copper, $2CuBrO^3 + 5 aq.$, crystallises from a concentrated solution in light-blue or blue-green crystals, which are very soluble in water, do not effloresce in the air, but crumble to a greenish-white powder in vacuo over sulphuric acid. They retain a small portion of their water even at 180° C., but give it off at 200°, together with part of the bromine. The aqueous solution mixed with a little ammonia yields a light-blue precipitate, consisting of a basic salt, $6Cu^2O.Br^2O^5 + 10$ aq., which at 200° gives off its water and becomes greyish-green.

Ammonio-bromate of Copper, $2NH^3.CuBrO^3$, separates as a dark-blue crystalline powder on adding alcohol to a solution of bromate of copper in excess of ammonia. It dissolves in a small quantity of water, and is decomposed by excess of water, with separation of a basic salt. When heated it decomposes with deflagration.

Bromates of Iron.—A solution of ferric hydrate in bromic acid, yields by evaporation over sulphuric acid, a syrup, which, after drying over the water-bath, leaves a nearly pure basic salt, $5Fe^4O^6.Br^2O^5 + 30$ aq., insoluble in water.

A solution of ferrous carbonate in bromic acid yields by evaporation in vacuo, octahedral crystals of *neutral ferrous bromate*, $FeBrO^3$, the solution of which easily decomposes, with separation of the basic ferric salt.

Bromate of Lanthanum. $LaBrO^3 + 3$ aq. — Amethyst-coloured crystals (? containing didymium), which give off 20 per cent. water at 160° C.

Bromate of Lead. $2PbBrO^3 +$ aq.—Obtained by precipitation, or better by dissolving carbonate of lead in warm bromic acid; it then crystallises on cooling in small shining prisms, isomorphous with the strontium salt. The crystals are permanent in the air, and do not give off any water over sulphuric acid; they dissolve in 75 pts. water at mean temperature. The salt begins to give off oxygen and bromine at 180° C., a small quantity of brown peroxide of lead being formed at the same time, whereas at a stronger heat, red lead or the yellow protoxide is formed; the residue contains protoxide with a small quantity of bromide.

Bromate of Lithium, $LiBrO^3$, crystallises from a syrupy solution over sulphuric acid, in needles, which effloresce in a dry atmosphere, but deliquesce when exposed to the open air.

Bromate of Magnesium. $MgBrO^3 + 3$ aq. — Large regular octahedrons, which dissolve in 1·4 pts. water at 15° C.; melt in their water of crystallisation at a moderate heat, give off the greater part of it at 200° C.; and the last portion at a somewhat higher temperature, oxygen being at the same time evolved.

Bromate of Manganese is formed by dissolving manganous oxide in bromic acid, but decomposes very quickly.

Bromates of Mercury. — *The mercuric salt*, $HgBrO^3 +$ aq., is obtained by pouring bromic acid on recently precipitated mercuric oxide, as a white powder, which dissolves in 600 pts. of cold and 64 pts. boiling water. It dissolves also in excess of warm bromic acid, and crystallises in small prisms on cooling. Hydrochloric acid dissolves it with decomposition. At 130° — 140° C. it decomposes with detonation, yielding a sublimate of mercurous and mercuric bromide, and a residue of mercuric oxide; but giving off part of the bromine and oxygen as gas. Ammonia added to the warm aqueous solution throws down a compound of mercuric bromate with oxide of dimercurammonium, $2HgBrO^3.(NH^2Hg^2)^2O$, which does not yield any ammonia when treated with potash. It is decomposed by heat with violent detonation.

Mercurous bromate, Hg^2BrO^3 or $HhgBrO^3$, is obtained as a white powder by precipitation, or by completely saturating bromic acid with mercurous oxide. From a solution of the oxide in a slight excess of bromic acid, it separates by evaporation in shining crystalline laminæ. Water decomposes it, forming a basic salt, $Hhg^2O.2HhgBrO^3$. It decomposes with detonation when heated.

Bromate of Nickel. $NiBrO^3 + 3$aq. — Green regular octahedrons having their summits replaced by cube-faces. Thin plates cut parallel to the cube-faces act strongly on polarised light (Marbach, Pogg. Ann. xciv. 412). The salt gives off water when heated. It dissolves in 3·6 pts. of cold water, also in ammonia, and on adding alcohol to the ammoniacal solution, a blue-green powder is precipitated, consisting of *ammonio-bromate of nickel*, $NH^3.NiBrO^3$, or *bromate of nickel-ammonium* $(NH^3Ni)BrO^3$.

Bromate of Palladium appears to be produced by dissolving palladous hydrate in bromic acid.

Bromate of Platinum.—Platinic sulphate decomposed by bromate of barium yields a yellow filtrate, which, when evaporated, gives off oxygen and bromine-vapour, and deposits platinic bromide.

Bromate of Potassium. $KBrO^3$. — Prepared by adding bromine to a warm, moderately concentrated solution of potash, till the liquid acquires a permanent yellowish tint; the salt then separates almost completely on cooling, and may be purified from bromide of potassium by washing with water, and recrystallisation. It forms colourless anhydrous crystals of specific gravity 3·271 (Kremers). From a hot solution it crystallises in needles, but by slow cooling it is obtained in four- and six-sided plates, or in cubes with rounded summits; by spontaneous evaporation in small scales, or sometimes in dendritic masses. According to Fritzsche, it always crystallises in forms of the regular system; but, according to Rammelsberg, in rhombohedrons, having the angles of the terminal edges = 86° 18′, and in forms derived therefrom. It dissolves in 32·1 pts. water at 0° C., in 18·5 pts. at 10°, in 14·4 pts. at 20°, in 7·5 pts. at 40°, in 4·4 pts. at 60°, in 2·9 pts. at 80°, and in 2 pts. at 100° (Kremers, Pogg. Ann. xcii. 497; xciv. 255; xcvii. 1; xcix. 25, 58). According to Pohl, 1 pt. of the salt dissolves in 17·5 pts. water at 17° C. The crystals deposited from a solution, either perfectly neutral or slightly acidulated with acetic acid, decrepitate with violence at 300°—350° C., and crumble to a powder, which, if thrown into water, gives off bubbles of pure oxygen gas as it dissolves; but the solution when evaporated yields nothing but pure bromate of potassium, probably reproduced by absorption of oxygen from the air. The crystals deposited from an alkaline solution decrepitate but slightly when heated, and the powder dissolves in water without perceptible evolution of gas. (Fritzsche, J. pr. Ch. xxiv. 285.)

Bromate of potassium is decomposed by strong sulphuric acid, with violent decrepitation and evolution of bromine and oxygen. When heated *per se*, it melts at a temperature above 350° C., and then decomposes, with evolution of oxygen, slowly at first, but afterwards with explosive violence, beginning to glow at one point, and then quickly becoming incandescent through the entire mass. When mixed with combustible bodies, it explodes with great violence when struck or heated.

Bromate of Silver. $AgBrO^3$.—Obtained by precipitation as an amorphous white powder quickly turning grey when exposed to light. According to Rammelsberg, it forms shining quadratic prisms (P : P in the terminal edges = 121° 58·7, in the lateral edges = 86° 38), isomorphous with chlorate of silver. When rapidly heated, it explodes with deflagration, giving off part of the bromine in the form of yellow vapour. It dissolves sparingly in water and in nitric acid, more easily in ammonia, the solution yielding by spontaneous evaporation, colourless prisms, which are quickly decomposed by water, and are very unstable even in the dry state.

Bromate of Strontium. $2SrBrO^3 + aq.$—Small shining rhomboïdal prisms, with truncated lateral edges, isomorphous with the barium-salt. Ratio of axes = 1 : 1·1642 : 1·2292. Inclination of clino-diagonal to principal axis = 89°. The crystals dissolve in 3 pts. of water at ordinary temperatures; do not lose weight over sulphuric acid, become anhydrous at 120° C., and at a higher temperature are quickly resolved into oxygen gas and bromide of strontium.

Bromates of Tin.—*Stannic hydrate* unites slowly with bromic acid, and forms, after drying over oil of vitriol, a vitreous mass, which loses 18 per cent. in weight at 180° C. *Stannous chloride* forms a white precipitate with bromate of potassium.

Uranic Bromate.—A solution of uranic hydrate in bromic acid yields, by evaporation over oil of vitriol, a yellow uncrystallisable syrup which decomposes by evaporation, giving off bromine and leaving a basic salt.

Bromate of Yttrium.—Sparingly soluble in water; remains in the anhydrous state when its solution is evaporated.

Bromate of Zinc. $ZnBrO^3 + 3\,aq.$ — Regular octahedrons modified by cube-faces; isomorphous with the magnesium-salt. It dissolves in 1 pt. water at ordinary temperatures, is permanent in the air, melts in its water of crystallisation at 100° C., and becomes anhydrous at 200°, but undergoes decomposition at the same time, giving off bromine-vapour and oxygen, and leaving pulverulent oxide of zinc. The salt is decomposed by a small quantity of ammonia, but dissolves completely in excess of ammonia, the solution yielding by evaporation over hydrate of potassium:

Ammonio-bromate of zinc, or *bromate of zinc-ammonium*, $2NH^3ZnBrO^3 + 3\,aq.$ in small prismatic crystals, which, when exposed to the air, become moist and yellow, and smell of free bromine. Water and alcohol decompose them with separation of hydrate of zinc. At a gentle heat, the salt decomposes with a loud hissing noise, and gives off bromine together with nitrogen gas and water.

BROMIC SILVER. Native bromide of silver. (See Silver.)

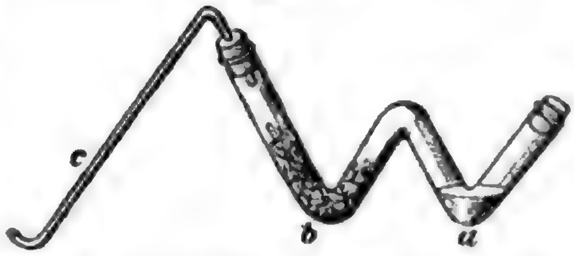
BROMIDES. Compounds of bromine with electro-positive radicles. Bromine, like chlorine, is monatomic, 1 at. of it being capable of uniting with 1 at. of hydrogen or other monatomic radicle, 2 at. of bromine with 1 at. of a diatomic radicle, *e.g.* bromide of ethylene $(C^2H^4)''Br^2$, 3 at. of bromine with 1 at. of a triatomic radicle, *e.g.* bromide of glyceryl $(C^3H^5)'''Br^3$. Bromine is less powerfully electro-negative than chlorine; consequently bromides are for the most part decomposed by chlorine.

Bromide of Hydrogen. Hydrobromic or Bromhydric Acid. HBr.—This compound is gaseous at ordinary temperatures, and is composed of equal measures of bromine-vapour and hydrogen united without condensation. It is not readily formed by the direct union of its elements. A mixture of hydrogen and bromine-vapour does not unite when exposed to the sun's rays; neither does it explode when a red-hot wire or a burning taper is introduced into it; but combination takes place slowly in the immediate neighbourhood of the hot body, and more quickly when the mixture of bromine and hydrogen is passed through a red-hot tube, or when a platinum wire immersed in it is kept red-hot by the electric current.

Preparation.—1. By the action of water on tribromide of phosphorus:

$$PBr^3 + 3H^2O = H^3PO^3 + 3HBr.$$

Fig. 113.



A few grammes of bromine are introduced into the bend *a* of the apparatus (*fig.* 113), and in the bend *b* are placed some small pieces of phosphorus, moistened with water, and separated by pounded glass. The bromine at *a* is gently heated by a spirit-lamp, and the vapour passing over to *b* forms bromide of phosphorus, which is immediately decomposed by the water, yielding phosphorous acid, which remains in the tube, and hydrobromic acid, which passes on through the delivery-tube *c*, and may be collected over mercury.—2. By decomposing bromide of sodium or potassium with strong sulphuric acid:

$$2NaBr + H^2SO^4 = Na^2SO^4 + 2HBr.$$

The hydrobromic acid thus produced is, however, mixed with vapour of bromine and sulphurous anhydride, produced in the manner represented by the equation:

$$2NaBr + 2H^2SO^4 = 2Br + SO^2 + 2H^2O + Na^2SO^4;$$

the bromine may be separated by agitation with mercury; but the sulphurous anhydride is not easily removed.—3. The aqueous solution of the acid may be prepared by decomposing a solution of bromide of barium with sulphuric acid diluted with an equal weight of water, and distilling the filtered liquid.—4. Also by passing sulphuretted hydrogen into a mixture of bromine and water:

$$10Br + 2H^2S + 4H^2O = 10HBr + H^2SO^4 + S$$

The liquid is filtered to separate the precipitated sulphur, and the hydrobromic acid separated from the sulphuric acid by distillation.—5. By the action of bromine on hydriodic acid, on aqueous ammonia, and on many organic compounds, naphthalin, for example.

Properties.—Colourless gas having a very pungent odour, which excites coughing, and a strongly acid taste. Reddens litmus strongly, and excites itching and inflammation when applied to the skin. Fumes in the air more strongly than hydrochloric acid. Specific gravity, by experiment, 2·71 (Löwig); by calculation $\frac{80 + 1}{2} = 40{\cdot}5$, compared with hydrogen, or $40{\cdot}5 \times 0{\cdot}0693 = 2{\cdot}801$ compared with air. Liquefies at −92° F. (−69° C.), and solidifies at −100° F. (−73° C.) (Faraday). It is rapidly and copiously absorbed by water, forming a strongly acid solution, which, when saturated, has a density of 1·29, and fumes strongly in the air. This saturated solution boils at a temperature below 100° C., giving off the gas, and is thereby rendered weaker: a more dilute acid boils at a temperature above 100°, and a very dilute acid becomes stronger by boiling.

Decompositions.—1. The gas is not decomposed by heat alone.—2. *Potassium* introduced into it, even at ordinary temperatures, decomposes it completely, forming bromide of potassium, and leaving a volume of pure hydrogen equal to half that of the original gas. Tin produces the same effect when aided by a gentle heat. This reaction determines the composition of the acid; for the weight of 1 vol. of the gas (the observed specific gravity) diminished by the weight of half a volume of hydrogen, gives a number which is very nearly half the observed specific gravity of bromine (5·54 according to Mitscherlich):

$$2{\cdot}71 - \frac{0{\cdot}0693}{2} = 2{\cdot}68 = \frac{5{\cdot}36}{2}$$

Hence the gas is composed of equal volumes of bromine and hydrogen, united without condensation.—3. The gas, or its aqueous solution, is immediately decomposed by *chlorine*, hydrochloric acid being formed and bromine separated, recognisable by its red colour. *Iodine*, on the contrary, does not decompose hydrobromic acid. Hence the affinity of bromine for hydrogen is, under similar circumstances, less than that of chlorine, and greater than that of iodine.—4. The acid is also decomposed by *oxygen* and by highly oxidised bodies. The aqueous solution turns brown on exposure to the air, from separation of bromine, which remains dissolved. *Nitric acid* also separates the bromine, especially on heating the liquid. The mixture of the two acids dissolves gold, like nitrohydrochloric acid. Strong *sulphuric acid* decomposes it, yielding sulphurous anhydride, bromine, and water:

$$H^2SO^4 + 2HBr = SO^2 + 2H^2O + Br^2.$$

With *bromic acid*, it yields water and free bromine:

$$HBrO^3 + 5HBr = 3H^2O + Br^6.$$

5. With metallic *protoxides*, it forms water and a bromide of the metal: *e.g.* $2HBr + Ag^2O = 2AgBr + H^2O$. With *peroxides*, a similar decomposition takes place, attended also with evolution of bromine: *e.g.* $2HBr + MnO = MnBr + H^2O + Br$.

Combinations. — Hydrobromic acid unites directly with *ammonia* NH^3, forming hydrobromate of ammonia, $NH^3.HBr$, or bromide of ammonium, NH^4Br. Similarly with the compound ammonias, *methylamine*, *ethylamine*, &c., and with *phosphoretted hydrogen*. The aqueous solution dissolves certain *metallic oxides*, viz. the alkalis and earths, forming solutions, which may be supposed to contain hydrobromates of those oxides. It unites with many *hydrocarbons*, *e.g.* with oil of turpentine, forming the compound $C^{10}H^{16}.HBr$.

Bromides, Metallic. MBr. — Bromine unites directly with most metals. Potassium, arsenic, antimony, and tin unite with liquid bromine, producing vivid combustion; bismuth, iron, and mercury combine with it at ordinary temperatures without combustion; but on the application of heat, combustion takes place. Gold combines gradually with bromine at ordinary temperatures; platinum does not. With many metals, the application of heat is necessary to induce combustion. Bromides are also formed by the action of metals on hydrobromic acid gas (p. 672). Vapour of bromine passed over ignited potash, soda, baryta, or lime, forms a bromide of the metal and eliminates the oxygen; bromine decomposes oxide of silver, even at ordinary temperatures. Carbonates are also readily decomposed by it.

Nearly all bromides are soluble in water; bromide of lead however dissolves very sparingly, and bromide of silver and mercurous bromide are quite insoluble. The soluble bromides may all be produced by the action of hydrobromic acid on the corresponding oxides or carbonates; and on evaporating the solutions, water is in most cases given off, the metallic bromide remaining. Some of them, however, viz. the bromides of magnesium, aluminium, and the other earth-metals, are more or less decomposed during the evaporation of the solutions, giving off hydrobromic acid and leaving a mixture of bromide and oxide of the metal.

Metallic bromides are solid at ordinary temperatures; most of them fuse at a moderate heat, and volatilise at higher temperatures. They strongly resemble the chlorides. The bromides of gold and platinum are decomposed by mere exposure to heat; many others give up their bromine when heated in contact with the air. Chlorine, with the aid of heat, drives out the bromine and converts them into chlorides. Hydrochloric acid also decomposes them at a red heat, giving off hydrobromic acid. Strong sulphuric or nitric acid decomposes them, with evolution of hydrobromic acid, which, if the sulphuric or nitric acid is concentrated and in excess, is partly decomposed, with separation of bromine and formation of sulphurous anhydride or nitric oxide (p. 672). Bromides heated with sulphuric acid and peroxide of manganese or chromate of potassium, give off free bromine. If the bromide is quite pure, the evolved bromine is completely decolorised by ammonia; but if chlorine is also present, cholorochromic acid distils over, together with the bromine, and the distillate then forms a yellow liquid with ammonia.

Bromides in solution are easily decomposed by chlorine, either in the form of gas or dissolved in water, the liquid acquiring a red or reddish-yellow colour, according to the quantity of bromine present; and on agitating the liquid with ether, that liquid dissolves the bromine, forming a red solution, which rises to the surface. (See BROMINE.

Soluble bromides give with *nitrate of silver*, a white precipitate of bromide of silver, greatly resembling the chloride, but much less soluble in ammonia; insoluble in hot nitric acid. *Mercurous nitrate* produces a yellowish-white precipitate; and *acetate of lead*, a white precipitate much less soluble in water than the chloride. *Nitrate of palladium* produces in solutions of bromides not containing chlorine, a black precipitate of bromide. Chloride of palladium produces no precipitate; neither does the nitrate, if soluble chlorides are present.

Bromides of Organic Radicles. Bromine unites with organic radicles both basic and acid. The compounds are formed in the same manner as the corresponding chlorides, which they also resemble in most of their properties, though they are less volatile. They contain, in two volumes of vapour, one, two, or three volumes of bromine-vapour, according as the organic radicle which they contain is mono-, di-, or tri-atomic, *e. g.*:

2 vol.	bromide of	trityl	C^3H^7Br	contain	1 vol. bromine
„	„	tritylene	$(C^3H^6)''Br^2$	„	2 vol. „
„	„	glyceryl	$(C^3H^5)'''Br^3$	„	3 vol. „

1. The *bromides of the alcohol-radicles, hydrobromic or bromhydric ethers,* are obtained by distilling the corresponding alcohols with hydrobromic acid or bromide of phosphorus: *e. g.*:

$$\underset{\text{Alcohol.}}{C^2H^5.H.O} + PBr^3 = \underset{\text{Bromide of ethyl.}}{C^2H^5Br} + HBr + \underset{\text{Oxybromide of phosphorus.}}{PBr^3O}$$

Distilled with alkalis, they yield the corresponding alcohol and a bromide of the alkali-metal.

2. The *bromides of acid-radicles* are produced by the action of bromide of phosphorus on the corresponding acids, or by the action of chlorides of acid-radicles on certain metallic bromides: *e. g. bromide of acetyl*, $C^2H^3O.Br$; *bromide of succinyl*, $(C^4H^4O^2)''Br^2$. Alkalis decompose them, with formation of a metallic bromide, and a salt of the corresponding organic acid, *e. g.*:

$$\underset{\text{Bromide of succinyl.}}{(C^4H^4O^2)''Br^2} + 2KHO = \underset{\text{Succinate of potassium.}}{C^4H^4O^2.K^2.O^2} + KBr.$$

3. The *bromides of aldehyde-radicles* are monatomic bromides of the general form, $C^nH^{2n-1}Br$: *e. g. bromide of vinyl*, C^2H^3Br. They are isomeric with the monobrominated diatomic alcohol-radicles, *e.g.* C^3H^5Br, with bromotritylene, $C^3{}^{H^5}_{Br}$. They are volatile liquids, obtained by the action of alcoholic potash on the bromides of the diatomic alcohol-radicles: their properties and reactions are analogous to those of the corresponding chlorides (*q. v.*)

4. Many other organic radicles, such as oil of turpentine, its isomers and homologues, likewise unite with bromine and with hydrobromic acid, forming definite compounds, sometimes liquid, sometimes crystalline, *e.g. bromide of cajputene*, $C^{10}H^{16}Br^4$; *hydrobromate of turpentine-oil*, $C^{10}H^{16}.HBr$, &c.

BROMINDAMITE. See the next article.

BROMINDOPTENE. The name of a doubtful compound, which Erdmann obtained, together with bromisatin and dibromisatin, by the action of bromine on indigo. It was resolved by potash into bromindoptic (bromophenissic) acid, and a volatile body, called by Erdmann bromindamite, but doubtless identical with tribromophenylamine. (Handw. d. Chem. 1te Aufl. iv. 22.)

BROMINE. *Symbol* Br. *Atomic weight* 80.—This element was discovered in 1826 by Balard, who extracted it from the mother-liquor of the salt-marshes of Montpellier. It exists in sea-water; in the water of many salt-springs, especially in that of Theodorshall, near Kreuznach in Prussia, whence a large portion of the bromine of commerce is obtained; and, together with iodine, in the ash of sea-weed (*soude de varech*), whence larger quantities are extracted; also in sponges and many marine animals. As bromide of silver, it is found native in Mexico and Chili, and at Huelgoeth in Bretagne; very small quantities are found in Silesian zinc-ore and in English rock-salt.

Preparation.—1. *From the mother-liquor of sea-water or saline-springs.* After these waters have been freed by crystallisation from the greater part of the chlorides and sulphates of sodium and potassium, the remaining liquid contains bromine, chiefly in the form of bromide of magnesium. This liquid is mixed in a retort with peroxide of manganese and hydrochloric acid, and distilled. Chlorine is then evolved in the liquid, and decomposes the bromide of magnesium, setting free the bromine, which distils over into the receiver, in the form of a heavy dark-red liquid, surmounted by an aqueous solution of bromine.—2. *From the mother-liquor of varec.* This liquid contains iodine and bromine, in the proportion of about 1 pt. bromine to 8 iodine. The iodine is first precipitated either by passing chlorine gas into the liquid, till a sample taken out gives no precipitate either with chlorine-water or with iodide of potassium; or it is precipitated as free iodine and cuprous iodide, by adding cupric sulphate to the liquid: ($Cu^2SO^4 + 2NaI = Na^2SO^4 + Cu^2I + I$). The remaining liquid is then mixed with peroxide of manganese and strong sulphuric acid (the requisite proportions being first determined by trial on a small quantity) and distilled. The bromine then passes over as before, the decomposition being effected in the manner shown by the equation:

$$2MgBr + 2MnO + 2H^2SO^4 = Br^2 + Mg^2SO^4 + Mn^2SO^4 + 2H^2O.$$

The bromine which collects at the bottom of the receiver in either mode of preparation, is separated from the supersaturated aqueous solution by means of a tap-funnel, and further purified by distillation in contact with chloride of calcium. The aqueous solution is shaken up with ether; the red ethereal solution of bromine which rises to the top is treated with caustic potash, till its colour disappears, whereby bromide and bromate of potassium are produced; the liquid is evaporated to dryness; and the residue is ignited in a crucible, to convert the bromate $KBrO^3$, into bromide KBr. The whole quantity thus obtained is decomposed by distillation with peroxide of manganese and sulphuric acid, whereby the remaining quantity of bromine is obtained in the free state.

Commercial bromine is generally contaminated with chlorine, derived either from that which is used to separate it, or from the mother-liquor itself. It may be purified by saturating it with hydrate of barium, whereby bromide, chloride, bromate, and hypochlorite of barium are formed; evaporating and igniting to decompose the oxygen-salts; and treating the residue with alcohol, which dissolves the bromide of barium and leaves the chloride. The pure bromide is then decomposed with sulphuric acid and peroxide of manganese, as above.

Properties.—Bromine is, at ordinary temperatures, a liquid of a deep brown-red colour. It has a peculiar irritating, disagreeable odour; whence its name (*βρῶμος*), and a repulsive taste. It is highly poisonous; a drop placed on the beak of a bird is sufficient to destroy life. Specific gravity 2·966 (Balard); between 2·98 and 2·99 at 15° C. (Löwig); 3·1872 at 0° C. (Pierre). It is a non-conductor of electricity. At −22° C. it solidifies, forming a hard, brittle, laminated mass, having a dark lead-grey colour, and semi-metallic lustre: it retains the solid state for a long time, even at −12° C. It is very volatile; a few drops thrown into a large flask speedily fill it with red vapours. It boils at 63° C. (Pierre); at 58° (Andrews); at 45° (Löwig). Vapour-density 5·54 (Mitscherlich); by calculation, 80 compared with hydrogen; 5·544 (= 80 × 0·0693), compared with air.

Bromine dissolves sparingly in water, more readily in alcohol, and in all proportions in ether. With water at 0° C. it forms a solid hydrate, $Br . 5H^2O$, which is not decomposed between 15° and 20°.

Bromine resembles chlorine in many of its properties. It has a powerful affinity for hydrogen, though not quite so strong as that of chlorine, and hence it acts with energy upon many organic substances. It is a powerful bleaching agent, and corrodes wood and cork, first turning them yellow. A small quantity of it imparts a transient yellow colour to the skin; a larger quantity stains it permanently yellow, then brown, and a still larger quantity produces immediate corrosion and violent inflammation. It colours starch orange-yellow. It decomposes vapour of water when passed with it through a tube heated to bright redness, yielding hydrobromic acid and oxygen. A burning taper introduced into vapour of bromine, burns for an instant with a green light, and is then extinguished.

Bromine decomposes phosphoretted hydrogen, sulphydric acid, hydriodic acid, and metallic iodides, but the resulting bromine-compounds are decomposed by chlorine.

Bromine acts readily on many organic compounds, removing part of the hydrogen in the form of hydrobromic acid, while another portion of bromine takes the place of the hydrogen thus abstracted, 80 pts. bromine being always introduced for every 1 pt. of hydrogen removed. In this manner, bromacetic acid, $C^2H^3BrO^2$, and a considerable number of other brominated compounds, are formed.

Bromine unites with all the elementary bodies, and with many compound radicles. In all its compounds, except those with chlorine, fluorine, oxygen, and perhaps sulphur, it plays the part of the chlorous or electro-negative element. In this respect, it is intermediate between chlorine and iodine, expelling the latter from its combinations with positive radicles, and being itself expelled by the former (see BROMIDES, p. 672). We shall here describe only those compounds in which the bromine is electro-positive, viz. the chlorine, fluorine, oxygen, and sulphur-compounds: the others are described under the several positive radicles.

BROMINE, CHLORIDE OF. Bromine absorbs a large quantity of chlorine gas, forming a reddish-yellow, mobile liquid, very volatile, and giving off dark-yellow, strong-smelling, and tear-exciting vapours, which exert a powerful bleaching action, and in which metals burn quickly to chloride and bromide.

When chloride of bromine is mixed with a small quantity of water, and cooled to 0° C., or when gaseous chloride of bromine is passed through a glass tube moistened with water, the hydrated chloride of bromine is formed, which crystallises in needles or laminæ, and melts at 7° C. to a light yellow liquid. It is decomposed by ammonia, forming nitrogen gas, chloride of nitrogen, and bromide of ammonium. Chloride of bromine dissolves with yellow colour in water. The same solution is obtained by dissolving bromine in saturated chlorine-water; it has the odour and bleaching action of chloride of bromine; decomposes in sunshine into hydrochloric and bromic acids, and is decomposed in like manner by aqueous alkalis, yielding a chloride and a bromate of the alkali-metal. The aqueous solution is decomposed by ether, which separates and dissolves the bromine. (Handw. d. Chem. ii. [2] 475.)

BROMINE, DETECTION AND ESTIMATION OF. 1. *Reactions.*—Free bromine is recognised by its odour, the deep-red colour of its vapour, and the orange-yellow colour which it imparts to gelatinous starch. When it exists in aqueous solution in too small quantity to be recognised immediately, it may be separated by shaking up the liquid with ether, and proceeding as described below.

Bromine in the state of hydrobromic acid or a soluble metallic bromide, is detected by the reactions already described (pp. 672, 673). Small quantities of bromine are most easily recognised by cautiously adding chlorine-water till the solution assumes a red or yellow tint; if too much chlorine be added, chloride of bromine will be formed, which is colourless. On shaking the solution with ether, that liquid dissolves the bromine, and rises to the surface in the form of a red stratum. This may be separated by a pipette, or tap-funnel; neutralised with potash, which decolorises it, converting the bromine into bromide and bromate of potassium; and evaporated to dryness in a porcelain crucible. On igniting the residue, to convert it all into bromide, then introducing it into a test-tube, and heating with sulphuric acid and peroxide of manganese, bromine is given off in red vapours, which, if led into a solution of starch, colour it orange-yellow.

The presence of chlorides does not interfere with this reaction; if, however, the quantity of chlorine is very large compared with that of the bromine, as in saline waters, it is best to concentrate the solution till the greater part of the chlorides crystallise out, and search for bromine in the mother-liquor. If iodine is present, it must first be removed, either by precipitation with chloride of palladium, or by first adding just sufficient chlorine-water to precipitate the iodine, which is sure to be set free before the bromine: in fact, bromine itself separates iodine from its compounds; but the removal of the iodine is absolutely necessary, as its deep violet vapour would disguise the colour of the bromine, unless the quantity of the latter greatly predominated.

The methods of decomposing insoluble bromides will be given further on; likewise the methods of separating bromine from phosphorus, and other non-metallic elements. Bromates are reduced to bromides, either by ignition or by treatment with sulphurous or sulphydric acid.

2. *Quantitative Estimation.*—When bromine is present in a solution in the form of a bromide, it may be precipitated by nitrate of silver, the precipitate of bromide of silver being ignited in a porcelain crucible, with the same precautions as the chloride (see CHLORINE). It contains 42·55 per cent. bromine. If the solution is alkaline, it must be acidulated with nitric acid, added after the precipitation by nitrate of silver; if it were added before, a portion of the bromine might be set free and lost.

Insoluble bromides, *e.g. bromide of lead*, and *cuprous bromide*, may be decomposed by suspending them in water, and passing sulphuretted hydrogen through the liquid. The metal is then converted into sulphide, while hydrobromic acid remains dissolved together with excess of sulphydric acid. This excess may be removed by addition of ferric sulphate, which precipitates sulphur, and in the filtered liquid the bromine may be estimated, as above, by precipitation with nitrate of silver. *Bromide of silver* may also be decomposed by fusion with carbonate of sodium, or, better, with a mixture of carbonate of sodium and carbonate of potassium in equivalent proportion, in a porcelain crucible. The silver is thereby reduced to the metallic state, and may be weighed after washing. The bromine is then estimated by loss.

Another method of decomposing bromide of silver, is to treat it with dilute sulphuric acid and pure metallic zinc. The silver is then reduced by the nascent hydrogen, and the bromine passes into the solution as bromide of zinc. The silver may then be washed and weighed as before. This method, however, is not quite exact (see CHLORINE).—*Mercurous bromide* may be completely decomposed by a solution of pure caustic potash, a solution of bromide of potassium being formed, from which the bromine may be precipitated by nitrate of silver with addition of nitric acid.

Many *oxybromides* which are insoluble in water, are soluble in nitric acid. The acid should be dilute, and if heat is required, the materials must be placed in a flask having a glass stopper, and the heat kept as low as possible, otherwise bromine will escape. The bromine may then be thrown down as bromide of silver.

Volatile bromides, such as the bromides of sulphur, phosphorus, arsenic, and antimony, are completely decomposed by water, the bromine being converted into hydrobromic acid, from which it may be precipitated by nitrate of silver.

Bromates must be reduced to bromides by sulphurous or sulphydric acid; the bromine may then be precipitated by silver-solution, after the excess of the reducing agent has been removed by a ferric salt. Bromates may also be converted into bromides by ignition.

The quantity of *free bromine* in a solution, is estimated by treating it with excess of ammonia, whereby it is completely converted into bromide of ammonium, with evolution of nitrogen. The diluted solution is then treated with nitrate of silver.

Estimation of Bromine in presence of Chlorine.—There is no known method of effecting a complete separation of these elements, and when they occur together, their amounts must be estimated by an indirect method. This is effected by precipitating them both together by nitrate of silver; fusing and weighing the entire precipitate in a porcelain crucible; then remelting it; taking out a convenient portion on the end of a glass rod; cutting it when cold into small shavings; introducing them into a bulb-tube; and igniting them, after weighing, in a current of dry chlorine. The whole of the bromine is then expelled, provided the stream of chlorine is kept up for some time, and nothing but chloride of silver remains. This is weighed, and from its weight, and that of the mixture of chloride and bromide before decomposition, the quantities of chlorine and bromine may be found. For the difference of the weights (d) is clearly the difference between the weight of the bromine expelled and that of the chlorine which has taken its place; and for every 80 pts. of bromine expelled 35·5 pts. of chlorine have come in: hence we have the equations:

$$\mathrm{Br} - \mathrm{Cl} = d : \qquad \frac{\mathrm{Br}}{\mathrm{Cl}} = \frac{80}{35{\cdot}5}$$

$$\text{whence:} \qquad \mathrm{Br} = \frac{80}{80 - 35{\cdot}5}\, d = 1{\cdot}796\, d$$

that is to say: to find the quantity of bromine, *multiply the difference of the weights by* 1·796.

If the quantity of bromine is very small compared with the chlorine, this method does not give exact results. In that case, it is necessary to *concentrate the bromine*, that is, to increase the proportion of it in the precipitate subjected to the experiment. Now when a mixture containing a large quantity of soluble chloride with a small proportion of bromide, is treated with about one-sixth of the quantity of nitrate of silver required for complete precipitation, the whole of the bromine is precipitated, together with a portion of the chlorine. The liquid must be briskly agitated to cause the precipitate to settle down, but no heat must be applied. The precipitate is then to be ignited, weighed, and decomposed in a stream of chlorine in the manner just described. The remainder of the chlorine, now free from bromine, is precipitated as chloride of silver in the usual way. Another method of concentrating the bromine in a mixture of chloride of sodium containing a small quantity of bromide, is to treat the dry mixture with very strong alcohol, which dissolves the whole of the bromide of sodium, but only a small portion of the chloride. The filtered alcoholic solution is then evaporated, the residue is dissolved in water, and the bromine and chlorine are precipitated by nitrate of silver and estimated as before. To estimate the quantity of bromine in sea-water or a brine-spring, the liquid must be evaporated to dryness, a weighed quantity of carbonate of sodium having been previously added to prevent the loss of bromine and chlorine which might arise from the decomposition of the chloride and bromide of magnesium during the evaporation, and the dry residue treated with alcohol as above.

Estimation of Bromine in presence of Iodine.—The iodine is precipitated by chloride of palladium (or by the nitrate, if chlorides are present, p. 674), the excess of palladium removed by sulphuretted hydrogen, the excess of this last reagent by nitric acid or a ferric salt, and the bromine then precipitated by nitrate of silver.

(For other modes of estimation, see CHLORINE and IODINE.)

Field (Chem. Soc. Qu. J. x. 234) has shown that chloride of silver is completely decomposed by digestion with solution of bromide of potassium, the chlorine and bromine changing places; and that both bromide and chloride of silver are decomposed in like manner by iodide of potassium. Hence, if a solution containing chlorine, iodine, and bromine, be divided into three equal parts; each portion precipitated by nitrate of silver; the first precipitate dried and weighed; the second digested with bromide of potassium, then dried and weighed; and the third with iodide of potassium, then dried and weighed, the relative quantities of the three elements may be determined by an extension of the method of calculation above given (see also p. 224). Let the weights of the three precipitates be w, w', and w''; also let the atomic weights of chloride, bromide, and iodide of silver be c, b, and i respectively, and the unknown quantities of chloride, bromide, and iodide of silver, x, y, and z; then we have the three equations:

$$x + y + z = w$$

$$\frac{b}{c}x + y + z = w'$$

$$\frac{i}{c}x + \frac{i}{b}y + z = w''$$

The first and second give: $$x = \frac{c(w - w')}{b - c}$$

Substituting this value in the second and third, they become:

$$y + z = w' - \frac{b(w - w')}{b - c} \quad [= p]$$

$$\frac{i}{b}y + z = w'' - \frac{i(w - w')}{b - c} \quad [= q]$$

whence: $$y = \frac{b(q - p)}{i - b}$$

and: $$z = w - (x + y).$$

For the volumetric estimation of bromine, see ANALYSIS, VOLUMETRIC (p. 267). For the estimation of bromine in organic compounds, see ANALYSIS, ORGANIC (p. 247).

3. *Atomic Weight of Bromine.*—The older determinations of the atomic weight of bromine were much too low. Balard estimated it at 75·8, Liebig at 75·2, Berzelius at 78·2. The most exact determinations are due to Marignac (Biblioth. univ. de Genève, xlvi. 357), who found: 1. That 100 pts. pure silver dissolved in nitric acid and precipitated by bromide of potassium, yielded, as a mean, 174·065 pts. bromide of silver; whence, the atomic weight of silver being 108, that of bromine is $x = 74{\cdot}065 \times \frac{108}{100} = 79{\cdot}91$.—2. That 100 pts. silver required for precipitation, 110·36 pts. bromide of potassium; whence if Ag = 108 and K = 39·1, we have $100 : 110{\cdot}36 = 108 : 39{\cdot}1 + x$; whence $x = 80{\cdot}09$.—3. That 100 pts. bromate of potassium give off by ignition, on the average, 29·723 pts. oxygen, whence Br = 79·97. The mean of all these results is very nearly Br = 80, which is the number now universally adopted. Dumas arrived at the same result by igniting bromide of silver in chlorine gas, and determining the difference of weight thereby produced.

BROMINE, FLUORIDE OF. Fluorine is readily absorbed by bromine. The resulting compound, according to Leeson (Phil. Mag. Dec. 1844, p. 520) is liquid, easily soluble in water, and does not sensibly attack glass. It has been used as a means of accelerating the taking of photographic pictures by the electric light. (Compt. rend. xxxiii. 501.)

BROMINE, OXYGEN-ACIDS OF. The series of oxygen-compounds of bromine is by no means so complete as that of chlorine. No anhydrous oxide of bromine is known, and of the acids, only one has been obtained in the separate state and thoroughly examined, viz. Bromic acid, $HBrO^3$, already described (p. 669). All attempts to prepare a perbromic acid, analogous to perchloric acid, $HClO^4$, have been unsuccessful; but the existence of hypobromous acid, HBrO, is rendered probable by many experiments, though neither the acid itself, nor any of its salts, have yet been obtained in definite form.

When mercuric oxide is added to bromine-water, a sparingly soluble oxybromide of mercury is formed, together with a bleaching liquid, which, by distillation in vacuo, yields a liquid supposed to be *hypobromous acid* (Balard). According to Gay-Lussac, *hypobromous anhydride* may be obtained in the gaseous state in the same manner as hypochlorous anhydride. (See CHLORINE, OXIDES OF.)

When bromine is added to cold dilute aqueous alkalis, a metallic bromide is formed, together with a very small quantity of bromate, and a liquid, which does not smell of bromine, bleaches litmus and indigo and vegetable colours in general, and gives off nitrogen in contact with ammonia. On heating the liquid, no bromine is evolved, but a bromate is formed and the bleaching power is destroyed. These phenomena are precisely analogous to those which are exhibited when chlorine is dissolved in cold alkaline solutions. (See HYPOBROMOUS ACID.)

BROMINE, SELENIDE OF. See Selenium, Bromide of.

BROMINE, SULPHIDE OF. When bromine is brought in contact with flowers of sulphur at ordinary temperatures, a dark brown, fuming, oily liquid is formed, having an odour like that of sulphide of chlorine. It is not altered by cold water; but water at 10° C. decomposes it with slight explosion, forming sulphuric, hydrobromic, and sulphydric acids. When it is distilled, the first third of the distillate appears to consist of Br^2S^2, while the liquid remaining in the retort is a mixture of this compound with another sulphide of bromine, and, even when the distillation is completed, there still remains a viscid liquid containing bromine. (H. Rose, Pogg. Ann. xxviii. 550.)

BROMIODOFORM. $CHBr^2I$.—This compound is produced by treating iodoform with bromine. It is a colourless liquid, which solidifies to a camphorated mass at 0° C.; melts at $+6°$; is very volatile; has a penetrating odour and saccharine taste. It may be regarded as *dibrominated iodide of methyl.* (Sérullas, Ann. Ch. Phys. [2] xxxiv. 225; xxxix. 97.—Bouchardat, J. Pharm. xxiii. 10.)

BROMISATIC ACID. See Isatic Acid.

BROMISATIN. See Isatin.

BROMITE. Native bromide of silver, found in Mexico and in Chili. (See Silver, Bromide of.)

BROMITONIC ACID. See Citraconic Acid, Decompositions of.

BROMLITE. Syn. with Alstonite.

BROMO-COMPOUNDS or **BROMINATED COMPOUNDS.** Compounds resulting from the substitution of bromine for hydrogen, chiefly in organic bodies. They are produced by the action of bromine or of bromide of phosphorus on alcohols, acids, hydrocarbons, &c. Most of them are described under the several principal compounds, *e.g.* Bromobrucine under Brucine, &c.

BROMOFORM. $CHBr^3$.—Produced by the simultaneous action of bromine and caustic potash on wood-spirit, alcohol, or acetone; also by the action of bromine on aqueous citric or malic acid; and by decomposing bromal with alkalis. It is a limpid liquid of specific gravity 2·13, having an agreeable odour and saccharine taste. It is less volatile than chloroform, very little soluble in water, to which, however, it imparts its taste and odour; soluble in alcohol, ether, and essential oils. It dissolves small quantities of sulphur and phosphorus, and a large quantity of iodine. It burns with difficulty. When its vapour is passed through a red-hot tube, it is resolved into charcoal and bromine-vapour. Boiling potash-ley decomposes it more easily than chloroform, yielding formate and bromide of potassium. (Löwig, Ann. Ch. Pharm. iii. 295.—Dumas, Ann. Ch. Phys. [2] lvi. 120.)

BROMOPICRIN. CBr^3NO^2.—A product obtained by distilling picric acid with hypobromite of calcium (p. 923).

BROMOSAMIDE. See Salicylamide.

BROMOTRICONIC ACID. } See Citric and Citraconic Acids, Decompositions by bromine.
BROMOXAFORM. }

BROMUS. A genus of grasses. The ashes of *Bromus erectus* and *Bromus mollis* have been analysed by Way and Ogston (Journal of the Royal Agr. Soc. [2] xii. 530). 100 pts. of *Br. erectus* (air-dried) yielded 59·6 per cent. water, and 2·1 ash; of *Br. mollis*, 76·6 per cent. water and 1·4 ash.

100 pts. of ash were found to contain:

	K^2O	Na^2O	Ca^2O	Mg^2O	Fe^4O^3	SO^3	SiO^2	CO^2	P^2O^5	KCl	NaCl
Br. erectus . .	20·3	. .	10·4	5·0	0·26	5·5	38·5	0·5	7·5	10·6	1·4
Br. mollis . .	30·1	0·3	6·6	2·6	0·21	4·9	33·3	9·1	9·6	. .	3·1

BROMYRITE. Native bromide of silver. See Silver.

BRONZE. An alloy of copper and tin. See Copper.

BRONZITE. *Schillerspar. Diallage fibro-laminaire.*—A mineral belonging to the augite family (p. 476). It is massive, with laminar structure inclining to fibrous. Colour varying from yellowish-brown to pinchbeck-brown. Lustre from mother-of-pearl to bright adamantine (pseudo-metallic). Harder than felspar. Specific gravity 3·201 to 3·25. Like all the augites, it is a metasilicate, its general formula being M^2SiO^3 or $M^2O.SiO^2$, the M^2O denoting lime, magnesia, manganous oxide, and ferrous oxide in variable proportions, the magnesia, however, predominating. It is found in large masses in beds of serpentine.

Delesse examined a mineral from the serpentine of Houx in the Vosges, which resembled bronzite in its large amount of magnesia (56·33 Si^2O; 1·50 Mn^4O^3 and Cr^4O^3; 6·73 Fe^2O; 31·93 Mg^2O; 1·40 Ca^2O; 2·11 loss by ignition); but differed from it in not possessing the same metallic lustre and pinchbeck-brown colour, and in being less distinctly cleavable, especially parallel to oP; specific gravity 3·154 (Ann. Min. [4] xviii. 318). (For other analyses of bronzite, see Gm. Handb. iii. 403, 404; Garrett, Sill. Am. J. [2] xv. 333; Kjerulf, Bischof's Lehrb. d. chem. u. phys. Geolog. ii. 1495.)

BROOKITE. *Jurinite. Arkansite.*—One of the forms of native titanic anhydride TiO^2, which is trimorphous. The crystals belong to the trimetric system, and generally exhibit very complicated combinations, among which we may assume, as the primary form, the pyramid P, in which the lengths of the brachydiagonal, macrodiagonal, and principal axis, are to one another, as 0·5951 : 1 : 0·5558. Angle of the terminal edges in the brachydiagonal section = 135° 46′; in the macrodiagonal section = 101° 37′; and of the lateral edges = 94° 44. The crystals exhibit, together with P, the faces $\infty\bar{P}\infty$ and $\infty\breve{P}2$, likewise other pyramids and horizontal prisms; and are often reduced to the tabular form by predominance of the faces $\infty\breve{P}\infty$. Cleavage parallel to $\infty\bar{P}\infty$. Yellow, red, brown, or black, with adamantine or semi-metallic lustre. Transparent to opaque. Streak yellowish-white. Hardness = 5·5 to 6·0. Specific gravity = 3·85 to 4·22. Brittle. It is found at Oisans in Dauphiné, at Tremadoc in Wales, on the St. Gothard, in the Valorsina and the Griesernthal in Switzerland, at Miask in the Ural, and at Magnet Cove in Arkansas. The crystals from the last-mentioned locality, were at first regarded as a distinct species, called *Arkansite.* (Kopp, Handw. d. Chem. ii. [2] 521; Krystallographie, p. 256.)

BROSSITE. A variety of bitterspar from the Brossa valley in Piedmont and other localities, distinguished by a rather large amount of iron. A specimen from Traversella, analysed by Hirzel (Zeitsch. f. Pharm. 1850, p. 24), yielded 11·13 per cent. ferrous carbonate.

BROUSONETTIA TINCTORIA or *Morus tinctoria.* — The plant which yields yellow-wood. (See MORUS and MORINTANNIC ACID.)

BROWN BERRIES. — The fruit of *Rubus fructicosus.* See RUBUS.

BRUCINE. *Canimarine. Vomicine.*—$C^{23}H^{26}N^2O^4 + 4H^2O$ (Pelletier and Caventou (1819), Ann. Ch. Phys. [2] xii. 118; xxvi. 53.—Pelletier and Dumas, *ibid.* xxiv. 176.—Corriol, J. Pharm. xi. 495.—Liebig, Ann. Ch. Phys. [2] xlvii. 172; Ann. Ch. Pharm. xxxi. 50.—Regnault, Ann. Ch. Phys. [2] lxviii. 113). This vegetable alkaloid exists, together with strychnine, in nux vomica (the seed of *Strychnos nux vomica*), in the bean of St. Ignatius (the seed of *Strychnos Ignatii*), in the wood of *Strychnos Colubrina*, and in *upas tieute*, an extract prepared from the bark of the *Strychnos tieute*, and used by some of the natives of the East Indian Archipelago, for poisoning their arrows. It also exists in large quantity, and unaccompanied by strychnine, in false angustura bark, originally supposed to be the bark of *Brucia antidysenterica*, but now ascertained to belong to a species of strychnos, probably *Strychnos nux vomica.*

Preparation.—1. *From false angustura bark.*—The pulverised bark is treated with ether to remove fatty matter, then digested in strong alcohol; the dry alcoholic extract is dissolved in water; the colouring matter precipitated by subacetate of lead; the excess of lead removed by sulphuretted hydrogen; and the liquid, which contains the brucine in solution, is boiled with magnesia, again filtered and evaporated. The brucine is thus obtained in the form of a granular mass, generally coloured. To purify this product, it is saturated with oxalic acid; the oxalate of brucine is washed with absolute alcohol cooled to 0° C. which dissolves the colouring matter, then redissolved in water, and decomposed by lime or magnesia; and the brucine thus set free, is redissolved in alcohol and crystallised by slow evaporation (Pelletier and Caventou). Thénard (Traité de Chimie, 6th ed. iv. 281), recommends as an economical mode of preparing brucine, to treat the bark with boiling water, add oxalic acid to the aqueous decoction, concentrate by evaporation, and purify the oxalate of brucine with cold alcohol, as above.

2. *From the seeds of Strychnos nux vomica, &c.* — The mother-liquors obtained in the preparation of strychnine from these seeds (see STRYCHNINE), contain brucine, which may be obtained from them by concentrating to the consistence of syrup, and slightly supersaturating with dilute sulphuric acid. The mixture, if left to itself for a few days, deposits crystals of sulphate of brucine, which are to be pressed, redissolved in boiling water, and decolorised by animal charcoal. The brucine is then separated by ammonia.

Properties.—Brucine crystallises by slow evaporation from its solution in hydrated alcohol, in oblique rhomboïdal prisms, often rather large, and sometimes agglomerated in heads like mushrooms. By rapid crystallisation from boiling water, nacreous laminated masses are obtained, having the aspect of boric acid. The crystals contain 4 at. water of crystallisation (= 15·45 per cent.); they effloresce quickly in dry air, and melt in their water of crystallisation at a little above 100° C. They dissolve in 850 pts. of cold, and 500 pts. of boiling water; they are very soluble in alcohol, sparingly in essential oils, insoluble in ether and in fat oils. The alcoholic solution turns the plane of polarisation to the left; specific rotatory power = $-61° 27'$. Acids diminish the rotatory power.

Brucine is poisonous, and acts on the animal economy like strychnine, but with much less energy.

Decompositions.—1. Strong *nitric acid* colours brucine deep red, forming a peculiar nitro-compound (cacotheline), and evolving nitrite of methyl, together with nitric oxide and carbonic anhydride, this last not being a direct product of the reaction, but resulting from the decomposition of oxalic acid previously formed. (Strecker, Ann. Ch. Pharm. xci. 76.)

$$C^{23}H^{26}N^2O^4 + 5HNO^3 = \underset{\text{Cacotheline.}}{C^{20}H^{22}N^4O^9} + \underset{\substack{\text{Nitrite of}\\ \text{methyl.}}}{CH^3.NO^2} + \underset{\substack{\text{Oxalic}\\ \text{acid.}}}{C^2H^2O^4} + 2NO + 2H^2O$$

The addition of protochloride of tin to the mixture changes the red colour to a fine violet. This, together with the red colour first produced, is quite characteristic of brucine, and serves to distinguish it from other alkaloids.—2. Strong *sulphuric acid* imparts to brucine, first a rose, then a yellow, and then a yellowish-green colour.—3. Brucine boiled with peroxide of lead and excess of sulphuric acid, forms a brown or red mass. This character further distinguishes brucine from strychnine, which, when treated with sulphuric acid and peroxide of lead, assumes a blue colour, changing through violet and red to yellow.—4. Brucine distilled with *sulphuric acid and peroxide of manganese*, gives off inflammable vapours and a liquid (probably hydrate of methyl), which burns with a blue flame; the same liquid is produced on treating brucine with mercuric oxide, or with sulphuric acid and chromate of potassium, carbonic and formic acids being likewise evolved in the latter case.—5. *Chlorine* does not produce immediate turbidity in a solution of brucine, but colours it yellow, and afterwards red; this last colour disappears after a while, the liquid at the same time depositing yellow uncrystallisable flakes.—6. *Bromine* dissolved in alcohol, quickly attacks brucine, colouring it violet. With a weak solution of bromine and sulphate of brucine, a resinous matter is formed, together with *bromobrucine*.—7. *Iodine* forms with brucine two peculiar compounds. Iodide of ethyl converts it into *hydriodate of ethylbrucine.*

Combinations.—The SALTS OF BRUCINE have a bitter taste, and are for the most part crystallisable. Strong nitric acid colours them red. They are decomposed, not only by mineral alkalis, but also by morphine and strychnine, which precipitate the brucine. When diluted with water and mixed with a slight excess of tartaric acid, they are not precipitated by acid carbonates of alkali-metals.

ACETATE OF BRUCINE is very soluble and uncrystallisable.

CHLORATE OF BRUCINE.—Transparent rhombs. Decomposes suddenly when strongly heated.

HYDROCHLORATE OF BRUCINE, $C^{23}H^{26}N^2O^4.HCl$, or *Chloride of Brucium*, $C^{23}H^{27}N^2O^4.Cl$ (at 140° C.) A solution of brucine in dilute hydrochloric acid, yields the salt on cooling in crystalline tufts, moderately soluble in water. The *chloromercurate*, $C^{23}H^{26}N^2O^4.HCl.2HgCl$, is obtained as a crystalline magma on mixing the alcoholic solutions of the two component salts; and if the mass be heated with a small quantity of alcohol and strong hydrochloric acid, the liquid on cooling, deposits the double salt in long needles, which must be washed, first with a large quantity of water, and then with strong alcohol.

The *chloroplatinate*, $C^{23}H^{26}N^2O^4.HCl.PtCl^2$, is obtained as a precipitate of a fine yellow colour, by mixing a solution of sulphate of brucine with dichloride of platinum.

HYDROFERROCYANATES OF BRUCINE.—Three of these salts are known: α. $4C^{23}H^{26}N^2O^4.4HCy.2FeCy + 2H^2O$. Precipitated on mixing a solution of ferrocyanide of potassium with nitrate of brucine, in shining needles, sparingly soluble in cold, more soluble in hot water and alcohol; very hygroscopic. When heated to 100° C. or boiled with water, it decomposes, giving off hydrocyanic acid, and depositing a blue precipitate. β. The alcoholic solutions of brucine and hydroferrocyanic acid form a white amorphous precipitate soluble in excess of brucine. It is nearly insoluble in water and in alcohol, has an acid reaction, and is rapidly decomposed by heat. γ. A cold solution of brucine forms with ferricyanide (red prussiate) of potassium, a deep yellow crystalline precipitate, which appears to be more stable than the salt, &c. (Brandes, Ann. Ch. Pharm. lxvi. 266.)

HYDROFLUATE OF BRUCINE.—A solution of brucine in warm, moderately concentrated hydrofluoric acid, deposits, on cooling, small colourless prisms, moderately soluble in water, sparingly in boiling alcohol, nearly insoluble in cold alcohol. Gives off 3·34 per cent. water at 100° C.

Hydriodate of Brucine. $C^{23}H^{26}N^2O^4.HI + aq.$—Rectangular laminæ, or very short prisms; sparingly soluble in cold, more soluble in hot water; dissolves in alcohol more readily than in water. (Regnault.)

Iodate of Brucine.—A solution of brucine in iodic acid, not in excess, yields by evaporation two salts, viz. an acid salt, which crystallises in hard, transparent, four-sided prisms, and an opaque silky salt, which appears to contain an excess of base.

Iodides of Brucine. α. $(C^{23}H^{26}N^2O^4)^2.I^3$.—Orange-yellow precipitate, obtained by adding to a cold alcoholic solution of brucine, a quantity of tincture of iodine not sufficient to form the compound β. (Analysis 33·3 per cent. iodine; calc. 32·4 per cent.)

β. $C^{23}H^{26}N^2O^4.I^3$.—Produced by triturating brucine with excess of iodine, either in powder or in alcoholic tincture. Brown powder soluble in hot alcohol. Treated with a hot dilute acid, it gives off iodine and yields a salt of brucine. With nitrate of silver, it gives a precipitate of iodide of silver. Gave by analysis 36·13 per cent. C; 3·69 H, and 45·66 I; calc. 35·8 C, 3·4 H, and 48·9 I. (Pelletier, Ann. Ch. Phys. [2] xliii. 176.)

Nitrate of Brucine. $C^{23}H^{26}N^2O^4.HNO^3 + 2aq.$—A solution of brucine in dilute nitric acid yields this salt in colourless four-sided prisms, bevelled at the summits. Less soluble in water than nitrate of strychnine.

Oxalate of Brucine crystallises in long needles, especially when the acid is in excess. Sparingly soluble in absolute alcohol.

Perchlorate of Brucine.—Small prisms, sparingly soluble in cold water, more soluble in hot water and in alcohol. Gives off 5·4 per cent. water at 170° C., and explodes at a higher temperature.

Periodate of Brucine crystallises from an alcoholic solution by evaporation at 30° or 40° C. in beautiful colourless needles, which are decomposed by heat with a slight noise. Moderately soluble in water and alcohol; the solutions turn brown when exposed to the air. (Bödeker, Ann. Ch. Pharm. lxxi. 64.—Langlois, Ann. Ch. Phys. [3] xxxiv. 278.)

Phosphates of Brucine. α. $(C^{23}H^{26}N^2O^4)^2.H^3PO^4$, or $(C^{23}H^{27}N^2O^4)^2.H.PO^4$. (at 100° C.)—A solution of brucine in tribasic phosphoric acid yields the salt, when concentrated, in large shortened prisms, having a faint yellowish colour, sparingly soluble in cold water, but dissolving in any proportion in hot water. Neutral to litmus paper. The crystals contain water, which they lose on exposure to the air. At 100° they fuse in their water of crystallisation to a resinous mass, from which it is difficult to expel the last traces of water.—β. *Acid Salt.* Obtained by using an excess of acid. Crystallises in large rectangular plates, very soluble and efflorescent.—γ. *Phosphate of Brucine and Soda* $C^{23}H^{26}N^2O^4.NaH^2PO^4$ (at 100° C.) Obtained by digesting brucine with ordinary phosphate of sodium. Short opaque prisms. (Anderson, Phil. Mag. [3] xxxiii. 163.)

Picrotoxate of Brucine crystallises from a boiling solution in white, silky, flexible needles.

Sulphate of Brucine.—The *normal salt*, $(C^{23}H^{26}N^2O^4)^2.H^2SO^4 + 7aq.$ is obtained by saturating brucine with dilute sulphydric acid. Long needles, very soluble in water, sparingly in alcohol; gives off its water at 130° C. *An acid sulphate* is obtained by crystallising the normal salt with sulphuric acid, and removing the excess of acid by washing with ether.—*Double sulphates.* On adding brucine to a solution of sulphate of copper or iron, part only of the metallic base is precipitated.

Sulphocyanate of Brucine. $C^{23}H^{26}N^2O^4.HCyS$.—Obtained by saturating an alcoholic solution of brucine with a moderately concentrated solution of sulphocyanic acid. Colourless scales, anhydrous, soluble in water, infusible at 100° C.

Tartrates of Brucine. α. *Normal tartrates.* $(C^{23}H^{26}N^2O^4)^2.C^4H^6O^6 + 5\frac{1}{2}aq.$ 8 aq. and 14 aq.—Obtained in limpid well-defined crystals by dissolving 2 at. brucine in a hot aqueous solution of 1 at. tartaric acid. Very soluble in hot, sparingly in cold water.—α. The *tartrate* (dextro-rotatory) is deposited immediately in limpid laminæ, containing 8 at. water, 7½ at. of which are given off at 100° C., and the remainder at 150° (in all 13·22 per cent.; by calculation 13·18 per cent.) Crystallised from 95 per cent. alcohol, the same salt contains only 5½ at. water, or 11 at. water to 2 at. of the salt, 5 of which are given off at 100° C., and the remainder at 150° (in all 10 per cent.; by calculation 9·5 per cent.) The *antitartrate* (lævo-rotatory) always contains $14H^2O$, whether crystallised from water or from strong alcohol. It effloresces quickly in summer; gives off 20·66 per cent. water at 100°, and 1 per cent. more at 150° (in all 21 per cent. = 14 at.)

β. *Acid tartrates.* $C^{23}H^{26}N^2O^4.C^4H^6O^6 + 5aq.$—Obtained by mixing brucine and tartaric acid in equal numbers of atoms. The *tartrate* precipitates immediately and completely, as a granular crystalline powder. It is always anhydrous, whether crystallised from water or from alcohol. Begins to decompose at about 200° C. The *antitartrate* contains 5 at. water (calc. 15·7 per cent.; exp. 14·5 per cent.): gives off 13·3 per cent. (4½ at.) at 100°, the rest at 150°. Very soluble in hot, sparingly in cold water. Effloresces easily in dry air. (Pasteur, Ann. Ch. Phys. [3] xxxviii. 472.)

THIOSULPHATE, OR HYPOSULPHITE OF BRUCINE $(C^{23}H^{26}N^2O^4)^2.H^2S^2O^3 + 5aq.$ (air-dried), is formed when a solution of brucine, mixed with alcohol and sulphide of ammonium, is exposed for some time to the air. It crystallises in prismatic needles, which dissolve in 105 pts. of cold water, and give off 1 at. water when dried over oil of vitriol. (How, Ed. N. Phil. J. [new ser.] vol. xcviii).

Substitution-derivatives of Brucine.

BROMOBRUCINE, $C^{23}H^{25}BrN^2O^4$.—When a solution of bromine in dilute alcohol is added to an aqueous solution of sulphate of brucine, a resinous substance immediately forms: and if the addition of the bromine be continued till two-thirds of the brucine is converted into this substance, the decanted solution then precipitated by ammonia, the precipitate dissolved in very weak alcohol, and boiling water containing a little alcohol poured by small portions into the liquid, and afterwards a little pure water, also boiling, a slight turbidity soon appears; and on leaving the solution to cool, bromobrucine is deposited in small needles, having a slight brown colour. It gave by analysis 17·5 per cent. bromine (calc. 16·9 per cent.) It is not coloured red by strong nitric acid. (Laurent, Ann. Ch. Phys. [3] xxiv. 314.)

ETHYLBRUCINE. $C^{23}H^{25}(C^2H^5)N^2O^4$.—The *hydriodate* of this base is obtained by treating a cooled alcoholic solution of brucine with excess of iodide of ethyl, in crystals containing $2[C^{23}H^{25}(C^2H^5)N^2O^4.HI] + aq.$ insoluble in water, but readily soluble in hot alcohol. Potash does not separate the base from this salt; but on treating the solution with recently precipitated oxide of silver, ethylbrucine [? hydrate of ethylbrucium, $C^{23}H^{25}(C^2H^5)N^2O^4.H.O$, analogous to hydrate of ammonium] is obtained. This base dissolves readily in water, alcohol, and ether, but cannot be obtained in the solid state. The solution has a strong alkaline reaction, precipitates ferric oxide, zinc-oxide, and alumina, redissolving the two latter in excess. It decomposes ammonia-salts, and absorbs carbonic acid from the air. With nitric acid, it gives the same red colour as brucine. It neutralises acids completely. The nitrate and hydrochlorate crystallise, their solutions however becoming coloured during evaporation. The hydrochlorate forms with dichloride of platinum a crystalline double salt, containing $C^{23}H^{25}(C^2H^5)N^2O^4.HCl.PtCl^2$. (Gunning, J. pr. Chem. lxvii. 46.)

BRUCITE. *Nemalite. Lancasterite. Native Magnesia.*—MgHO, the magnesium being sometimes partly replaced by iron. Crystallises in rhombohedral forms. Primary form R = 82° 15′, generally forming the combinations oR . ∞ R. Cleavage very easy parallel to the base. It is usually foliated or massive; also fibrous, the fibres being separable and elastic. Hardness = 1·5. Specific gravity 2·35 (Hardinger). White inclining to grey, blue or green, with pearly lustre. Streak white. Transparent in various degrees, sometimes translucent on the edges only. Sectile. Flexible in thin laminæ. Gives off water when heated, but does not fuse. Dissolves in acids without efflorescence. It accompanies other magnesian minerals in serpentine, in Unst, one of the Shetland isles, where it is sometimes found in regular crystals; at Pyschminsk in the Ural; at Goujat in France; at Hoboken New Jersey; and in the State of New York. (Dana, ii. 133.)

The name *Brucite* is also used as a synonyme of CHONDRODITE (*q. v.*)

BRUNOLIC ACID. A substance obtained by Runge from coal-tar naphtha (Pogg. Ann. xxi. 65, 315; xxxii. 308). When the alkaline liquid obtained by treating coal-tar naphtha with milk of lime, is mixed with an acid, a mixture of phenic or carbolic acid, rosolic acid and brunolic acid separates out; and on distilling this mixture with water, the phenic acid passes over, leaving a brown pitchy residue, containing rosolic and brunolic acid. When this mixture is dissolved in a small quantity of alcohol, and milk of lime added, a rose-coloured solution is formed, containing rosolate of calcium, while brunolate of calcium separates as a brown precipitate, which when decomposed by hydrochloric acid, yields brunolic acid in brown flakes. It appears to combine with bases, but neither the acid itself nor any of its salts have yet been obtained in a definite state.

BRUNSWICK-GREEN. A green pigment consisting of oxychloride of copper, $Cu^8Cl^2O^3 = 2CuCl.3Cu^2O$, prepared by moistening copper turnings with hydrochloric acid or solution of sal-ammoniac, and leaving them in contact with the air. The oxychloride then forms on the surface, and is washed off with water, and dried at a gentle heat. (See COPPER.)

BRYOIDIN. One of the constituents of the resin of arbol-a-brea (p. 354).

BRYONIN. The bitter principle of the root of the red-berried bryony (*Bryonia dioica*). It may be obtained by treating the root with boiling water, precipitating the filtered liquid with subacetate of lead, decomposing the precipitate with sulphuretted hydrogen, evaporating the filtered liquid, and exhausting the residue with alcohol (Brandes and Firnhaber, Brandes' Arch. Pharm. iii. 356). It is a yellowish-white mass, sometimes red or brownish; tastes sweetish at first, then styptic and very bitter. Soluble in water and alcohol, insoluble in ether. Sulphuric acid dissolves it, forming a blue liquid, which changes to green. It is not altered by alkalis. The aqueous solution forms white precipitates with nitrate of silver, mercurous nitrate, and subacetate of lead. Bryonin acts as a drastic purgative, and in large doses is poisonous. (Gerh. Traité, iv. 274.)

According to Walz (Chem. Centralb. 1859, p. 5), the alcoholic extract of bryony root contains two bitter substances, bryonin and bryonitin, which may be separated by treating the aqueous infusion of the alcoholic extract with subacetate of lead, which precipitates the greater part of the bryonitin, leaving bryonin in solution. *Bryonin*, when freed from adhering resin by treatment with absolute ether, is a white or slightly coloured granular substance, transparent in thin layers, and according to Walz, contains $C^{48}H^{80}O^{19}$; but the simpler formula, $C^{5}H^{8}O^{2}$, agrees well enough with the results of the analysis. It appears to be a glucoside, and is resolved by boiling with dilute sulphuric acid, into glucose, and two amorphous bodies, viz. bryoretin, soluble in ether, and hydrobryoretin, insoluble in ether, but soluble in alcohol:

$$\underset{\text{Bryonin.}}{C^{48}H^{84}O^{21}} = \underset{\text{Bryoretin.}}{C^{21}H^{35}O^{7}} + \underset{\text{Hydro-bryoretin.}}{C^{21}H^{37}O^{8}} + \underset{\text{Glucose.}}{C^{6}H^{12}O^{6}}$$

Bryonitin forms a white crystalline mass, soluble in water and ether, insoluble in alcohol. Walz regards the bryonin of Brandes and Firnhaber as an impure substance.

BRYORETIN. See the last article.

BUBULIN (from βοὸς, ox). The name of a peculiar substance, said by Morin to exist in cow-dung, and to be copiously precipitated by metallic salts, tincture of galls, and alum, and therefore to be active in the application of cow-dung to calico-printing.

BUCHOLZITE. A silicate of aluminium, varying in composition between $Al^{4}O^{3}.SiO^{2}$ and $2Al^{4}O^{3}.3SiO^{2}$, and probably nothing but fibrous disthene mixed with quartz. (See DISTHENE and SILLIMANITE.)

BUCKLANDITE. See EPIDOTE.

BUCKTHORN. See RHAMNUS.

BUCKWHEAT. *Polygonum fagopyrum*, and *P. tartaricum*.—A plant indigenous in Asia, but much cultivated in the North of Europe, where the flour is used for food. The dry plant yields on the average, 43 per cent. by weight of grain, and 57 straw.

The seed of buckwheat contains on the average:

	Air dried.	Anhydrous.
Nitrogenous matter	8·6	10·0
Starch, &c.	51·9	60·5
Woody fibre, &c.	23·1	26·9
Ash	2·2	2·5
Water	14·2	

Pierre (Compt. rend. xlvi. 203) found in 100 pts. of buckwheat-seed, 2·1 pts. nitrogen, 0·5 phosphoric anhydride, and 3·2 fat; in 100 pts. of commercial buckwheat flour: 1·3 pts. nitrogen; in 100 pts. of the coarse yellow flour: 5·6 nitrogen, 2·4 phosphoric anhydride, and 7·2 fat; in the bran, 2·4 nitrogen, 1·2 phosphoric anhydride, and 4·8 fat. Mulder found in 100 pts. of buckwheat flour 7·5 pts. nitrogenous constituents, and the same in the bran.

Composition of the Ash of the Grain and Straw of Buckwheat.

	Grain.			Straw.					
	1	2	3	4	5	6	7	8	9

1. Analysed by Bichon (Ann. Ch. Pharm. l. 419). 2, 3. By Sprengel (J. techn. Chem. vi. 402; x. 350). 4—9. By Wolff (J. pr. Chem. lii. 65). 4. Straw of buckwheat grown in unmanured soil; 5, on soil manured with chloride of sodium; 6. with nitrate of potassium; 7, with potashes; 8, with sulphate of magnesium; 9, with lime.

Sprengel found in the air-dried straw, 3·20 per cent. ash.

Colouring Matters of Buckwheat.—The leaves contain a yellow colouring-matter, first observed by Nachtigal (Jahresber. f. Chem. 1849, p. 713), further examined by Schunck (Chem. Gaz. 1858, Jan. 18; Jahresber. 1857, p. 489). According to Schunck, its composition may be most simply expressed by the formula, $C^3H^4O^2$, and it is probably identical with *rutin* (*q. v.*), and with Moldenhauer's *ilixanthin.* It crystallises in yellow needles, dissolves sparingly in cold water, more readily in boiling water, more still in alcohol. Alkalis dissolve it, forming a deep yellow solution, from which it is precipitated by acids; if, however, the solution be exposed to the air, the colouring matter is transformed into an amorphous substance, easily soluble in water, and no longer precipitable by acids. Hydrochloric and sulphuric acids change the yellow colour of the crystalline substance to deep orange: but water restores it. Dilute sulphuric acid does not decompose it, even at boiling heat; nitric acid converts it into oxalic acid. With oxide of lead, it forms a bright yellow compound, like chromate of lead, and communicates a bright yellow colour to cotton stuffs mordanted with acetate of alumina. The presence of foreign matters in the crude extract of buckwheat straw, renders the colour somewhat impure. According to Nachtigal, 5 pts. of buckwheat straw contain as much colouring matter as 1 pt. of quercitron. According to Schunck, 1000 pts. of the fresh leaves contain rather more than 1 pt. of pure colouring matter.

Buckwheat straw has been said to yield indigo by fermentation; a statement which, however, is not confirmed by the observation of Schunck (Handw. d. Chem. 2te Aufl. ii. [2] 551. *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 467.)

BUCURUMANGA RESIN. A fossil resin, occurring in an auriferous alluvium near Bucurumanga in New Granada. It is light yellow, transparent, somewhat heavier than water; becomes strongly electric by friction; is insoluble in alcohol; swells up in ether and becomes opaque. It melts when heated, and burns in the air without residue. It resembles amber in outward appearance, but does not yield succinic acid by dry distillation. It contains 82·7 per cent. carbon, 10·8 hydrogen, and 6·5 oxygen. (Boussingault, Ann. Ch. Phys. [3] vi. 507.)

BUENIN. A substance obtained by Buchner, from the bark of *Buena hexandra.*

BUHRSTONE. A cellular flinty quartz rock.

BUKKU LEAVES. The leaves of *Diosma crenata*, a rutaceous plant growing at the Cape of Good Hope. Gassincourt (Buchn. Répert. Pharm. xxvi. 328) found in 1000 pts. of them, besides gum, resin, &c., 6·6 pts. of a volatile oil, having a gold-yellow colour, a sharp irritating taste and odour, lighter than water, and somewhat soluble therein. Brandes (Arch. d. N. Apoth. Ver. xxii. 229) found malic and oxalic acids in the leaves, besides albumin, gum, resins, &c.; and in 1000 pts. 88 pts. volatile oil, and 40 pts. of a yellowish-brown bitter substance, soluble in water, which he called *diosmin.* Landerer (Buchner's Répert. lxxxiv. 63) found in the alcoholic tincture of bukku leaves, a crystalline bitter deposit, which, however, was insoluble in water.

BURATITE. A hydrated carbonate of zinc, copper, and calcium, occurring in verdigris-green, radiated, acicular crystals, or plumose aggregations, of specific gravity 3·32, at Chessy and Frammont in France, and at Volterra and Temperino in Tuscany (Delesse, Ann. Ch. Phys. [3] xviii. 478). It is very variable in composition, and is probably a mixture of several minerals.

BURETTE. See Analysis, Volumetric (p. 256).

BURGUNDY PITCH or **RESIN.** *Poix de Bourgogne, Pix alba, Poix blanche*, is the white pitch obtained from pine-wood. The resin of *Pinus picea* purified by repeated boiling with water, is also called *Burgundy pitch.* (See Pine-resins and Pitch.)

BURSERA GUMMIFERA. *Gommart.*—A terebinthaceous tree growing in the Antilles. It yields a dry white resin having a crystalline fracture, and an odour of turpentine, also like that of elemi. It is but slightly fusible, but diffuses itself through boiling water in small tenacious granules. The resin distilled with water yields 47 per cent. of a coloured volatile oil (*Gommart-oil, Essence de gommart*), which, when purified by standing in contact with potash, then with potassium, and rectification, has the same odour, composition, and vapour-density as oil of turpentine, and forms with hydrochloric acid, two compounds, one of which is crystalline and consists of $C^{10}H^{16}.2HCl$. (H. Deville, Ann. Ch. Phys. [3] xxvii. 90.)

BUSTAMITE. Native silicate of manganese. See Rhodonite.

BUTEA GUM. *Bengal Kino.*—The juice of *Butea frondosa*, Roxb., often sent into the market instead of genuine kino. It forms black-brown, slightly lustrous, brittle lumps, has an astringent taste, and yields pyrocatechin by dry distillation.

BUTIC ACID. A solid fatty acid, which Heintz obtained (Pogg. Ann. xc. 137), though not pure, by partially precipitating an alcoholic solution of the solid fatty acids of butter with acetate of magnesium, this acid then forming the less soluble compound. Heintz is of opinion that in the pure state it would have the composition of arachidic acid $C^{20}H^{40}O^2$. (See p. 353.)

BUTTER. The fatty non-azotised constituent of milk. It is suspended in the milk in minute globules, and rises to the surface, when the milk is left at rest, in the form of cream, together with a certain quantity of casein and the other constituents of the milk. Butter is obtained from cream by agitation or *churning*, which causes the fat-globules to unite in larger masses and separate completely from the watery liquid, called *butter-milk*. Butter thus obtained and in the state in which it is commonly used, consists of $\frac{5}{6}$ pure fat or real butter and $\frac{1}{6}$ of butter-milk, from which it may be separated by melting it in a tall vessel at about 60° C., decanting the clear fat which floats at the top, and washing with water at 40° C. Ordinary butter from cow's milk, is composed, according to Chevreul, of stearin, margarin, and olein, with small quantities of butyrin, caproin, and caprin, to which its odour is due. According to Heintz, it contains olein, a large quantity of palmitin, and a small quantity of stearin, together with very small quantities of glycerides, yielding by saponification, myristic acid and *butic acid*, $C^{20}H^{10}O^2$ (*vid. sup.*)

Butter dissolves in 28 pts. of boiling alcohol of specific gravity 0·82. It is very apt to turn rancid, a change which consists in the separation of the fatty acids from the glycerin, and may be prevented to a certain extent by salting or by melting it, so as to separate the foreign matters which induce the decomposition.

"At Constantinople, the butter brought from the Crimea and the Kirban, is kept sweet by melting it while fresh over a very slow fire, and removing the scum as it rises. By melting butter in this manner, and then salting it, it may be kept good and fine-tasted for two years; moreover, this melting, if carefully done, injures neither the taste nor colour. Thénard too recommends the same method. He directs the the melting to be done on a water-bath, or at a heat not exceeding 140° Fahr.; and to be continued till all the caseous matter has subsided to the bottom, and the butter is transparent. It is then to be decanted, or strained through a cloth, and cooled in a mixture of pounded ice and salt, or at least in cold spring water, othewise it will become lumpy by crystallising, and likewise not resist the action of the air so well. Kept in a close vessel, and in a cool place, it will thus remain six months or more, nearly as good as at first, particularly after the top is taken off. If beaten up with one-sixth of its weight of the cheesy matter when used, it will in some degree resemble fresh butter in appearance. The taste of rancid butter, he adds, may be much corrected by melting and cooling in this manner.

"Another mode of curing butter, is as follows: Take one part of sugar, one of nitre, and two of the best Spanish great salt, and rub them together into a fine powder. This composition is to be mixed thoroughly with the butter, as soon as it is completely freed from the milk, in the proportion of one ounce to sixteen; and the butter thus prepared is to be pressed tight into the vessel prepared for it, so as to leave no vacuities. This butter does not taste well, till it has stood at least a fortnight: it then has a rich marrow flavour, that no butter ever acquires; and with proper care may be kept for years in this climate, or carried to the East Indies, if packed so as not to melt.

"At Kebba, in the interior of Africa, Mungo Park informs us, there is a tree much resembling the American oak, producing a nut in appearance somewhat like an olive. The kernel of this nut, by boiling in water, affords a kind of butter, which is whiter, firmer, and of a richer flavour than any he ever tasted made from cows' milk, and will keep without salt the whole year. The natives call it *shea toulou*, or tree butter. Large quantities of it are made every season." U.

Butter is often largely adulterated with water and salt, which are introduced while the butter is in the melted state and incorporated by stirring till the whole is cold. The proportion of water may be determined very nearly by melting a portion of the butter in a narrow glass vessel, such as a common ounce phial, and leaving it to stand in a warm place till the water settles to the bottom. The quantity of the water should not exceed 1 per cent. The amount of salt is determined by calcination, any quantity beyond 5 per cent. may be regarded as adulteration. Butter is also frequently adulterated with lard, in places where that kind of fat is cheap. (For the preparation of butter, see *Ure's Dictionary of Arts, Manufactures, and Mines*, also *Muspratt's Chemistry*, i. 397.)

BUTTER OF ANTIMONY, TIN, &c. Old names for anhydrous metallic chlorides having a buttery consistence.

BUTYL and derivatives. Syn. TETRYL and derivatives.

BUTYLACTIC ACID. *Oxybutyric acid.* $C^4H^8O^3 = (C^4H^6O)''.H^2.O^2$. (A. Wurtz, Ann. Ch. Pharm. cvii. 197.)—This acid has hitherto been obtained only by the oxidation of amyl-glycol (p. 208); but it might doubtless be produced also by the oxidation of butyl-glycol, as well as by other processes. It is prepared by gently heating 14 pts. of amyl-glycol with 30 pts. nitric acid (HNO^3) and 42 pts. water, and evaporating over quick lime; it then remains in the form of a syrupy liquid.

Butylactic acid bears to butyric acid the same relation that lactic acid bears to propionic acid, and in consequence of this relation, it is regarded as dibasic (see LACTIC ACID), although all the salts yet obtained from it contain but one atom of metal in place of hydrogen. The *barium-salt*, $C^4H^7BaO^3$, is uncrystallisable, dissolves in all proportions, and with moderate facility, in dilute alcohol, but is insoluble in absolute alcohol; ether precipitates it from the alcoholic solution. The *calcium-salt*, $C^4H^7CaO^3$ (dried at 120° C.), separates from the aqueous solution by spontaneous evaporation in warty crystals, which dissolve readily in water and in absolute alcohol, but are insoluble in ether. The *zinc-salt*, $C^4H^7ZnO^3 + aq.$, crystallises in shining laminæ, which dissolve in 160 pts. of water at 15° C., but are insoluble in absolute alcohol. The crystals are permanent in the air, but give off 11 per cent. (2 at.) water at 100° C.

BUTYRACETIC ACID. *Pseudo-acetic Acid.* $C^3H^6O^2$ or $C^2H^4O^2.C^4H^8O^2$.—An acid first obtained by Nöllner in 1841 (Ann. Ch. Pharm. xxxviii. 229), as a product of the fermentation of a mother-liquor from the preparation of tartaric acid containing a considerable quantity of tartrate of calcium, or by converting crude tartar into impure tartrate of calcium, and fermenting the product. Nöllner designated this acid *pseudo-acetic acid*, from its resemblance to acetic acid. Berzelius regarded it as a mixture of acetic and butyric acids. Nicklès, however (Compt. rend. xxxiii. 419), showed that, although this acid is easily resolved into acetic and butyric acids, it is, nevertheless a distinct acid, and gave it the name butyracetic acid. Dumas, Malaguti, and Leblanc (Compt. rend. xxv. 781), showed that it is identical in composition and boiling point with propionic acid, which it also resembles in its other physical properties, and moreover stated that its salts are identical with the propionates in composition and crystalline form. Nicklès, on the other hand, maintained that the salts differ in certain respects from the corresponding propionates. Lastly, the acid has been examined by Limpricht and v. Uslar (Ann. Ch. Pharm. xciv. 321), who have shown that butyracetate of barium yields, by dry distillation, propylal, propione, and propylene (tritylene), in which respect it exactly resembles the propionate, but that, on the other hand, butyracetic acid separates spontaneously or by distillation, into acetic and butyric acids, which is *not* the case with propionic acid. On the whole, therefore, butyracetic acid must be regarded as a distinct acid. It appears to be produced only by the fermentation of tartrate of calcium; acid tartrate of potassium, whether crude or purified, yields by fermentation nothing but acetic acid. According to later experiments of Nicklès (J. Pharm. [3] xxxiii. 351), it is likewise obtained by pouring a mixed solution of equivalent qualities of an acetate and a butyrate into dilute sulphuric acid.

Butyracetic acid resembles propionic acid in most of its properties. It mixes in all proportions with water, and is separated therefrom unaltered by chloride of calcium, a property which distinguishes it from a mere mixture of butyric and acetic acids. According to Dumas, it boils constantly at 140° C.; but, according to Limpricht and v. Uslar, it begins to boil at 120°, at which temperature nearly pure acetic acid passes over, and the boiling point gradually rises to 160°, when butyric acid distils over, the boiling point not remaining stationary for any time at 140°. It does not yield either a definite anhydride or a definite ether, but in both cases a mixture of acetate and butyrate.

Butyracetate of Barium, $C^3H^5BaO^2 + \frac{1}{2}aq.$, resembles the propionate in composition and properties; but on decomposing it with sulphate of copper, the acid which is set free separates into butyric and acetic acids (Nicklès). The *calcium-salt*, $C^3H^5CaO^2$, forms silky needles, or, according to Nicklès, regular octahedrons, which effloresce in the air. The *copper-salt* crystallises in dark blue-green tables, which give off part of their water of crystallisation at 100° C. It rotates on water, dissolves sparingly in water, more easily in alcohol.

The *neutral lead-salt* crystallises from a very concentrated solution at low temperatures in cauliflower-like masses. It melts when heated, giving off part of its acid, and deliquesces in moist air. A concentrated solution, to which chloride of barium is added as long as the precipitate first formed disappears on agitation, yields by slow evaporation, a double salt which crystallises in square prisms containing barium and lead, and likewise chlorine. The *basic lead-salt* is formed by boiling the preceding with oxide of lead. It crystallises from a moderately concentrated solution at a little above 0° C., in octahedrons which contain 42 per cent. water, undergo aqueous fusion below 19°, and dissolve readily in alcohol. From a very concentrated solution or from fusion, it crystallises in tables; at very low temperatures, however, in spherical segments, which, when gently heated, split from the centre outwards with a slight noise. By mixing the boiling solution of the lead-salt with a little ammonia, a crystalline powder is precipitated. (Nöllner.)

The *mercurous salt* crystallises in satiny scales, which are reddened by light. The *potassium-salt* crystallises in very deliquescent thin tables. The *silver-salt* separates on cooling from a boiling solution of the ammonium-salt, mixed with a boiling solution of nitrate of silver, in shining needles resembling acetate of silver and sparingly soluble in water. The *sodium-salt* crystallises from a somewhat dilute solution in deliquescent octahedrons; from a more concentrated solution, as a white tallowy amorphous mass, or as a radio-crystalline mass. The *zinc-salt* is soluble in water, but decomposes by boiling.

BUTYRAL and BUTYRALDEHYDE, C^4H^8O. — Two compounds are known which have the composition of the term in the butyric series corresponding to that of aldehyde in the acetic series; they are not, however, identical.

Butyral was obtained by Chancel (Ann. Ch. Phys. [3] xii. 416), among the products of the destructive distillation of butyrate of calcium. The crude product of this operation is a mixture of several substances, of which butyral, boiling at 95° C. is the most volatile, and can be separated from the others by fractional distillation.

Pure butyral is a colourless, very mobile liquid, with a burning taste, and a sharp and penetrating odour. Its density at 22° C. is 0·821, and it boils at 95°. It dissolves a small quantity of water. It is slightly soluble in water, and soluble in all proportions in alcohol, ether, and wood-spirit. It rapidly absorbs oxygen from the atmosphere, and is converted into butyric acid. It is oxidised by solid chromic acid with a slight explosion. It is very inflammable and burns with a brilliant flame. Heated with water and oxide of silver, it reduces part of the oxide to the state of metallic silver, butyrate of silver remaining in solution. On heating it with sulphuric acid, sulphurous acid is liberated, and a small quantity of butyric acid remains in solution. By dilute nitric acid, it is converted into nitropropionic acid. It forms crystalline compounds with acid sulphites of alkali-metals, analogous to those which aldehyde forms. By the action of pentachloride of phosphorus on butyral, hydrochloric acid, oxychloride of phosphorus, and a peculiar product, C^4H^7Cl, are formed:

$$C^4H^8O + PCl^5 = C^4H^7Cl + HCl + POCl^3.$$

This product is a colourless, oily, very mobile liquid, lighter than water, with a sharp odour and a biting taste. It is insoluble in water, but soluble in alcohol and in ether. It boils at a little over 100° C.; it is inflammable, and burns with a green-edged flame. It is probable that the action of pentachloride of phosphorus on butyral is analogous to its action on aldehyde, and gives rise to the compound $C^4H^8Cl^2$, homologous with chloride of ethylidene (p. 107), and that at the moment of its formation, this substance is decomposed into hydrochloric acid and the body above described.

Chlorinated Derivatives of Butyral. — Chlorine acts very energetically on butyral, with the formation of definite compounds containing chlorine in the place of hydrogen.

Monochlorinated Butyral. C^4H^7ClO.—Produced by passing a current of dry chlorine through butyral by diffused light. The gas is at first absorbed, with evolution of heat and pale red coloration; afterwards the colour disappears and the liquid gives off torrents of hydrochloric acid gas to the end of the operation. A rapid current of carbonic anhydride is then passed through the liquid heated somewhat below its boiling point, and it is then rectified. It is a transparent limpid liquid, heavier than water; boils at 141° C.; has a pungent tear-exciting odour. It is insoluble in water, but dissolves in alcohol, and its alcoholic solution does not cloud nitrate of silver. It does not form an amide with ammonia.

Dichlorinated Butyral, $C^4H^6Cl^2O$.—When dry chlorine is passed for three hours through butyral exposed to sunlight, the action is observed to slacken after some time. If carbonic anhydride be now passed through the liquid, which is afterwards rectified, a neutral oil is obtained boiling at 200° C.

Tetrachlorinated Butyral, $C^4H^4Cl^4O$. — Chlorine is passed for several days through butyral exposed to bright sunshine, the liquid being ultimately heated, and the action continued as long as hydrochloric acid gas continues to be evolved. When purified like the other substances, it forms a thick heavy neutral oil, which boils at a high temperature, with decomposition.

Butyraldehyde. $C^4H^8O = C^4H^7O.H$.—This body was obtained by Guckelberger among the products of the action of oxidising agents on fibrin, albumin, and casein.

For the full details of the process, Guckelberger's paper must be referred to (Ann. Ch. Pharm. lxiv. 39). The crude distillate resulting from the action was neutralised with chalk and distilled. A neutral distillate was obtained which consisted of the aldehydes of the acetic, propionic, butyric, and benzoic series. These were separated by fractional rectification, the portions between 70° and 100° C. which consisted of butyric aldehyde mixed with a little propionic aldehyde, being collected separately. Butyric aldehyde is much less soluble in water than propionic aldehyde, and may be separated from it by agitation with water. To obtain the butyraldehyde quite pure, it is agitated with ammonia, with which it forms a crystalline compound. This is decomposed by the addition of a concentrated solution of alum, the liquid distilled, and the distillate rectified over chloride of calcium.

When pure, it is a thin, colourless, transparent oil, which has the specific gravity 0·80 at 15° C. It boils at 68° to 75°, and has an ethereal, somewhat penetrating odour. The small quantity in which this substance has been found, has prevented its complete investigation; but almost all its properties, as far as they have been examined, are identical with those of butyral. It acidifies in the air; an aqueous solution mixed with ammonia, and then with nitrate of silver until the alkaline reaction disappears, gives, on the application of heat, a beautiful coating of metallic silver on the sides of the vessel. It differs from its isomer chiefly in its boiling point, its density, and in forming a crystalline compound with ammonia, which butyral does not.

Butyraldehyde-ammonia. $NH^3.C^4H^8O + 5aq.$ — Butyraldehyde forms with strong ammonia, a crystalline mass consisting of small acute rhombic octahedrons; from an alcoholic solution, the compound crystallises in large rhombic tables. The dry crystals do not alter in the air, but in the moist state they gradually become brown. Gently heated, they melt, and sublime at a few degrees above 100° C.; more strongly heated, they give off ammonia. Potash does not expel ammonia from them at ordinary temperatures. Aqueous acids or alum separate butyraldehyde. Butyraldehyde-ammonia is almost insoluble in water, but soluble in alcohol, and in ether.

Sulphuretted hydrogen passed into a solution of this body, appears to form a compound homologous with thialdine. When the liquid resulting from this action is treated with ether, a sulphuretted oil is obtained, which forms with hydrochloric acid a solid crystalline compound.

E. A.

BUTYRAMIDE. $C^4H^9NO = \left.\begin{matrix}C^4H^7O\\H^2\end{matrix}\right\}N.$ This compound, homologous with acetamide, is prepared by placing 1 pt. of butyric ether, and 6 pts. of strong aqueous ammonia, in a flask, and frequently agitating the mixture until the action is complete, which generally takes from eight to ten days: the liquid is then evaporated to one-third, and on cooling the butyramide crystallises out:

$$\underset{\text{Butyric ether.}}{C^4H^7(C^2H^5)O^2} + NH^3 = \underset{\text{Butyramide.}}{C^4H^9NO} + \underset{\text{Alcohol.}}{C^2H^6O}$$

It crystallises in snow-white, nacreous, transparent tables, which melt at 115° C. to a colourless liquid, and volatilise without residue. It has a sweet, cooling taste, with bitter aftertaste. It is readily soluble in water, also in ether and in alcohol. Its vapour is inflammable. Passed over red-hot lime, or distilled with anhydrous phosphoric acid, it loses water and yields butyronitrile (cyanide of trityl):

$$\underset{\text{Butyramide.}}{C^4H^9NO} - H^2O = \underset{\text{Butyronitrile.}}{C^4H^7N}$$

Its aqueous solution is decomposed by boiling with fixed alkalis, yielding ammonia and an alkaline butyrate:

$$C^4H^9NO + KHO = C^4H^7KO^2 + NH^3.$$

By pentachloride of phosphorus, it is converted into cyanide of trityl, oxychloride of phosphorus, and hydrochloric acid:

$$C^4H^9NO + PCl^5 = C^4H^7N + POCl^3 + 2HCl.$$

It is decomposed by nitrous acid, with formation of butyric acid, water, and nitrogen:

$$\underset{\text{Butyramide.}}{C^4H^9NO} + \underset{\text{Nitrous acid.}}{HNO^2} = \underset{\text{Butyric acid.}}{C^4H^8O^2} + H^2O + N^2$$

Mercuric Butyramide. C^4H^8HgNO, is obtained by boiling mercuric oxide with solution of butyramide. The filtered solution, when concentrated, deposits the compound in small nacreous crystals, more lustrous than butyramide, which they otherwise resemble.

E. A.

BUTYRIC ACID. $C^4H^8O^2 = \left.\begin{matrix}C^4H^7O\\H\end{matrix}\right\}O.$—Butyric acid is a member of the series of volatile fatty acids, of the general formula $C^nH^{2n}O^2$. It was discovered by Chevreul, who obtained it by saponifying butter with alkalis. It occurs in nature both in the free state, and in combination with bases. It is found in perspiration, in the juice expressed from human flesh, and from that of animals; in crude oil of amber; and in cod-liver oil. It is found in all liquids containing lactic acid, as a product of the transformation of this substance. Butyric acid is also contained, together with several fatty acids of the same series, in combination with glycerin, in butter from cows and goat's milk. This compound of butyric acid with glycerin is inodorous, and it is to its decomposition on standing, by which butyric acid is set free, that the odour of rancid butter is chiefly due. Butyric acid is a frequent product of the oxidation of organic substances, as when fibrin is treated with sulphuric acid and peroxide of manganese, or when oleic acid is oxidised by nitric acid. It has also been found among the products of the destructive distillation of tobacco (Zeise) and of peat (Sullivan, Jahresber. d. Chem. 1858, 280). Lastly, it has been found in several plants, in certain beetles, and in certain mineral waters. (Gm. x. 76; xiii. 388; Handw. d. Chem. ii. [2] 561.)

The most important mode of its formation, and that on which the present methods used for its preparation are based, depends on the metamorphosis which starch, sugar, &c. undergo in the presence of substances which act as ferments. Pelouze and Gélis have found that butyric acid can be obtained from all amylaceous and saccharine matters, which can be transformed into lactic acid, such as cane-sugar, milk-sugar, starch, dextrin, &c. These substances exposed in water to a temperature of 25° to 30° C. in contact with old cheese, or some other decaying nitrogenous substance, first undergo the lactic fermentation, and are ultimately converted into butyric acid. This latter phase is attended with disengagement of carbonic anhydride and hydrogen:

$$\underset{\text{Lactic acid.}}{C^6H^{12}O^6} = \underset{\text{Butyric acid.}}{C^4H^8O^2} + 2CO^2 + H^4.$$

The original process given by Pelouze and Gélis, has subsequently been modified by Bensch, whose method is essentially as follows: 6 lbs. of cane-sugar and ½ an oz of tartaric acid are dissolved in 26 lbs. of boiling water, and left to stand for some days to allow the cane-sugar to pass into grape-sugar. To this solution, about 4 oz. of decayed cheese, diffused in 8 lbs. of sour skim-milk, together with 3 lbs. of chalk, are added, and the whole is left in a place the temperature of which is uniform at about 30—35° C. The mixture is frequently stirred, and generally solidifies after ten or twelve days, to a thick mass of lactate of calcium. If this be allowed to stand under the same conditions, the evaporated water being renewed, it again becomes liquid, gas bubbles rise, and at the expiration of five to six weeks, when the disengagement of gas has ceased, the whole of the lactic acid (and therefore the whole of the sugar), has passed into butyric acid, which is present as butyrate of calcium. The operation seems to succeed best with large quantities of substance.

The above solution of butyrate of calcium is mixed with an equal bulk of water, and a solution of eight pounds of crystallised soda is added, with agitation. The solution filtered off from the carbonate of calcium is evaporated to ten pounds, and decomposed by the careful addition of five and a half pounds of sulphuric acid, previously diluted with an equal weight of water. The greater part of the butyric acid then separates as an oily layer on the surface of the solution of the acid sulphate of sodium, and is removed by means of a tap-funnel. In order to obtain the butyric acid still contained in the solution of sulphate of sodium, it is distilled, the distillate neutralised with carbonate of sodium, evaporated, and the acid separated as before by means of sulphuric acid.

The united portions of crude butyric acid, which, besides water, always contain some sulphate of sodium, are mixed with sulphuric acid (about one ounce to one pound) in order to prevent the separation of neutral sulphate of sodium, which would cause convulsive distillation. The distillate consisting of aqueous butyric acid is mixed with fused chloride of calcium, and rectified. At first, dilute acid passes over accompanied by traces of hydrochloric acid; this afterwards gives place to concentrated acid, which when fractionally distilled, is obtained of a constant boiling point and quite pure. It is better to use sulphuric than hydrochloric acid in the decomposition of butyrate of calcium, as the latter causes the mixture to froth up, and it is difficult to free the butyric acid completely from hydrochloric acid.

Butyric acid may also be prepared by saponifying butter with an alkali, and distilling the soap with sulphuric acid. But this method is never used for the preparation of *pure* butyric acid, as its separation from the accompanying soluble fatty acids is very difficult and troublesome.

Properties.—Butyric acid, when pure, is a colourless, transparent, and very mobile liquid, having an odour suggestive both of vinegar and of rancid butter. It has a very sour and burning taste, and attacks the skin like the strongest acids. It boils at

157° C. under 760 mm. pressure (Kopp), and distils without alteration. Its vapour-density varies with the temperature; at 261° C. it was found to be 3·7, corresponding to 2 vols. The vapour is inflammable, and burns with a blue flame. The density of the liquid acid is 0·9886 at 0° C.; 0·9739 at 15°; and 0·9675 at 25°. It does not solidify at 20°, but in a mixture of solid carbonic acid and ether it crystallises in plates. Butyric acid is soluble in all proportions in water, alcohol, and wood-spirit.

Decompositions.—1. Butyric acid dissolves in *sulphuric acid* without alteration in the cold; at higher temperatures, the greater part distils off unchanged.—2. It also dissolves in *nitric acid* in the cold; by prolonged ebullition with nitric acid of specific gravity 1·40, it is transformed into succinic acid:

$$\underset{\text{Butyric acid.}}{C^4H^8O^2} + O^2 = \underset{\text{Succinic acid.}}{C^4H^6O^4} + H^2O.$$

3. *Iodic acid* does not act upon butyric acid.—4. Butyric acid is energetically attacked by *chlorine*, with formation of hydrochloric acid and of dichlorobutyric acid, $C^4H^6Cl^2O^2$. If the action of the chlorine be continued, the butyric acid is ultimately converted into tetrachlorobutyric acid, $C^4H^4Cl^4O^2$. *Iodine* has scarcely any action on butyric acid.—5. By the action of *pentachloride of phosphorus*, chloride of butyryl, C^4H^7OCl, oxychloride of phosphorus, and hydrochloric acid are formed:

$$\underset{\text{Butyric acid.}}{C^4H^8O^2} + PCl^5 = \underset{\text{Chloride of butyryl.}}{C^4H^7OCl} + POCl^3 + HCl.$$

6. With *pentasulphide of phosphorus*, it forms thiobutyric acid (p. 694).

$$\underset{\text{Butyric acid.}}{5\left(\left.\begin{matrix}C^4H^7O\\H\end{matrix}\right\}O\right)} + P^2S^5 = \underset{\text{Thiobutyric acid.}}{5\left(\left.\begin{matrix}C^4H^7O\\H\end{matrix}\right\}S\right)} + P^2O^5.$$

BUTYRATES.—Butyric acid is monobasic, the butyrates being represented by the general formula $C^4H^7MO^2 = C^4H^7O.M.O.$

When quite dry, they are inodorous; but when moist, they possess a strong odour of butter. They are mostly soluble in water, and crystallisable. Many of them rotate when thrown upon water.

Butyrate of Ammonium, $C^4H^7(NH^4)O^2$.—A deliquescent salt, which gives butyronitrile, C^4H^7N, when distilled with anhydrous phosphoric acid.

Butyrate of Allyl. }
Butyrate of Amyl. } See BUTYRIC ETHERS (p. 695).

Butyrate of Barium. $C^4H^7BaO^2 + 2aq.$—Obtained by neutralising butyric acid with baryta-water. The filtered solution evaporated in the cold yields long flattened prisms, which are quite transparent, and contain 2 at. water. They melt at a temperature below 100° C., without any loss of weight, to a transparent liquid. The salt dissolves in 2·27 pts. of water at 10°, and rotates on the surface. When butyrate of barium is crystallised from a hot concentrated solution, it contains 10·5 per cent. of water = 1 at. water of crystallisation, its formula being $C^4H^7BaO^2 + aq.$

Butyrate of Copper. $C^4H^7CuO^2 + H^2O$.—According to Chevreul, and to Pelouze and Gélis, this salt contains 2 at. water; according to Liès-Bodart, 1 at. water. It is obtained by the addition of a cupric salt to a solution of butyrate of potassium. The bluish-green precipitate formed is crystallised from boiling water, which yields it in crystals of the monoclinic or oblique prismatic system. By prolonged ebullition with water, the salt is partially decomposed into subsalt and free butyric acid. By distillation at about 250° C., butyrate of copper is completely decomposed into a liquid which appears to be pure butyric acid, a gas composed of equal volumes of carbonic oxide and carburetted hydrogen, and a residue of finely divided metallic copper mixed with carbon. When butyrate of copper is rapidly heated to a high temperature, there is produced, along with other substances, a white crystalline body, which is cuprous butyrate. A compound corresponding to Schweinfurt-green (p 15) is obtained by mixing a solution of butyrate of copper with solution of arsenious acid. A yellowish-green amorphous precipitate forms, which afterwards becomes crystalline, and exhibits the pure green colour belonging to Schweinfurt-green. It is a double salt of arsenite and butyrate of copper, $C^4H^7CuO^2.2AsCuO^2$.

Butyrate of Calcium. $C^4H^7CaO^2$ (at 140°C.).—Obtained like the barium-salt. Crystallises in delicate needles; melts on being heated in its water of crystallisation, which it gives off with tolerable facility. The dry salt, on being distilled, gives an oily distillate, consisting principally of butyral and butyrone. This salt rotates when thrown on water. It dissolves in 5·7 pts. of water at 15° but crystallises out so completely when the solution is heated, that the whole becomes solid. On cooling, it again becomes liquid.

Butyrate of Calcium and Barium.—The aqueous solution of 2 pts. butyrate of calcium, and 3 pts. butyrate of barium, deposits octahedrons of this double salt on spontaneous evaporation.

Butyrate of Iron.—Iron does not decompose dilute butyric acid, but gradually oxidises at the expense of a portion of the acid, the oxide combining with the remainder. A yellowish basic salt which separates, appears to be soluble in a large quantity of water.

Butyrate of Ethyl. See BUTYRIC ETHERS (p. 695).

Butyrates of Lead.—The *neutral* salt, $C^4H^7PbO^2$, is obtained in fine silky needles by abandoning the solution of lead-oxide in butyric acid to spontaneous evaporation over oil of vitriol. The same salt is precipitated by butyric acid from a solution of neutral acetate of lead, as a colourless very heavy oil, which solidifies after some time only. *Basic-salt*, $C^4H^7PbO^2.Pb^2O$. Alkaline butyrates give a copious white precipitate with solutions of subacetate of lead. When a mixture of acetic and butyric acids is saturated with lead-oxide, rose coloured crystals of basic butyrate of lead are formed. These are decomposed by the carbonic acid of the air, but are held in solution by the acetate which adheres to them.

Butyrate of Magnesium. $2(C^4H^7MgO^2) + 5aq.$—Beautiful white laminæ, like crystallised boric acid. The water of crystallisation is easily expelled.

Mercurous Butyrate.—White shining scales, like mercurous acetate.

Butyrate of Methyl. See BUTYRIC ETHERS (p. 696).

Butyrate of Potassium. $C^4H^7KO^2$.—Carbonate of potassium is neutralised with aqueous butyric acid, and the solution evaporated. Crystallises in indistinct cauliflower-like groups. Very deliquescent; dissolves in 0·8 of water at 15° C. Rotates on water. There appears to be an *acid* butyrate of potassium. When butyrate of potassium is distilled with an equal quantity of arsenious anhydride, there is obtained, besides secondary products, an oily liquid blackened by reduced arsenic, and smelling like alkarsin; it is either alkarsin or the term corresponding to it in the butyric series (p. 412.)

Butyrate of Sodium is like the potassium-salt, but less deliquescent.

Butyrate of Silver. $C^4H^7AgO^2$.—Butyrate of potassium mixed with nitrate of silver forms white shining scales, like acetate of silver. The salt does not deflagrate when heated, but leaves metallic silver mixed with a little charcoal.

Butyrate of Strontium. $C^4H^7SrO^2$ (dry).—Long flat needles like the barium-salt; fusible; soluble in 3 pts. of water.

Butyrate of Zinc. $C^4H^7ZnO^2$.—Aqueous butyric acid dissolves carbonate of zinc at ordinary temperatures; the filtered solution evaporated in vacuo leaves shining fusible laminæ. The aqueous solution is decomposed by repeated evaporation into basic salt and free butyric acid.

Substitution-derivatives of Butyric Acid.

DIBROMOBUTYRIC ACID. $C^4H^6Br^2O^2$.—Cahours (Ann. Ch. Phys. [3] xix. 495) obtained an acid of this composition, by the action of bromine on citraconate or itaconate of potassium, to which he gave the name *bromotriconic acid.* It is now commonly regarded as a brominated derivative of butyric acid, and as such finds its description here. When bromine is gradually added, until slightly in excess, to a solution of citraconate of potassium in 1½ pts. of water, carbonic acid is evolved, and a heavy yellowish oil is deposited, which is a mixture of two substances, the one an acid, the other a neutral oil. This is washed with water and treated with potash, which dissolves out the acid, and leaves the neutral oil unchanged. On adding dilute acid to the alkaline solution, the acid is deposited sometimes as a heavy yellowish oil, sometimes in fine crystalline needles: the two substances are identical in composition.

The oily acid has a slight amber colour; it has a peculiar odour, feeble at ordinary, but irritating at higher temperatures. It is much heavier than water, in which it is slightly soluble; it is quite soluble in alcohol and in ether. It is partially decomposed by distillation, with formation of hydrobromic acid fumes, and leaves a carbonaceous residue. Sometimes the oily acid changes spontaneously into a mass of crystals. It is attacked by nitric acid with disengagement of red fumes. Strong potash-ley dissolves it, disengaging a peculiar odour, after which the addition of acid no longer precipitates an oil.

The oily acid forms with *ammonia* an acid salt, $C^4H^5(NH^4)Br^2O^2.C^4H^6Br^2O^2$, which crystallises in yellowish white unctuous scales, easily soluble in water and in alcohol. The silver-salt, $C^4H^5AgBr^2O^2$, is obtained by adding nitrate of silver to a solution of the ammonia-salt, as a curdy precipitate, which, after standing some time, unites into a pitchy mass.

Dibromobutyric Ether.—$C^4H^5(C^2H^5)Br^2O^2$, is obtained with difficulty. A solution of the acid in absolute alcohol is saturated at 70°—80°C. with hydrobromic acid gas; the solution is distilled; the distillate is mixed with water, and the resulting precipitate is washed first with dilute carbonate of soda, then with pure water, and finally dried over oil of vitriol. It emits an irritating odour when heated, and has a sharp taste.

Further experiments are required to prove that Cahours' bromotriconic acid is the true dibromobutyric acid, and it is to be regretted that its discoverer should not have fully cleared up this point. Cahours obtained the following results in attempting to obtain dibromobutyric acid directly. Bromine was added to a solution of butyrate of potassium, until a few drops of a brominated acid were precipitated; the whole was then evaporated to dryness, dissolved in alcohol, filtered, and a few drops of sulphuric acid added, which precipitated an acid different from butyric acid and less odorous, but soluble in water and in alcohol. It did not appear to be identical with bromotriconic acid.

DICHLOROBUTYRIC ACID. $C^4H^6Cl^2O^2$. (Pelouze and Gélis, Ann. Ch. Phys. [3] x. 447.)—The best method of preparing this acid is to pass dry chlorine gas in bright sunshine, through about 40 grm. of butyric acid, placed in a Liebig's bulb-apparatus. At first, the absorption is very rapid; subsequently, hydrochloric acid is disengaged, and the liquid assumes a yellowish-green colour. The absorption becomes slower and more difficult, and the current of chlorine must be continued for several days before it ceases to be absorbed. Dry carbonic acid gas is now passed through it, at a temperature of 80°—100° C. to expel the hydrochloric acid: the residue is dichlorobutyric acid.

It is a colourless viscid liquid, heavier than water, and having a peculiar odour, somewhat like that of butyric acid. It is insoluble in water, but entirely soluble in alcohol. It can be distilled to a great extent without alteration, but a portion always decomposes. It burns with a green-edged flame.

Its potassium-, ammonium-, and sodium-salts are soluble. Its silver-salt is sparingly soluble.

Dichlorobutyric Ether, $C^4H^5(C^2H^5)Cl^2O^2$, is prepared by gently heating an alcoholic solution of dichlorobutyric acid with sulphuric acid. An oily compound ether having an ethereal odour, is deposited, which is washed with water and distilled.

TETRACHLOROBUTYRIC ACID. $C^4H^4Cl^4O^2$. (Pelouze and Gélis, *loc. cit.*)—This acid is produced by the continued action of chlorine upon butyric acid in bright sunshine: the chlorobutyric acid at first formed is ultimately converted into a white, solid, crystalline mass, which when pressed between paper, and crystallised from ether, is obtained in the form of white oblique, rhombic prisms, which melt at 140° C., distil without decomposition, and smell like butyric acid. Its silver-salt, $C^4H^3AgCl^4O^2$, is sparingly soluble.

Tetrachlorobutyric Ether. $C^4H^3(C^2H^5)Cl^4O^2$.—In a solution of tetrachlorobutyric acid in several times its bulk of alcohol, the addition of oil of vitriol immediately produces a crystalline mass, which melts at a gentle heat, and separates into two layers, the heavier of which is tetrachlorobutyric ether. It has an ethereal odour, and burns with a green flame, giving off white fumes of hydrochloric acid.

THIOBUTYRIC ACID, $C^4H^8OS = \left.\begin{matrix}C^4H^7O\\ H\end{matrix}\right\}S$. *Sulphobutyric acid.* (Ulrich, Ann. Ch. Pharm. cix. 280.)—This acid is produced by the action of pentasulphide of phosphorus on butyric acid (p. 691). The substances in equivalent quantities are distilled together in a flask furnished with an inverted condensing apparatus, the action, which is violent at first, being assisted towards the end by gentle heating. After it has continued for several hours, the mixture is distilled, and the reddish liquid, which contains butyric acid and dissolved sulphur, as well as thiobutyric acid, is subjected to fractional distillation, the thiobutyric acid passing over at 130° C. It is a colourless liquid, of almost insupportable and persistent odour; boils at 130° C.; is sparingly soluble in water, readily in alcohol, and dissolves sulphur with yellowish colour. With *acetate of lead*, it forms a bulky white precipitate of thiosulphate of lead, C^4H^7PbOS, soluble in a large quantity of hot water, also in hot alcohol, and separating on cooling, in small colourless crystals. The salt decomposes readily, with separation of sulphide of lead.

E. A.

BUTYRIC ANHYDRIDE. *Anhydrous Butyric Acid.* $C^8H^{14}O^3 = \left.\begin{matrix}C^4H^7O\\ C^4H^7O\end{matrix}\right\}O$. (Gerhardt, Ann. Ch. Pharm. lxviii. 127.)—The formation of this body is analogous to that of the organic anhydrides in general, that is to say, it is formed by the action of chloride of butyryl on an alkaline butyrate.

It is prepared by treating 4 pts. of dry butyrate of sodium with **2** pts. of oxychloride of phosphorus, the oxychloride being added drop by drop to the butyrate, as in the preparation of acetic anhydride. The reaction consists of two stages, the first being the formation of chloride of butyryl and phosphate of sodium:

$$3C^4H^7NaO^2 + POCl^3 = Na^3PO^4 + 3C^4H^7OCl,$$

and the second, the formation of butyric anhydride by the action of this chloride on another portion of butyrate of sodium. When the reaction is complete, the mass is distilled, and the distillate redistilled over butyrate of sodium, in order to convert any remaining chloride of butyryl. The distillate from this is finally rectified, those parts only being collected which boil at 190° C.; the portions which pass over below this point contain butyric acid, the formation of which cannot well be avoided, from the deliquescent nature of the butyrate of sodium.

Like acetic anhydride (p. 20), butyric anhydride may be prepared by the action of benzoic chloride on butyrate of sodium. Five pts. of benzoic chloride are mixed with 8 pts. of butyrate of sodium in a retort, and distilled, and the distillate rectified, at first over butyrate of sodium, and then alone.

Butyric anhydride is a colourless, very mobile, and highly refracting liquid, of specific gravity 0·978 at 12·5° C. Its odour is very strong, but not disagreeable, and rather resembling butyric ether than butyric acid. It boils at 190°, and its vapour-density has been found to be 5·38. Exposed to the air, it gradually attracts moisture, and is converted into butyric acid. Poured into water, it does not dissolve like butyric acid, but rises to the surface as a colourless oil. In contact with aniline, it becomes heated, and forms butyranilide (phenylbutyramide):

$$(C^4H^7O)^2O + 2(N.H^2.C^6H^5) = 2(N.H.C^6H^5.C^4H^7O) + H^2O.$$

E. A.

BUTYRIC ETHERS. These compounds are formed from butyric acid by the substitution of 1 at. of an organic radicle, such as ethyl, methyl, &c. for 1 at. of hydrogen. They are for the most part formed by the direct action of butyric acid on the alcohols.

Butyrate of Allyl. $C^7H^{12}O^2 = C^4H^7(C^3H^5)O^2$.—Obtained by distilling butyrate of silver with iodide of allyl. After rectification, it is a colourless oily liquid, lighter than water, soluble in ether, smelling like butyrate of ethyl, and boiling at about 140° C. Heated with potash, it yields allyl-alcohol and butyrate of potassium. (**Cahours** and **Hofmann**, Phil. Trans. 1857, p. 555.)

Butyrate of Amyl. $C^9H^{18}O^2 = C^4H^7(C^5H^{11})O^2$, is a liquid boiling at 17·6° C. (**Delffs**). Specific gravity 0·852 at 15°. Index of refraction = 1·402.

Butyrate of Ethyl. *Butyric Ether.* $C^6H^{12}O^2 = C^4H^7(C{\cdot}H^5)O^2$.—This ether is readily produced by the action of butyric acid on alcohol, sulphuric acid being likewise present. It is also formed, according to Berthelot, by distilling a mixture of 1 pt. common ether, 3 pts. butyric acid, and 7 to 8 pts. sulphuric acid; but the distillate contains a large quantity of free butyric acid. To prepare it, 2 pts. butyric acid are dissolved in an equal weight of strong alcohol, and 1 pt. sulphuric acid is added to the mixture. The liquid becomes heated, and butyric ether immediately rises to the surface; but to complete the transformation, it is necessary to heat the mixture for a short time to about 80° C. The butyric ether is then decanted, shaken up several times with water, finally with addition of chalk and chloride of calcium, then dried over chloride of calcium and distilled.

Butyrate of ethyl is a transparent, colourless, very thin liquid, of specific gravity 0·90193. Boils at 119° C., under a pressure of 0·7465 mm. Vapour-density = 4·04. It has an agreeable odour, like that of pine-apples, and a sweetish taste, with bitter after-taste. It is very sparingly soluble in water, but dissolves in all proportions in alcohol and in ether. It is slowly decomposed by potash, into butyrate of potassium and alcohol.

To the presence of small quantities of butyric ether, the peculiar flavour of pine-apples, melons, and some other fruits, is due. Its formation in the fruit receives an obvious explanation, from the readiness with which the saccharine matters present pass on the one hand, into lactic and butyric acids, and on the other, into alcohol. The pine-flavoured rum, known as pine-apple rum, owes its flavour to the presence of this ether. When freshly distilled from molasses, rum has but little flavour, but this comes out on keeping, owing to the fact that a small quantity of butyric acid contained in it, gradually combines with the alcohol to form ether.

A solution of butyric ether is very extensively used in perfumery, and in confectionery, under the name of pine-apple oil. It is prepared for this purpose by the following process. Butter is saponified by a strong solution of potash-ley; the soap is dissolved in very little absolute alcohol, and to the solution is added a mixture of alcohol and sulphuric acid, until a strongly acid reaction is set up. The whole is then distilled, heat being applied as long as anything comes over with a fruity odour.

Butyrate of Ethylene, $C^{10}H^{18}O^4 = \left.\begin{array}{r}(C^4H^7O)^2\\(C^2H^4)''\end{array}\right\} O^2$, is obtained by heating bromide of ethylene for several days to 100° C. with butyrate of silver and a little free butyric acid, exhausting the product with ether, and distilling fractionally:

$$2(C^4H^7O.Ag.O) + C^2H^4Br^2 = 2AgBr + (C^4H^7O)^2.(C^2H^4)''.O^2.$$

It is a colourless liquid, of specific gravity 1·024 at 0° C.; smells like butyric acid, and boils at 239° to 241° C. (A. Wurtz, Ann. Ch. Phys. [3] lv. 400.)

Butyrate of Glyceryl. See **Butyrins.**

Butyrate of Methyl. $C^5H^{10}O^2 = C^4H^7(CH^3)O^2$.—A mixture of 2 pts. butyric acid with 1 pt. of wood-spirit and 1 pt. of strong sulphuric acid, becomes heated and separates into two layers, the upper of which is butyrate of methyl. In order that the transformation may be complete, it is well to agitate the mixture, and even to maintain it for some time at a temperature of from 50°—80° C. The product is purified like the ethyl-compound.

Butyrate of methyl is a transparent colourless liquid of specific gravity 1·0293. Boils at 102° C. Specific heat is 0·4918. Latent heat of vapour, 87·33. Vapour-density, 3·52. It has a pleasant odour, somewhat resembling that of pine-apples. It is scarcely soluble in water, but perfectly soluble in alcohol and in ether. E. A.

BUTYRIDIN. This name was given by Berthelot to a compound formed from butyric acid and glycerin, to which he at first assigned the formula $C^{14}H^{26}O^7$ ($= 2C^4H^8O^2 + 2C^3H^8O^3 - 3H^2O$), but which he afterwards found to be identical with dibutyrin (p. 695).

BUTYRINS. (Berthelot, Ann. Ch. Phys. [3] xli. 261.)—By the direct action of butyric acid on glycerin, a series of compounds analogous to the acetins is obtained. They are *monobutyrin*, $C^7H^{14}O^4$, *dibutyrin*, $C^{11}H^{20}O^5$, and *tributyrin*, $C^{15}H^{26}O^6$. They contain the elements of glycerin and butyric acid, minus those of water. Their formation may be thus expressed:

$$\begin{array}{cccccccc}
\underset{\text{Glycerin.}}{C^3H^8O^3} & + & \underset{\substack{\text{Butyric}\\\text{acid.}}}{C^4H^8O^2} & - & H^2O & = & \underset{\substack{\text{Mono-}\\\text{butyrin.}}}{C^7H^{14}O^4} \\
\underset{\text{Glycerin.}}{C^3H^8O^3} & + & \underset{\substack{\text{Butyric}\\\text{acid.}}}{2(C^4H^8O^2)} & - & 2H^2O & = & \underset{\text{Dibutyrin.}}{C^{11}H^{20}O^5} \\
\underset{\text{Glycerin.}}{C^3H^8C^3} & = & \underset{\substack{\text{Butyric}\\\text{acid.}}}{3(C^4H^8O^2)} & - & 3H^2O & = & \underset{\text{Tributyrin.}}{C^{15}H^{26}O^6}
\end{array}$$

Viewing glycerin as a triatomic alcohol, we may consider the butyrins as glycerin $\left.\begin{array}{r}C^3H^5{}'''\\H^3\end{array}\right\} O^3$, in which 1, 2, or 3 at. of hydrogen are replaced by the radicle butyryl, C^4H^7O.

The butyrins are decomposed by alkalis, and also by the alkaline earths, baryta and lime, with formation of a butyrate and elimination of glycerin. Dissolved in alcohol and treated with hydrochloric acid, they yield butyric ether and glycerin.

Monobutyrin, $C^7H^{14}O^4 = \left.\begin{array}{r}(C^3H^5)'''\\H^2\\C^4H^7O\end{array}\right\} O^3$.—This body is formed, but only in small proportions, by exposing a mixture of butyric acid with excess of glycerin, to the action of the sun or of diffused daylight for several months. It is also obtained by heating butyric acid with glycerin to a temperature of 200° C. for three hours, care being taken not to exceed this temperature. It is a colourless, neutral, odoriferous, oily liquid, having an aromatic and bitter taste, without any after-taste. At −40° C., it remains liquid, and as mobile as at ordinary temperatures. It rapidly acidifies when exposed to the air.

Dibutyrin, $C^{11}H^{20}O^5 = \left.\begin{array}{r}(C^3H^5)'''\\H\\(C^4H^7O)^2\end{array}\right\} O^3$.—Whenever in the preparation of monobutyrin, the temperature exceeds 220° C., some dibutyrin appears to be formed, but it is best prepared by heating a mixture of glycerin and butyric acid to 275° for several hours. It is a colourless, neutral, oily, odoriferous liquid, of specific gravity 1·081. It volatilises at 320° without perceptible alteration. Cooled down to −40°, it remains liquid, but its fluidity diminishes. By aqueous ammonia, it is decomposed, with formation of butyramide.

Tributyrin, $C^{15}H^{26}O^{6} = \left.\begin{matrix}(C^{3}H^{5})'''\\(C^{4}H^{7}O)^{3}\end{matrix}\right\}O^{3}$. — This substance is formed by heating butyrin with 10 to 15 times its weight of butyric acid to 240° C. for four hours. It is a neutral, oily liquid, with an odour analogous to that of the preceding compounds, and a pungent taste, with irritating aftertaste. It is very soluble in alcohol and ether, but insoluble in water.

Natural Butyrin. — A butyrin which is probably tributyrin, is contained in small quantities in butter, along with caproin, caprin, olein, and margarin. It has not been obtained free from these substances. According to Pelouze and Gélis, this compound may be prepared artificially by gently heating a mixture of butyric acid, glycerin, and concentrated sulphuric acid. On adding a large quantity of water, a slightly yellowish oil separates, which must be washed with water, in which it is insoluble. It is soluble in all proportions in alcohol and ether, from which solutions it is separated by the addition of water. Saponified by potash, it yields glycerin and butyrate of potassium. It has not been obtained pure, and is most probably a mixture of the butyrins above described.
E. A.

BUTYRITE. A compound formed from butyric acid and mannite in the same manner as the butyrins are formed from butyric acid and glycerin. Its properties have not been described. (Berthelot, Compt. rend. xxxviii. 688.)

The same name is sometimes applied to bog-butter (*q. v.*)

BUTYROCHLORHYDRIN. By the action of hydrochloric acid on a mixture of butyric acid and glycerin, a product (first observed by Pelouze) is obtained, which, according to Berthelot (Ann. Ch. Phys. [3] xli. 303), is a mixture of the compounds $C^{3}H^{6}(C^{4}H^{7}O)ClO^{2}$ and $C^{3}H^{5}(C^{4}H^{7}O)Cl^{2}O$, that is to say, of chlorhydrin ($C^{3}H^{7}ClO^{2}$) and dichlorhydrin ($C^{3}H^{6}Cl^{2}O$), in each of which 1 at. H is replaced by butyryl. No method of separating these two compounds has yet been devised.

BUTYROLEIC ACID. Bromeis (Ann. Ch. Pharm. xlii. 63) stated that butter contains an oily acid resembling oleic acid in most respects, but differing from it in not yielding sebacic acid by dry distillation. Bromeis assigned to this acid the formula $C^{34}H^{30}O^{4}.HO$. It appears, however, from the experiments of Gottlieb, that it is really identical with oleic acid, and exhibits the characters observed by Bromeis only after it has been considerably altered by exposure to the air.

BUTYROLIMNODIC ACID. See Bog-butter (p. 617).

BUTYROLACTIC ACID. $C^{7}H^{12}O^{4} = \left.\begin{matrix}(C^{3}H^{4}O)''\\C^{4}H^{7}O\\H\end{matrix}\right\}O^{2}$. — This acid, which is derived from lactic acid, $(C^{3}H^{4}O)''.H^{2}.O^{2}$, by the substitution of 1 at. butyryl for 1 at. hydrogen, has not yet been obtained in the free state; but Wurtz (Compt. rend. xlviii. 1092) has obtained its *ethyl-salt*, $(C^{3}H^{4}O)''.C^{4}H^{7}O.C^{2}H^{5}.O^{2}$, by digesting chlorolactate of ethyl with an alcoholic solution of butyrate of potassium in the water-bath for several days, then filtering to separate chloride of potassium, treating the filtrate with chloride of calcium, and rectifying:

$$\underset{\text{Chlorolactate of ethyl.}}{(C^{3}H^{4}O)''.C^{2}H^{5}.Cl.O} + \underset{\text{Butyrate of potassium.}}{C^{4}H^{7}O.K.O} = KCl + \underset{\text{Butyrolactate of ethyl.}}{(C^{3}H^{4}O)''.C^{4}H^{7}O.C^{2}H^{5}.O^{2}}.$$

It is an oily liquid, of specific gravity 1·024 at 0° C., having an odour something like that of butyric acid, insoluble in water, soluble in alcohol, and boiling between 200° and 210° C. The formation and constitution of this compound tend strongly to support the opinion that lactic acid is dibasic. (See Lactic Acid.)

BUTYRONE. $C^{7}H^{14}O$.—This body is the acetone or ketone of the butyric series, and is, therefore, homologous with acetic acetone. It represents butyral, in which 1 at. of hydrogen in the radicle is replaced by trityl:

$$\underset{\text{Butyral.}}{\left.\begin{matrix}C^{4}H^{7}O\\H\end{matrix}\right\}} \qquad \underset{\text{Butyrone.}}{\left.\begin{matrix}C^{4}H^{6}(C^{3}H^{7})O\\H\end{matrix}\right\}}$$

Its formation is analogous to that of its homologue, acetone. Butyrate of calcium carefully distilled in small portions is decomposed into butyrone and carbonate of calcium:

$$\underset{\text{Butyrate of calcium.}}{2(C^{4}H^{7}CaO^{2})} = \underset{\text{Carbonate of calcium.}}{Ca^{2}CO^{3}} + \underset{\text{Butyrone.}}{C^{7}H^{14}O}.$$

But when larger quantities are decomposed, the results are not so precise. The crude product is composed of at least four substances, butyral, butyrone, and two other substances of the ketone series. The butyrone is obtained pure by rectification, those parts being collected which boil at 140°—145° C. and these are again rectified, until a product of constant boiling point is obtained.

Butyrone, when pure, is a colourless limpid liquid, having a peculiar penetrating odour, and density = 0·83. It boils at 144° C., and its vapour-density has been found to be 4·0, which corresponds to two volumes for the formula $C^7H^{14}O$. Surrounded by a mixture of solid carbonic acid and ether, it solidifies to a crystalline mass. It is insoluble in water, but quite soluble in alcohol. It burns with a luminous flame. It immediately takes fire in contact with chromic acid. It is energetically attacked by nitric acid, with formation of nitropropionic acid, $C^3H^4(NO^2)O^2$, and of an ethereal liquid, which is probably butyrate of trityl, $C^4H^7(C^3H^7)O^2$.

Distilled with pentachloride of phosphorus, butyrone yields a compound, $C^7H^{13}Cl$, which Chancel terms *chlorobutyrone.* It is a colourless liquid, of penetrating odour, lighter than water, and insoluble therein. It boils at 116° C. Its alcoholic solution does not cloud nitrate of silver.

From the crude product of the distillation of butyrate of calcium, two substances with definite boiling points may be separated by treating the crude distillate with acid sulphate of sodium, to remove butyral and butyrone, and subjecting the remaining liquid to fractional distillation. One of these boils at 180° C., and has the specific gravity 0·827. It has the formula $C^8H^{16}O$, which is that of methyl-butyrone, $C^7H^{13}(CH^3)O$, or methyl-œnanthyl, $CH^3.C^7H^{13}O$. The latter view of its composition is suggested by the fact that it yields œnanthic acid when oxidised by nitric acid. The other compound boils at 222° C., and is a pale yellow liquid, which becomes solid at 12° C. Its composition is $C^{11}H^{22}O$, which would correspond to tetryl-butyrone, $C^7H^{13}(C^4H^9)O$, or tetryl-œnanthyl, $C^4H^9.C^7H^{13}O$. It appears to yield butyric and œnanthic acids by oxidation. (Limpricht, Ann. Ch. Pharm. cviii. 183.)

According to Friedel (Ann. Ch. Pharm. cviii. 125), the crude liquid obtained by the distillation of butyrate of calcium, contains, amongst other products, ethyl-butyryl, $C^6H^{12}O = C^2H^5.C^4H^7O$, a colourless liquid having a biting taste, an aromatic odour like that of butyrone, specific gravity = 0·833 at 0° C., and vapour-density = 3·58, and a much smaller quantity of methyl-butyryl, $C^5H^{10}O = CH^3.C^4H^7O$, of specific gravity 3·827 at 0° C., and vapour-density 3·13. E. A.

BUTYRONITRIC ACID. This name has been applied to the product of the action of nitric acid on butyrone.

BUTYRONITRILE or **CYANIDE OF TRITYL.** $C^4H^7N = C^3H^7.CN$.—This body is best prepared by distilling butyrate of ammonium or butyramide with anhydrous phosphoric acid:

$$\underset{\text{Butyrate of ammonium.}}{C^4H^{11}NO^2} - 2H^2O = \underset{\text{Butyronitrile.}}{C^4H^7N.}$$

It is a transparent colourless oil, of specific gravity 0·795 at 12·6° C., and boiling at 118·5°. It has an agreeable aromatic odour resembling that of bitter-almond oil. It dissolves in boiling potash, with evolution of ammonia and formation of butyrate of potassium:

$$\underset{\text{Butyronitrile.}}{C^4H^7N} + KHO + H^2O = \underset{\text{Butyrate of potassium.}}{C^4H^7KO^2} + NH^3.$$

E. A.

BUTYRUM ANTIMONII. A name applied to trichloride of antimony, on account of its buttery consistence and fusibility. Other chlorides of like consistence have also received similar names, *e. g. Butyrum stanni, Butyrum zinci,* &c.

BUTYRUREID. Syn. of BUTYRYL-UREA.

BUTYRYL. C^4H^7O.—The radicle of butyric acid and its derivatives. The following compounds of it are known:

Bromide of butyryl	$C^4H^7O.Br$
Chloride of butyryl	$C^4H^7O.Cl$
Iodide of butyryl.	$C^4H^7O.I$
Hydride of butyryl (butyric aldehyde)	$C^4H^7O.H$
Oxide of butyryl (butyric anhydride)	$(C^4H^7O)^2.O$
Hydrate of butyryl (butyric acid)	$C^4H^7O.H.O$
Butyryl-propyl (butyrone)	$C^4H^7O.C^3H^7$
Butyryl-urea or butyral-urea	$N^2(CO)''.H^3.C^4H^7O.$

The name butyryl has likewise been applied to the hydrocarbon C^4H^7, sometimes regarded as the radicle of butyric acid.

BROMIDE OF BUTYRYL, $C^4H^7O.Br$, is produced by the action of bromide of phosphorus on butyric acid at 90°—100° C., purified by washing with water and rectification. (Béchamp.)

CHLORIDE OF BUTYRYL. $C^4H^7O.Cl$.—This body, like its homologue, chloride of acetyl, is produced by the action of 1 at. oxychloride of phosphorus on 3 at. butyrate of sodium:

$$\underset{\text{Butyrate of sodium.}}{3C^4H^7NaO^2} + \underset{\text{Oxychloride of phosphate.}}{POCl^3} = \underset{\text{Chloride of butyryl.}}{3C^4H^7OCl} + \underset{\text{Phosphate of sodium.}}{Na^3PO^4}.$$

The powdered butyrate is gradually added to the oxychloride contained in a retort: for if the oxychloride were at once poured on the butyrate, a large quantity of anhydrous butyric acid would be formed. The mixture is distilled, and the liquid distillate rectified over a small quantity of butyrate of sodium, the temperature being kept as low as possible, in order to prevent the anhydrous acid formed during the rectification from distilling over with the chloride.

Chloride of butyryl is a colourless, mobile, strongly refracting liquid, heavier than water, and fuming slightly in the air. Its boiling point is 95°. It has a pungent odour like both butyric and hydrochloric acids. It is immediately decomposed by water into hydrochloric and butyric acids:

$$\underset{\text{Chloride of butyryl.}}{C^4H^7OCl} + H^2O = \underset{\text{Butyric acid.}}{C^4H^8O^2} + HCl.$$

With butyrate of sodium it yields chloride of sodium and butyric anhydride:

$$C^4H^7OCl + C^4H^7NaO = NaCl + C^8H^{14}O^3.$$

With ammonia it yields butyramide and hydrochloric acid:

$$C^4H^7OCl + NH^3 = C^4H^7O.H^2.N + HCl.$$

Iodide of Butyryl, $C^4H^7O.I$, produced by distilling butyrate of potassium with iodide of phosphorus, is a brownish liquid, which melts in contact with the air, and boils between 146° and 148° C. (Cahours.) E. A.

BUTYRYL-UREA. See Carbamide.

BUXINE. An alkaloid said to exist in all parts of the box-tree (*Buxus sempervirens.*) According to Fauré (J. Pharm. xvi. 428) it is obtained as an uncrystallisable mass, by boiling the aqueous solution of the alcoholic extract of the bark with magnesia, exhausting the resulting precipitate with alcohol, decolorising with animal charcoal, and evaporating. According to Couerbe (J. Pharm. January 1854, p. 51), it may be obtained in the crystalline form by treating the sulphate with nitric acid, whereby an admixed resin is destroyed or rendered insoluble, and precipitating by an alkali.

Buxine has a bitter taste and excites sneezing; it blues reddened litmus-paper; is nearly insoluble in cold water; dissolves readily in alcohol, sparingly in ether; insoluble in alkalis. It is decomposed by nitric acid. Its salts are more bitter than the base itself, and yield a gelatinous precipitate with alkalis. The sulphate is said to form crystalline nodules.

Trommsdorff (Tromm. N. J. xxv. [2] 66) obtained from box-leaves a substance probably identical with Fauré's buxine.

BYSSOLITE. A name applied to the fine capillary implanted crystals of actinolite, found on the St. Gothard and in the Tyrol.

BYSSUS MYTILI. The bundle of threads by which the common muscle (*Mytilus edulis*) adheres to other bodies, consists, according to Scharling (Ann. Ch. Pharm. xli. 48), of a mass resembling horny tissue, containing a small quantity of fat. According to Lavine (J. Chem. méd. xii. 124) it contains the salts which occur in sea-water.

BYTOWNITE. A granular massive mineral occurring in large boulders near Bytown, Canada West. The grains have one perfect cleavage and indications of another oblique thereto. Hardness = 6 to 6·5. Specific gravity 2·80 (Thomson); 2·733 (Hunt). It has a greenish-white colour and vitreous lustre, pearly on the cleavage surface. Translucent. According to Thomson (J. pr. Chem. viii. 489) it contains 47·57 per cent. silica, 29·65 alumina, 9·06 lime, 7·6 soda, 3·57 ferrous oxide, 0·2 magnesia, whence it appears to be a variety of barsowite (p. 517), the alumina being partly replaced by ferric oxide and the lime by soda. T. S. Hunt (Sill. Am. J. [2] xii. 213) regards it as a variety of anorthite. A dark bluish-green granular mineral or rock from Perth, Canada, which has been called Bytownite, is considered by the same chemist as a mixture of bytownite and hornblende.

C

CABBAGE. (See BRASSICA.)—Infusion of red cabbage, obtained by pouring hot water on the leaves, is a convenient test for acids and alkalis. A certain quantity of alkali, just sufficient to neutralise the acid in the juice, turns it blue; any further quantity changes the blue to green; and acids turn it red.

CABBAGIINE. A bitter principle, obtained from the cabbage-tree (*Geoffraga inermis*, or *G. jamaicensis*), also called *Jamaicine* (*q. v.*)

CABOCLE. A mineral resembling red jasper or felsite, found in the diamantiferous sand of the province of Bahia. It has a density of 3·14 to 3·19; scratches glass slightly; turns white before the blowpipe, but does not melt; dissolves partially in warm strong sulphuric acid, leaving a white earthy residue, which dissolves in the acid at a higher temperature, and is precipitated therefrom by water. Damour (L'Institut. xxi. 78) found in the red massive mineral, phosphoric acid, alumina, lime, baryta, ferrous oxide, and water.

CACAO. The seeds or leaves of the *Theobroma cacao* and other species of the same genus (Nat. Ord. *Sterculiaceæ*), natives of South America and the West Indies, which are extensively cultivated in those countries, and in the tropical parts of Asia and Africa, are remarkable for their nutritive properties, and yield the well-known substances, cocoa and chocolate. They contain large quantities of fatty matter and vegetable albumin, and about 2 per cent. of an organic base, *theobromine*, $C^7H^8N^4O^2$, resembling caffeine. The ash is very rich in phosphoric acid. Shelled beans of good quality exhibit, before roasting, the following composition per cent.: 52 cacao-butter, 20 albumin, fibrin, &c., 2 theobromine, 10 starch, 2 cellulose, 4 inorganic matter, and 10 water, besides small quantities of colouring matter and essential oil. (Payen, Traité de Pelouze et Frémy, vi. 529.)

Cacao-beans have also been analysed by Tuchen (Inaugural Dissertation, Göttingen, 1857; and by A. Mitscherlich (*Der Cacao und die Chocolade*, Berlin, 1859), with the following results:

	Tuchen.						Mitscherlich.	
	Guaya-quil.	Suri-nam.	Caracas.	Para.	Marag-nan.	Trinidad.	Guaya-quil.	Caracas.
Theobromine	0·63	0·56	0·55	0·66	0·38	0·48	1·2—1·5	
Cacao-red	4·56	6·61	6·18	6·18	6·56	6·22	3·5— 5	
Cacao-butter	36·38	36·97	35·08	34·48	38·25	36·42	45—49	46—49
Glutin	2·96	3·20	3·21	2·99	3·13	3·15	13—18	
Starch	0·53	0·55	0·62	0·28	0·72	0·51	14—18	13·5—17
Gum	1·58	0·69	1·19	0·78	0·63	0·61		
Extractive matter	3·44	4·18	6·22	6·62	3·32	5·48		
Humic acid	8·57	7·25	9·28	8·63	8·03	9·25		
Cellulose	30·50	30·00	28·66	30·21	29·77	29·86	5·8	
Ash	3·03	3·00	2·91	3·00	2·92	2·98	3·5	
Water	6·20	6·01	5·58	5·55	5·48	4·88	5·6—6·3	
Starch-sugar	—	—	—	—	—	—	0·34	
Cane-sugar	—	—	—	—	—	—	0·26	
	98·38	99·02	99·48	99·38	99·19	99·84		

Mitscherlich's results do not differ from those of Payen, more than might be expected in the analysis of different varieties; those of Tuchen, which differ widely from both the preceding, probably refer to the unshelled beans.

The starch of cacao-beans exhibits granules of peculiar form, quite distinct from those of the cereals and leguminosæ; by this means, the flour of either of the latter may be detected when used to adulterate chocolate.

The ash of the shelled beans has been analysed by Letellier (Pelouze et Frémy, *loc. cit.*), and by Zedeler (Ann. Ch. Pharm. lxxviii. 348), with the following results:

K^2O	Na^2O	Ca^2O	Mg^2O	SO^3	CO^2	P^2O^5	$3Fe^4O^3.P^2O^5$	Cl	SiO^2	
33·4		11·0	17·0	4·5	1·0	29·6		0·2	3·3	(Letellier).
37·14	1·23	2·9	16·0	1·5	1·2	39·6	0·17	1·7		(Zedeler).

The kernels of the theobroma are used as an article of nutriment, either in the natural state, or prepared in various ways. The simplest and best form is that of the seeds roughly crushed, termed *cocoa-nibs*, which, however, require two hours' boiling, as, owing to the peculiar nature of the inner seed-coating, which passes down into the substance of the cotyledons, the prolonged application of heat and moisture is necessary to dissolve the contents. *Flake-cocoa* is merely the seeds crushed between rollers. To prepare *chocolate*, the beans, after being carefully picked, to free them from mouldy or worm-eaten ones, are gently roasted over a fire in an iron cylinder, with holes in the ends to allow the vapour to escape. When the aroma begins to be well developed, the process is considered complete. The beans are then turned out, cooled, and freed from their husks by fanning and sifting. The husks, which often amount to 20 or 25 per cent. of the beans, should not be thrown away, as they contain half their weight of soluble or mucilaginous matter, which yields a tolerable nutriment. The seeds are then converted into a paste, either by trituration in a mortar heated to 130° F., or more generally by a machine impelled by steam, and the paste is put into moulds and sent into the market; it always improves by keeping. Sometimes the beans, before being roasted, are left to rot or ferment in heaps, in order to separate the kernels from the soft pulpy mass which surrounds them in the fruit.

The chocolate of different countries varies according to its mode of preparation, and the ingredients contained in it. When the kernels alone are used, or only a little sugar is added, the chocolate is called "Chocolat de santé." But vanilla, cloves, cinnamon, and other aromatics, are frequently added; also rice, almonds, starch, &c. Simple chocolate is mostly preferred in this country, the perfumed sorts in France, Italy, and Spain, where the consumption is immense. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i.; also *Penny Cyclopædia*, art. THEOBROMA.)

Cacao-butter, or *Cacao-fat*, is extracted from the beans by pounding them in a slightly heated mortar, till they are reduced to a pulp, then adding a small quantity of water, and squeezing the pulp in a cloth between two plates of metal previously heated to the temperature of boiling water. It has an agreeable taste and odour, is white, semi-transparent, insoluble in water, soluble, especially with aid of heat, in alcohol, ether, and oil of turpentine. It has the consistence of suet, melts at 30° C., but does not resume the solid state till cooled to 23°. It consists chiefly of stearin, with a little olein. It is used more in France than in this country, for making soap, candles, and pommade. The soap made from it must not be confounded with that made from *cocoa-nut oil*, which is a very different product, obtained from the cocoa palm (*Cocos nucifera*).

Cacao-red is the colouring matter of cacao-beans. It is separated by precipitating the aqueous or alcoholic decoction of the beans with acetate of lead, and decomposing the washed precipitate with sulphuretted hydrogen. The solution thus obtained is neutral, has a bitter taste, and yields lilac or greyish precipitates with acetate of lead and protochloride of tin; dark green, or brown-green, with ferric salts; and green of various shades, or sometimes violet with ferrous salts; the colour of the precipitate varies in each case, according as the cacao-red in the solution is more or less mixed with other substances.

The solution of cacao-red absorbs oxygen during evaporation, and becomes acid, the colouring matter being in fact converted into a kind of tannic acid. This modified cacao-red gives, for the most part, green precipitates with iron and lead salts; that obtained from Guayaquil cacao, gives pale reddish precipitates with acetate of lead and with lime-water, reddish-white with sulphate of magnesium and ammonium. It is precipitated by gelatin, whereas unaltered cacao-red is not.

The alteration produced by the roasting of cacao-beans, appears to affect the cacao-red more than any of the other constituents.

CACHALAGUA, or **CANCHA LAGUA**, is the South American name of the *Chironia chilensis*, a gentianaceous plant, which, according to Bley (Arch. Pharm. xxxvii. 85), contains resin and a bitter principle.

CACHOLONG. A variety of OPAL (*q. v.*)

CACHOUTANNIC, or **CACHUTIC ACID.** See CATECHU.

CACODYL. See ARSENIDES OF METHYL (p. 403).

CACOTHELINE. $C^{20}H^{22}N^4O^9 = C^{20}H^{22}(NO^2)^2N^2O^5$.—A product of the decomposition of brucine by nitric acid (p. 682). It partly separates in orange-yellow crystalline flakes after the action has ceased, and an additional quantity may be obtained by precipitating the red liquor with alcohol. From a solution in water strongly acidulated with nitric acid, it separates in yellow scales. It is but very sparingly soluble in boiling water, still less in boiling alcohol, and insoluble in ether. When heated, it decomposes suddenly, in the manner characteristic of nitro-compounds. Exposed to diffused light in a stoppered bottle, it soon becomes dark brown on the surface. Potash dissolves it easily, forming a yellowish-brown liquid. Ammonia dissolves it immediately, forming a yellow liquid, which on boiling changes first to green, afterwards to brown. Cacotheline unites with metallic oxides: with baryta, it forms a soluble compound, containing $2C^{20}H^{22}N^4O^9.Ba^2O$. It combines also with acids, but the salts are decomposed by water. When *dichloride of platinum* is added to a solution of cacotheline in hydrochloric acid, the liquid, after a few hours, yields a crystalline precipitate containing 48 per cent. platinum = $C^{20}H^{22}N^4O^9.HCl.PtCl^2$.

When cacotheline is left for some hours in the red nitric solution in which it has been formed, it changes into another body, which has the colour of chrome-yellow, is insoluble in water, and explodes when heated. (Strecker, Compt. rend. xxxix. 62.)

CACOXENE. A native ferric phosphate, found in the Hrbeck mine, near Zbiron in Bohemia, in radiated tufts of yellow or brownish-yellow colour, becoming brown on exposure. Specific gravity = 3·38. Hardness = 3—4. Of the following analyses, *a* and *b* are by von Hauer (Jahrb. geolog. Reichsanst. 1854, 67); *c* by Richardson (Thomson's Mineralogy, i. 476):

	P^2O^5	Fe^4O^3	H^2O	Ca^2O	Mg^2O	SiO^2	
a . .	19·63	47·64	32·73	—	—	—	= 100
b . .	25·74	41·46	32·83	—	—	—	= 100
c . .	20·5	43·1	30·2	1·1	0·9	2·1	= 97·9

a and *c* agree nearly with the formula $2Fe^4O^3.P^2O^5 + 12$ aq., or $3fe^2O.2fe^3PO^4 + 12$ aq. The analysis *b*, which, however, is said by von Hauer to have been made with less pure material, approaches more nearly to $3Fe^4O^3.2P^2O^5 + 20$ aq. Former analyses by Steinmann, which showed 10—11 per cent. alumina, were doubtless made with impure specimens. (Rammelsberg's Mineralchemie, p. 331.)

CACTUS. Vogel obtained from the flowers of *Cactus speciosus*, by extraction with weak alcohol, 30 per cent. of a carmine-red dye, insoluble in ether and in absolute alcohol. The petals, after the removal of this substance, yielded to a mixture of alcohol and ether, from 5 to 10 per cent. of a scarlet substance. Both these colouring matters are soluble in water. (J. Pharm. xxii. 664.)

F. Field (Chem. Soc. Qu. J. iii. 57) has analysed the ash of a species of cactus (not named) growing in Chili. The fresh plant yielded 1·35, the dry plant 16·79 per cent. of ash, containing in 100 pts. 57·15 pts. of soluble and 42·73 of insoluble salts. The air-dried plant yielded 85·09 per cent. water. The composition of the ash per cent. is: 7·83 K^2O, 28·19 Na^2O, 10·65 Ca^2O, 7·75 Mg^2O, 0·34 Mn^4O^3, 6·09 SO^3, 16·49 SiO^2, 6·40 P^2O^5, 1·38 phosphates of calcium, magnesium, and iron, and 14·87 NaCl.

CADET'S FUMING LIQUID. See ARSENIDES OF METHYL (p. 403).

CADIE-GUM. A very pure kind of gamboge, probably from *Hebradendron cambogioïdes*.

CADMIUM. *Symbol* Cd. *Atomic weight* 56. Atomic volume in the gaseous state = 1.

This metal is frequently found associated with zinc, and derives its name from *cadmia fossilis*, a denomination by which the common ore of zinc was formerly known. It appears to have been discovered about the same time (1818) by Stromeyer (Gilb. Ann. lx. 193) and by Hermann (*ibid.* lix. 95, 113; lxvi. 274), but its more exact investigation is due to Stromeyer.

Cadmium occurs in small quantity in several varieties of native sulphide, carbonate, and silicate of zinc, viz. in the radiated blende of Przibram in Hungary, to the amount of 2 or 3 per cent.; in the blende of Nuissière, to the amount of 1·14 per cent.; in silicate of zinc from Freiberg and from Derbyshire; in carbonate of zinc from Mendip; in carbonate and silicate of zinc from the Cumberland mines; in the zinc ores of the Harz and of Silesia. The zinc flowers obtained as a secondary product in the smelting of the Silesian ores, contain, according to Hermann, as much as 11 per cent. of cadmium. Commercial English zinc frequently also contains cadmium. The only pure native compound of cadmium is the sulphide called *Greenockite*, found at Bishopstown in Renfrewshire.

Preparation.—In the process of reducing ores of zinc, the cadmium which they contain comes over among the first products of distillation, owing to its greater volatility. It may be separated from zinc in an acid solution by sulphydric acid, which throws down the cadmium as a yellow sulphide. This sulphide dissolves in concentrated hydrochloric acid, affording the chloride of cadmium, from which the carbonate may be precipitated by an excess of carbonate of ammonia. Carbonate of cadmium is converted by ignition into the oxide; and the latter yields the metal when mixed with one-tenth of its weight of pounded coal, and distilled in a glass or porcelain retort, at a low red heat.

Properties.—Cadmium is a white metal, with a slight tinge of blue. It has a strong lustre, and takes a fine polish; by exposure to the air, it gradually acquires a whitish-grey tarnish. It has a compact texture and fibrous fracture, and easily crystallises in regular octahedrons. It is soft, though harder and more tenacious than tin; very flexible, and crackles like tin when bent; very malleable and ductile. Its specific gravity is, after fusion, 8·604, after hammering, 8·6944. Specific heat 0·05669 (Regnault), 0·0576 (Dulong and Petit). Cadmium melts below a red heat, and volatilises somewhat below the boiling point of mercury without emitting any particular odour. The density of its vapour as determined by experiment at 1040° C. is 3·94, referred to air as unity (Deville and Troost, Ann. Ch. Pharm. cxiii. 46). Now the calculated value for a condensation to 1 vol. is found by multiplying the atomic weight by the density of hydrogen $= 56 \times 0{\cdot}0693 = 3{\cdot}88$. Hence cadmium-vapour follows the usual law of condensation (p. 441).

Cadmium dissolves in hot hydrochloric or dilute sulphuric acid, taking the place of the hydrogen in the acid; but its best solvent is nitric acid. The bromide, iodide, and many of the organic salts of cadmium, the acetate for example, are soluble in water; the rest, *e. g.* the carbonate, borate, phosphate, and arsenate, are insoluble in water, and are obtained by precipitation. Most cadmium-salts are colourless; they have a disagreeable metallic taste and act as emetics. The solutions, even of the neutral salts, redden litmus. Those cadmium-salts which are insoluble in water are soluble in sulphuric, hydrochloric, or nitric acid, also in ammoniacal salts.

Cadmium, in nearly all its compounds with electro-negative elements, plays the part of a monatomic radicle, the chloride being $CdCl$, the oxide Cd^2O, &c.

CADMIUM, ALLOYS OF. But few alloys of cadmium are known. 100 pts. *copper* retain at a red heat 82·2 pts. cadmium, forming an alloy having nearly the composition $CdCu^2$. It is very brittle, has a fine-grained scaly structure, and a yellowish white colour. With *mercury*, cadmium forms a hard, brittle, silver-white amalgam, which crystallises in octahedrons, and contains 21·7 per cent. cadmium $= CdHg^2$. 100 pts. *platinum* retain at a red heat, 117·3 pts. cadmium $= Cd^2Pt$. The alloy is almost silver-white, very brittle, very fine-grained, and refractory in the fire. (Stromeyer.)

CADMIUM, BROMIDE OF. $CdBr$.—Cadmium absorbs bromine-vapour at a heat near redness, forming white fumes of the bromide, which crystallises on cooling, and when strongly heated sublimes in white nacreous laminæ. The *hydrated bromide*, $2CdBr.H^2O$, obtained by dissolving the oxide or carbonate in hydrobromic acid, forms white efflorescent needles, which give off half their water at 100° C., and the rest, without melting, at 200°.

Bromide of cadmium forms crystalline compounds with the bromides of potassium, sodium, and barium. The *barium-salt*, $CdBr.BaBr + 2aq.$, forms large, shining, colourless crystals, isomorphous with the corresponding chloride. A solution of the bromides of cadmium and *potassium* in equivalent proportions, first yields crystals containing $2CdBr.KBr + \frac{1}{2}aq.$, afterwards crystals of $CdBr.KBr$; both compounds resemble the corresponding double chlorides (C. v. Hauer, J. pr. Chem. lxiv. 477; lxvii. 169). A solution of equivalent quantities of bromide of cadmium and bromide of *sodium* yields the compound $2CdBr.NaBr + \frac{5}{2}aq.$ in small, shining, six-sided tables. (Croft, Chem. Gaz. 1856, p. 121.)

CADMIUM, CHLORIDE OF. $CdCl$.—A solution of oxide of cadmium in hydrochloric acid yields a crystalline hydrated chloride, $CdCl.H^2O$; and this when fused yields the anhydrous chloride in the form of a transparent, laminated, pearly mass, which melts at a heat below redness, and sublimes at a higher temperature in transparent micaceous laminæ.

A solution of chloride of cadmium mixed with excess of ammonia yields, by spontaneous evaporation, *ammoniochloride of cadmium*, $NH^3.CdCl$, or *chloride of cadmammonium*, $NH^3Cd.Cl$.—A *triammonio-chloride of cadmium*, $3NH^3.CdCl$, is obtained by exposing dry pulverised chloride of cadmium to the action of gaseous ammonia. It gives off ⅔ of its ammonia when exposed to the air, and is converted into the preceding compound. (Croft, Phil. Mag. [3] xxi. 355.)

Chloride of cadmium forms crystalline compounds with the chlorides of many other metals. These compounds, which have been particularly studied by C. v. Hauer (J. pr. Chem. lxiv. 477; lxvii. 169; Jahresber. d. Chem. 1855, p. 392; 1856, p. 394; Chem. Soc. Qu. J. viii. 250), crystallise by evaporation from mixed solutions of the component chlorides. The following have been obtained:

The *ammonium-salt*, $NH^4Cl.CdCl + \frac{1}{2}aq.$, crystallises in slender needles; the mother-liquor yields by spontaneous evaporation, transparent shining rhombohedrons of $2NH^4Cl.CdCl$.

Potassium-salts. $KCl.2CdCl + \frac{1}{2}aq.$ separates, by spontaneous or by more rapid evaporation, from a solution of 1—2 at. chloride of potassium to 1 at. chloride of cadmium, in fine silky needles, which give off their water at 100° C., and at a higher temperature melt and give off part of their chlorine. The mother-liquor, or a solution of at least 3 at. chloride of potassium to 1 at. chloride of cadmium, yields by spontaneous evaporation, the salt 2KCl.CdCl, in large limpid crystals, somewhat less (?) soluble than the preceding.

Sodium-salt. NaCl.CdCl + $\frac{3}{2}$aq. (air-dried.)—Small, turbid, watery crystals, which give off 1 at. water at 100 C., and the remainder at 150°—160°.

Barium-salt. BaCl.CdCl + 2 aq.—Separates from a solution of equivalent quantities of the two chlorides, in large shining crystals, which are permanent in the air, lose half their water at 100° C., the rest at 160°, and at a red heat give off part of their chlorine, and melt to a colourless liquid, which does not crystallise. According to Rammelsberg's determination, the crystals are monoclinic, the obliquely inclined axes making an angle of 75° 45′. Ratio of the clinodiagonal, orthodiagonal, and principal axis = 0·8405 : 1 : 0·5128. Observed faces, $\infty P . \infty P \infty . (\infty P \infty) . + P . - P . 0P . (2P \infty)$. Inclination of faces, $\infty P : \infty P \infty = 140° 50′$; $\infty P : 0P = 101° 0′$; $0P : + P = 137° 40′$.

Strontium-salt. SrCl.2CdCl + $\frac{7}{2}$aq.—Crystallises from a solution of 1 to 2 at. chloride of cadmium and 1 at. chloride of strontium in transparent, colourless, acuminated crystals.

Calcium-salts.—A solution of 3 at. chloride of calcium to 4 at. chloride of cadmium deposits the salt CaCl.2CdCl + $\frac{7}{2}$aq. in deliquescent bevelled prisms, arranged in stellate groups. A hot concentrated solution of 2 at. chloride of cadmium and 1 at. chloride of calcium deposits, on cooling, large deliquescent crystals of the salt 2CaCl. CdCl + aq.

Magnesium-salts.—A solution of 1 to 2 at. chloride of cadmium to 1 at. chloride of magnesium yields MgCl.2CdCl + 6 aq. in large transparent crystals. From a solution of 2 at. chloride of magnesium to 1 at. chloride of cadmium, the salt 2MgCl.CdCl + 12 aq. separates in deliquescent tabular crystals.

Manganese-salt. MnCl.5CdCl + 6 aq.—Crystallises from a solution of 2 at. chloride of cadmium and 1 at. chloride of manganese, in pale rose-red or colourless prisms.

Iron-salt. FeCl.2CdCl + 6 aq.—Crystallises from a solution of equivalent quantities of the two chlorides, in colourless prisms, which soon turn green and yellow by exposure to the air.

Cobalt-salt. CoCl.2CdCl + 6 aq.—Somewhat deliquescent prisms, of the colour of chloride of cobalt.

Nickel-salts. NiCl.2CdCl + 6 aq. crystallises by spontaneous evaporation from a solution containing the two salts in the required proportions, in dark green prisms; and the mother-liquor, or the original solution, if it contains a slight excess of chloride of nickel, yields 2NiCl.CdCl + 6 aq. in large, dark green, rhombic prisms.

Copper-salt. CuCl.CdCl + 2 aq.—Crystallises from a solution containing equivalent quantities, in slender shining prisms, grouped in tufts, green when moist, blue when dry.

Chloride of cadmium forms double salts with the hydrochlorates of many organic bases. Greville Williams (Chem. Gaz. 1855, 450) obtained the *quinoline-salt*, $C^9H^7N.HCl.2CdCl$, as a hard crystalline mass; and other compounds have been obtained by J. Galletly (Ed. N. Phil. J. iv. 94), viz.:

Cinchonine-salt.	$C^{20}H^{24}N^2O.HCl.CdCl + \frac{1}{2}$ aq.
Morphine-salts.	$C^{17}H^{19}NO^3.HCl.7CdCl + 2$ aq., and $C^{17}H^{19}NO^3.HCl.2CdCl + \frac{3}{2}$ aq.
Narcotine-salt.	Semi-crystalline, sparingly soluble mass.
Nicotine-salt.	$C^{10}H^{14}N^2.2HCl.5CdCl$. Crystallisable.
Lutidine-salt.	$C^7H^9N.HCl.3CdCl$. Very soluble feathery crystals.
Piperine-salt.	$C^{34}H^{38}N^2O^6.2HCl.9CdCl + 3$ aq. Straw-yellow needles.
Strychnine-salt.	$C^{21}H^{22}N^2O^2.HCl.CdCl$. Sparingly soluble in water.
Toluidine-salt.	$2(C^7H^9N.HCl).3CdCl +$ aq. Very soluble scales.

CADMIUM, DETECTION AND ESTIMATION OF. 1. *Blowpipe Reactions.*—All cadmium-compounds, when heated on charcoal in the inner blowpipe flame with carbonate of sodium or cyanide of potassium, give a brown incrustation of cadmic oxide. A little cadmium, in presence of zinc, may be detected by heating the mixture with carbonate of sodium for an instant in the inner flame, when a slight incrustation of cadmic oxide will be formed. Much longer heating is required for the formation of zinc-oxide. With *borax* and *microcosmic salt*, cadmic oxide forms a bead which is yellowish while hot, colourless when cool.

2. *Liquid Reactions.*—*Zinc* immersed in a solution of a cadmic salt, throws down metallic cadmium in dendrites. *Sulphydric acid gas*, passed through cadmium-solutions, even when a large excess of acid is present, precipitates the whole of the cadmium in the form of sulphide, which has a lemon-yellow colour at first, but afterwards becomes orange-yellow. A similar effect is produced by *alkaline sulphydrates*, the precipitate being insoluble in excess. The hydrated sulphides of manganese, iron, cobalt, and nickel, when recently precipitated, likewise throw down sulphide of cad-

mium from cadmic salts (Anthon, J. pr. Chem. x. 353). *Caustic alkalis* throw down white hydrate of cadmium, very easily soluble in a slight excess of ammonia, but insoluble in potash or soda. Sulphydric acid likewise precipitates sulphide of cadmium from the solution in excess of ammonia. The *neutral* and *acid carbonates* of *ammonium, potassium*, and *sodium* throw down white carbonate of cadmium, insoluble in excess of the alkaline carbonates. If the salt contains a large quantity of free acid, the precipitate dissolves in excess of carbonate of ammonia, but not otherwise (Stromeyer). *Phosphate of sodium* throws down white phosphate of cadmium. *Oxalic acid* and *alkaline oxalates* precipitate white oxalate of cadmium, insoluble in alkaline oxalates, but easily soluble in ammonia. The white precipitate produced by *ferrocyanide of potassium*, and the yellow precipitate produced by the *ferricyanide*, are soluble in hydrochloric acid. The addition of hyposulphite of sodium and hydrochloric acid does not produce a precipitate of sulphide of cadmium; neither is any precipitate produced by chromic acid, succinic acid, alkaline benzoates, or tincture of galls.

Cadmium is the only metal which forms a yellow sulphide insoluble in sulphide of ammonium.

3. *Quantitative Estimation.*—Cadmium is best precipitated from its solutions by carbonate of sodium; it is thereby obtained as a carbonate, which, by ignition, yields the brown oxide containing 87·5 per cent. of the metal.

4. *Separation from other Elements.*—From the metals of the second and fourth groups, and from all non-metallic elements except selenium and tellurium, cadmium may be separated by sulphuretted hydrogen; from *selenium, tellurium*, and the metals of Group 1, Subdivision A (p. 217), by the insolubility of its sulphide in sulphide of ammonium. The sulphide is then dissolved by nitric acid, and the cadmium precipitated by carbonate of sodium, as above.

From *bismuth, lead*, and *mercury*, cadmium may be separated by the solubility of its oxide in ammonia, or of its cyanide in cyanide of potassium: from *lead* also by sulphuric acid, and from *mercury* by precipitating the latter in the metallic state by protochloride of tin. From *palladium*, it is also separated by the solubility of its cyanide in cyanide of potassium; from *silver*, by precipitating that metal as chloride. From *copper*, cadmium is separated by carbonate of ammonium, an excess of which redissolves the copper and not the cadmium: or better, by treating the solution of the two metals with excess of cyanide of potassium, which precipitates and redissolves them both, and passing sulphuretted hydrogen through the liquid, whereby the cadmium is precipitated, while the copper remains dissolved. (See COPPER.)

5. *Atomic Weight of Cadmium.*—Stromeyer found that 114·352 pts. protoxide of cadmium, Cd^2O, yielded 14·352 O; whence $14·352 : 100 = 16 : Cd^2$; and $Cd = \frac{1600}{2 \times 14·352} = 55·7$. Dumas (Ann. Ch. Pharm. cxiii. 27), from the mean of six experiments on the quantity of nitrate of silver required to precipitate the chlorine from chloride of cadmium, found for the atomic weight of cadmium, numbers varying from 55·89 to 56·38. He regards 56 as very near to the true value.

CADMIUM, FLUORIDE OF, CdF, is deposited from the aqueous solution on evaporation, in white, indistinctly crystalline crusts. It dissolves sparingly in pure water, more readily in aqueous hydrofluoric acid. (Berzelius.)

CADMIUM, IODIDE OF. CdI.—Prepared either in the dry way, or by digesting cadmium with iodine and water. Crystallises in large, transparent, six-sided tables, which are not altered by exposure to the air. It melts easily, and solidifies again in the crystalline form; gives off iodine at a higher temperature. Dissolves readily in water and alcohol, and crystallises unchanged from the solutions. Sulphydric acid slowly precipitates sulphide of cadmium from the aqueous solution.

Two *ammonio-iodides of cadmium* are known, viz. $NH^3.CdI$, which is deposited in small crystals from a solution of iodide of cadmium in hot aqueous ammonia; and $3NH^3.CdI$, which is a white powder produced by gently heating iodide of cadmium in ammonia-gas. (Rammelsberg, Pogg. Ann. xlviii. 153.)

Iodide of Cadmium and Potassium, CdI.KI + aq. crystallises in confused octahedrons from a solution of the two iodides in equivalent proportions. In like manner are obtained: $NH^4I.CdI$ + aq., apparently isomorphous with the potassium-salt; NaI.CdI + 3aq. in deliquescent prisms; BaI.CdI + ½ aq., also deliquescent; and SrI.CdI + 4aq. in large crystals, which deliquesce in moist, and effloresce in dry air. (Croft, Chem. Gaz. 1856, p. 121.)

CADMIUM, NITRIDE OF. (?) When an electric current is passed through a solution of sal-ammoniac, the positive pole being formed of cadmium, and the negative pole of platinum, the latter becomes covered with a spongy, lead-grey mass, which, after washing and drying, has a density of 4·8; 5 grains of it gave off when heated, 0·18 to 0·25 cub. in. of nitrogen gas free from hydrogen, and left a yellowish-green residue, containing globules of cadmium. (Grove, Phil. Mag. [3] xix. 99.)

CADMIUM, OXIDES OF. Cadmium forms two oxides, viz. a protoxide, Cd^2O, and a suboxide, Cd^4O. The protoxide dissolves in acids without evolution or absorption of oxygen, and forms salts of corresponding composition: *e. g.* the sulphate, Cd^2SO^4, the nitrate $CdNO^3$, &c. These are indeed the only salts of cadmium; the suboxide when treated with acids, yields metallic cadmium and a protosalt.

Suboxide of Cadmium, Cd^4O, is obtained by heating the oxalate to about the melting point of lead. It is a green powder, resembling oxide of chromium, and is resolved by heat or by acids, into metallic cadmium and the protoxide. It does not however yield metallic cadmium when treated with mercury: hence it appears to be a definite compound, and not a mere mixture of the metal with the protoxide.

Protoxide of Cadmium, or *Cadmic Oxide*, Cd^2O, or CdO.—Cadmium, heated in the air, takes fire and is converted into protoxide. The same compound is formed when vapour of cadmium and aqueous vapour are passed together through a red-hot tube; but it is most easily prepared by igniting the hydrate, carbonate, or nitrate. It varies in colour from brown-yellow to blackish, according to the mode of preparation. By boiling cadmium for some time in a long-necked flask, the oxide may be obtained in purple crystals. Its specific gravity is 6·9502. It is quite fixed in the fire, and does not melt at the strongest white heat. It is easily reduced by charcoal before the blowpipe, and emits vapours of metallic cadmium, which is immediately reoxidised, and forms a red or brown deposit on the charcoal (p. 703). It is insoluble in water, but unites with it, forming a hydrate.

Hydrate of Cadmium, CdHO, is precipitated by potash from *dilute* solutions of cadmic salts; it may be obtained in indistinctly crystalline warty groups, by the action of aqueous ammonia on metallic cadmium in contact with iron or copper. It is white, absorbs carbonic acid from the air, is insoluble in the fixed alkalis, dissolves readily in caustic ammonia, but not in carbonate of ammonia. It dissolves easily in sulphuric, nitric, hydrochloric, and acetic acid.

CADMIUM, PHOSPHIDE OF. Grey, with faint metallic lustre; very brittle; difficult to fuse. Burns in the air with a bright flame, producing cadmic phosphate. Hydrochloric acid dissolves it, with evolution of phosphoretted hydrogen.

CADMIUM, SULPHIDE OF. Cd^2S, or CdS.—This compound occurs in the form of *Greenockite*, and is prepared as a pigment known by the name of *jaune brillant*. It is formed with difficulty by fusing cadmium with sulphur,—more readily by igniting cadmic oxide with sulphur; precipitated in yellow flakes when sulphydric acid or an alkaline sulphydrate is brought in contact with a cadmium-salt. The native sulphide crystallises in double six-sided pyramids and other forms of the hexagonal system, with cleavage parallel to the terminal and lateral edges of a six-sided prism. Specific gravity 4·8 (Brooke), 4·908 (Breithaupt). Hardness equal to that of calcspar. Of diamond lustre, semi-transparent, honey-yellow; yields an orange-yellow or a brick-red powder; becomes carmine-red when heated. Decrepitates when heated somewhat strongly (Brooke, Breithaupt). The artificial sulphide, in the precipitated state, is an orange-yellow powder, which, when heated to redness, becomes first brownish and then carmine-red. It melts at an incipient white heat, and solidifies on cooling, in transparent, lemon-yellow, micaceous laminæ. It is not volatile at any temperature (Stromeyer). Specific gravity of the fused artificial sulphide, 4·605. (Karsten).

In dilute hydrochloric acid it dissolves with difficulty, even when the acid is heated; but if the acid be strong, the sulphide dissolves with ease, even at ordinary temperatures, with violent evolution of sulphuretted hydrogen, and without separation of sulphur. At a red heat it slightly decomposes vapour of water; at a white heat, oxide of cadmium is formed (Regnault). It dissolves in nitric acid, with evolution of sulphuretted hydrogen and separation of sulphur. Very soluble in ammonia.

CADMIUM-ETHYL. Cadmium appears to form with ethyl a compound analogous to zinc-ethyl; but it has not yet been obtained in the pure state. Wanklyn (Chem. Soc. Qu. J. ix. 193), by heating cadmium-foil with half its weight of iodide of ethyl dissolved in an equal volume of ether in a sealed tube, obtained a liquid which passed over in fractional distillation between 180° and 220° C., gave off first white and then brown vapours on exposure to the air, and at length took fire, emitting a brown smoke. It smelt like zinc-ethyl, and was decomposed by water, with effervescence and formation of a white precipitate. It contained 36·8 per cent. cadmium, whereas the formula C^2H^5Cd requires 66 per cent. Hence the distillate appears to have contained about 56 per cent. of cadmium-ethyl, the remainder consisting of ether, iodide of ethyl, and perhaps certain hydrocarbons. (See also Sonnenschein, J. pr. Chem. lxvii. 169.)

CÆSIUM. *Symbol* Cs. *Atomic weight* = 124.—An alkali-metal, the chloride of which has lately been discovered by Bunsen and Kirchhoff, in the mother-liquors of certain saline-waters in Germany. Its compounds give a spectrum distinguished by two blue lines, one rather faint at about the middle of the blue space of the normal spectrum, and the other much brighter, situated more towards the violet end. It was by this peculiar spectrum that the metal was discovered (page 214).*

CAFFEIC ACID. See Caffetannic Acid.

CAFFEINE or **THEINE.** $C^8H^{10}N^4O^2$, or $C^{16}H^{10}N^4O^4$. (Gm. xiii. 223; Gerh. i. 542.)—Caffeine was discovered in coffee by Runge, in the year 1820 (Materialien zur Phytologie, 1821, i. 146). Oudry (Mag. Pharm. xix. 49), in 1827, found in tea a crystalline subtance, which he called theine, supposing it to be a distinct compound; but Jobst (Ann. Ch. Pharm. xxv. 63) and Mulder (Pogg. Ann. xliii. 160), in 1838, showed that it was identical with caffeine. Martius, in 1840 (Ann. Ch. Pharm. xxxvi. 93), discovered the same substance in guarana, the dried pulp of *Paulinia sorbilis*; and Stenhouse, in 1843 (Phil. Mag. [3] xxiii. 426), obtained it from Paraguay tea, the leaves and twigs of *Ilex Paraguayensis*. The same chemist has shown (Phil. Mag. [4] vii. 21) that it exists in the leaves as well as in the berries of the coffee-plant. The exact composition of caffeine was first demonstrated in 1832 by Pfaff and Liebig (Ann. Ch. Pharm. i. 17). Its combinations and reactions have been especially studied by Stenhouse (*loc. cit.;* also Ann. Ch. Pharm. xlv. 366; xlvi. 227), Nicholson (Chem. Soc. Qu. J. iii. 321), Péligot (Ann. Ch. Phys. [3] xi. 128) and Rochleder (Ann. Ch. Pharm. lxxi. 1; lxxiii. 56 and 123). Its alkaline nature was first demonstrated by Herzog. (Ann. Ch. Pharm. xxvi. 344; xxix. 171.)

Preparation. a. From Tea or Coffee.—1. The mode of extraction generally adopted is to treat tea or coffee with boiling water and mix the infusion with subacetate of lead to precipitate the tannin. Péligot adds subacetate of lead in excess, then ammonia. The mixture is boiled for some time, the lead-precipitate carefully washed on a filter with boiling water, the filtrate freed from excess of lead by sulphuretted hydrogen, and after a second filtration, evaporated at a gentle heat. On cooling, it yields an abundant crystallisation of nearly pure caffeine, and an additional quantity may be obtained by concentrating the mother-liquor and leaving it to crystallise.—2. Caffeine may also be obtained by saturating the free acid contained in infusion of tea or coffee with carbonate of potassium; treating the liquor with with infusion of gall-nuts; mixing the precipitate with dry hydrate of lime; exhausting the mixture with alcohol; expelling the alcohol from the filtrate by distillation; and dissolving the residue in boiling water or boiling ether (Robiquet and Boutron, J. Pharm. xxiii. 108).—3. Five pts. of ground coffee are mixed with 2 pts. of slaked lime, and the mixture is exhausted with alcohol in a displacement apparatus. The extract is then dried, pulverised, and again treated with alcohol; the alcohol separated from the extracts by distillation; the fat oil which floats on the surface is removed; the watery liquid is evaporated to the crystallising point; and the crystals of caffeine are pressed and decolorised by animal charcoal: 50 kilogrammes of coffee thus treated yielded more than 250 grammes of caffeine (Versmann, Arch. Pharm. [2] lxviii. 148).—4. Ground coffee is digested for a week with commercial benzene, which takes up caffeine and oil of coffee. Both remain behind when the benzene is distilled off, and may be separated by hot water, which dissolves the caffeine and leaves it in large crystals when evaporated. The oil may also be dissolved out by ether, which leaves the caffeine undissolved (Vogel, Chem. Centralb. 1858, p. 367).—5. Payen exhausts coffee with ether, then washes it thoroughly with alcohol of 60 per cent., concentrates the solutions to a slightly syrupy consistence, and mixes them with three times their volume of 85 per cent. alcohol, whereupon the liquid separates into two layers, the lower being viscid and the upper fluid. The latter, which contains the greater part of the caffeine, is decanted, and freed from the greater part of the alcohol by distillation; and the syrupy residue is mixed with one-fourth of its bulk of alcohol at 90° C., and left to itself in a cool place: it then deposits crystals, which are recrystallised from alcohol. They consist, according to Payen, of caffetannate (chlorogenate), of caffeine and potassium, and when submitted to dry distillation, yield a sublimate of caffeine (Ann. Ch. Phys. [3] xxvi. 108).—6. Caffeine or theine being volatile, may also be prepared by sublimation. For this purpose, waste useless tea is gradually heated in a sublimation apparatus, like that used for preparing benzoic acid, but not so strongly as to decompose the theine. Part of the sublimate is quite pure; the rest may be purified by recrystallisation from water. (Heiynsius, J. pr. Chem. xlix. 317.)

According to the results of an extensive series of experiments made by Graham, Stenhouse, and Campbell (Chem. Soc. Qu. J. ix. 33), coffee contains from 0·8 to

---

* See Appendix to this volume.

1 per cent. of caffeine; tea about 2 per cent. **Stenhouse** (Ann. Ch. Pharm. lxxxix. 246) obtained from a sample of black tea from Kimaon on the Himalaya, 1·97 per cent. theine, and from another sample of good black tea 2·13 per cent. According to **Péligot** (Ann. Ch. Phys. [3] xi. 68), Hyson tea contains from 2·2 to 3·4 per cent., and gunpowder tea from 2·2 to 4·1 per cent. of theine. According to Robiquet and Boutron (*loc. cit.*) Martinique coffee yields 0·36 per cent., Mocha coffee 0·206, and Cayenne coffee 0·2 per cent. of caffeine.

b. From Guarana.—Guarana mixed with $\frac{3}{10}$ of its weight of quick lime is repeatedly boiled with alcohol of 33° Beck; the filtrate is evaporated a little; the greenish fatty oil which separates on cooling is removed; the residual alcoholic liquid completely evaporated; and the dry residue is heated: caffeine then sublimes, at first yellowish-white, afterwards quite white.—2. Twenty-four grammes of guarana powder are boiled with a quart of water; the cold solution is precipitated with basic acetate of lead; the bulky brownish-red precipitate filtered off, and repeatedly digested with hot water; and the lead is separated from the filtrate by sulphuretted hydrogen. The liquid separated from the sulphide of lead is evaporated in the water-bath to dryness; the residue dissolved in a little boiling alcohol, filtered, and allowed to crystallise; and the crystals thus obtained are purified by pressing and recrystallisation. Guarana contains about 5 per cent. of caffeine. (**Stenhouse.**)

c. From Paraguay Tea.—The filtered decoction is precipitated with neutral acetate of lead and the filtrate with basic acetate (or it is boiled with litharge), and the liquid decanted from the precipitate is evaporated to dryness, a tough, dark brown, hygroscopic mass then remaining. From this residue, caffeine may be obtained, either by sublimation, or by reducing it to powder, mixing it with sand, and treating it with ether. After distilling off the ether, feebly coloured caffeine crystallises, and may be purified by repeated crystallisation. The product amounts to 0·13 per cent. of the Paraguay tea. (**Stenhouse.**)

[For a full account of the methods of preparing caffeine, see Gmelin's Handbook, *loc. cit.*]

Properties.—Caffeine crystallises from water in slender needles, having the aspect of white silk, and containing 8·4 per cent. water of crystallisation ($C^8H^{10}N^4O^2 + H^2O$), which is not given off completely at 150° C. (**Mulder**). Specific gravity of the crystals 1·23 at 19° C. (**Pfaff**). It has a slightly bitter taste, and grates between the teeth. Melts at 178°, and sublimes completely at 185° in capillary and feathery needles (**Mulder**). It is sparingly soluble in cold water and alcohol, still less in ether. Boiling water dissolves it more freely, and the solution solidifies in a pulp on cooling. The crystals which separate from ether and alcohol are anhydrous.

Decompositions.—1. Caffeine, when quickly and strongly *heated*, suffers partial decomposition, giving off vapours which have the odour of methylamine.—2. Strong *sulphuric acid* decomposes it after continued heating.—3. When *chlorine* is passed into a thick magma of caffeine and water, the crystals gradually disappear, and a mixture of several substances is obtained, varying in composition according to the duration of the action. With a comparatively small quantity of chlorine, the products are amalic acid, $C^6H^6N^2O^4$, methylamine and chloride of cyanogen, together with chlorocaffeine, $C^8H^9ClN^4O^2$. The formation of the three first-mentioned products is represented by the equation:

$$C^8H^{10}N^4O^2 + 2H^2O + Cl^4 = C^6H^6N^2O^4 + CH^5N + CNCl + 3HCl.$$

The resulting liquid heated in the water-bath gives off hydrochloric acid, and a gas smelling like chloride of cyanogen, and granular crystals of amalic acid separate, succeeded (if too much chlorine has not been passed through the liquid) by chlorocaffeine in light flocks and crusts. If the action of the chlorine be prolonged, the compound $C^5H^6N^2O^3$, called *nitrotheine* by Stenhouse, *cholestrophane* by Rochleder, and *dimethylparabanic acid* [$C^3(CH^3)^2N^2O^3$] by Gerhardt, is produced:

$$\underset{\text{Amalic acid.}}{C^6H^6N^2O^4} + Cl^2 + H^2O = \underset{\text{Nitrotheine.}}{C^5H^6N^2O^3} + CO^2 + 2HCl.$$

4. Caffeine boiled with *hydrochloric acid* and *chlorate of potassium* yields alloxan or a similar body, the aqueous solution of which colours the skin red and imparts to it a peculiar odour. The solution gives with ammonia the colour of murexid, and with alkalis and ferrous salts the colour of indigo.—5. Strong *nitric acid* boiled with caffeine gives off nitrous fumes, and forms a yellow liquid, which assumes the purple colour of murexid on adding a drop of ammonia (this reaction furnishes a test for caffeine). If the ebullition be continued, the liquid becomes colourless, no longer exhibits the purple colour with ammonia, and yields by evaporation crystals of dimethylparabanic acid (nitrotheine), floating in a mother-liquor containing a salt of methylamine.—6. Caffeine boiled with very strong *potash-ley* evolves a considerable quantity of methylamine.—7. With *soda-lime* it gives off ammonia, forms carbonate of sodium,

carbonate of calcium, and a large quantity of cyanide of sodium. This reaction distinguishes caffeine from piperine, morphine, quinine, and cinchonine, which do not form cyanide of sodium when similarly treated. (Rochleder.)

Compounds of Caffeine.—Caffeine is a weak base: it dissolves in acids, forming salts which have an acid reaction, and are for the most part decomposed by evaporation, caffeine free from acid being deposited.

Hydrochlorate of Caffeine, $C^8H^{10}N^4O^2.HCl$, is obtained in crystals by dissolving caffeine in very strong hydrochloric acid, not diluted either with water or with alcohol, and concentrating by gentle evaporation. If either water or alcohol be added, nothing but caffeine crystallises out. The salt forms large, transparent, efflorescent crystals, belonging to the trimetric system, $\infty P \,.\, \bar{P}\infty \,.\, \infty\breve{P}\infty$. Inclination of the faces, $\infty P : \infty\bar{P} = 118° 30' : \bar{P}\infty : \infty\bar{P}\infty = 116° 30'$.

Chloroaurate of caffeine, $C^8H^{10}N^4O^2.HCl.AuCl^3$, crystallises from alcohol in orange-coloured needles (Nicholson). The *chloromercurate*, $C^8H^{10}N^4O^2.2HgCl$, obtained by mixing an alcoholic solution of caffeine with excess of mercuric chloride, forms needles resembling caffeine, soluble in water, hydrochloric acid, alcohol, and oxalic acid, nearly insoluble in ether. The *cyanomercurate*, $C^8H^{10}N^4O^2.2HgCy$, prepared in like manner forms prisms belonging to the dimetric system, sparingly soluble in cold water and alcohol. The *chloroplatinate*, $C^8H^{10}N^4O^2.HCl.PtCl^2$, forms small distinct orange-yellow crystals, sparingly soluble in water, alcohol, and ether. With *chloride of palladium*, hydrochlorate of caffeine forms a beautiful brown precipitate, and the filtered liquid deposits yellow scales of another compound, not unlike iodide of lead.

A solution of caffeine does not precipitate *sulphate of copper*, *protochloride of tin*, *acetate of lead*, or *mercurous sulphate*. Boiled with *sesquichloride of iron*, it forms, on cooling, a brown-red precipitate, perfectly soluble in water, and probably consisting of a double salt similar to the preceding. With *nitrate of silver*, caffeine forms the compound $AgNO^3.C^8H^{10}N^4O^2$, which separates on mixing concentrated solutions of caffeine and nitrate of silver, in white crystalline hemispheres, adhering firmly to the sides of the vessel. It is sparingly soluble in cold, more readily in hot water and alcohol; detonates when heated.

Sulphate of Caffeine is difficult to crystallise, and is easily decomposed by water.

Tannate of Caffeine is obtained as a white precipitate when an aqueous solution of caffeine is added in excess to aqueous tannic acid. It contains 41·9 per cent. caffeine and 58·1 tannic acid (Mulder). An infusion of tea, by its tannin, also precipitates a solution of caffeine.

CAFFEONE. The aromatic principle of coffee. It may be isolated by distilling 5 or 6 lbs. of roasted coffee with water, agitating the aqueous distillate with ether, and afterwards evaporating the ether. It is a brown oil, heavier than water, slightly soluble in boiling water. An almost imponderable quantity of it is sufficient to aromatise more than a quart of water. (Pelouze et Frémy, Traité, iv. 449.)

CAFFETANNIC ACID. *Caffeic Acid. Chlorogenic Acid.* $C^{35}H^{38}O^{17}$? (Pfaff, 1830, Scher. lxi. 487.—Rochleder, Ann. Ch. Pharm. lix. 300; lxiii. 193; lxvi. 35; lxxxii. 196.—Liebich, *ibid.* lxxi. 97.—Stenhouse, *ibid.* lxxxiii. 244.—Payen, Ann. Ch. Phys. [3] xxvi. 108.—Gerh. Traité, iii. 886.)—This acid exists in coffee berries to the amount of 3 to 5 per cent. as a calcium- and magnesium-salt, and, according to Payen, as a double salt of caffeine and potassium. According to Rochleder, it is also found in Paraguay tea. It is prepared by mixing an alcoholic infusion of coffee or Paraguay tea with water to separate the fatty matter; then boiling the liquid, adding acetate of lead, decomposing the precipitate with sulphuretted hydrogen, and evaporating the filtered liquid. It forms a yellowish brittle mass, which may with difficulty be obtained in colourless, mammellated, crystalline groups. It dissolves easily in water, less in alcohol; has an astringent taste, and reddens litmus strongly. Melts when heated, then chars, and gives off the odour of roasted coffee. By dry distillation it yields water and a thick oil, which solidifies on cooling, and consists of oxyphenic acid (Rochleder). Strong sulphuric acid dissolves it with the aid of heat, forming a blood-red liquid. Distilled with peroxide of manganese and sulphuric acid, it yields quinone (Stenhouse). It dissolves with yellow colour in potash and in ammonia. The ammoniacal solution in contact with the air quickly turns green, producing *viridic acid*, $C^{14}H^{14}O^8$ (?) (Rochleder.)

Caffetannic acid colours ferric salts green. It does not precipitate ferrous salts, but, on adding ammonia, a nearly black precipitate is obtained. It does not precipitate tartar-emetic or gelatin, but precipitates quinine and cinchonine. It reduces nitrate of silver in specular form if the liquid is heated.

The formula of caffetannic acid is not definitely fixed. Rochleder first supposed it to be $C^{16}H^{18}O^8$, but afterwards gave the preference to $C^{14}H^{16}O^7$. Gerhardt (Traité, iii. 886) suggested $C^{35}H^{38}O^{17}$, according to which caffetannic acid would be a homologue of gallotannic acid, $C^{27}H^{22}O^{17}$, differing from it by $8CH^2$. Pfaff supposes it contains two acids, *caffeic* and *caffetannic*; but Rochleder found only one, viz. caffetannic acid, with traces of citric acid.

The *caffetannates* are but little known. The *potassium*-salt is amorphous, soluble in water, insoluble in alcohol, and turns brown from oxidation on exposure to the air. The *barium*- and *calcium*-salts are yellow, and quickly turn green on exposure to the air. The *lead*-salt is a white precipitate of very variable composition.

The *caffetannate of caffeine and potassium*, prepared as already described (p. 706), forms spheroïdal groups of crystals, which become electric by friction. They are very soluble in water, less soluble in aqueous alcohol, nearly insoluble in absolute alcohol. The aqueous solution turns brown when exposed to the air. They are decomposed by dry distillation, swelling up strongly and yielding a sublimate of caffeine. Gently heated with potash, they assume a red or orange colour. Heated with strong sulphuric acid, they yield a liquid of deep violet colour, with a bronze pellicle on the surface. Nitric acid colours them orange-yellow.

CAÏNCIC ACID. $C^{16}H^{26}O^7$ (?) (François, Pelletier, and Caventou, 1830, J. Pharm. xvi. 465.—Liebig, Ann. Ch. Phys. [2] xlvii. 185.—Rochleder and Hlasiwetz, Ann. Ch. Pharm. lxxvi. 238.—Gerh. Traité, iii. 746.)—Found in the root of caïnca (*Chiococca anguifuga*, Martius), a rubiaceous plant growing in Brazil, and used as a remedy against the bites of serpents; also in the root of *Chiococca racemosa* (*L.*), a plant much used in the Antilles for the cure of syphilis and rheumatism.

It is prepared: 1. By exhausting caïnca root with alcohol, concentrating the alcoholic extract, mixing it with water, and adding milk of lime to the filtered liquid till it loses its bitterness. An insoluble basic caïncate of calcium is thus produced, which is decomposed by a hot alcoholic solution of oxalic acid. The filtered solution, when evaporated, yields caïncic acid in shining needles (Pelletier and Caventou).—2. From the root of *Chiococca racemosa*, by exhausting the bark of that root with alcohol; mixing the solution with neutral acetate of lead, which throws down caffetannate of lead, together with some caïncate and phosphate; then treating the filtrate with subacetate of lead, which forms a yellow precipitate containing the greater part of the caïncic acid, with only traces of caffetannic acid. This precipitate being decomposed by sulphuretted hydrogen, and the filtrate sufficiently concentrated, the caïncic acid is deposited in crystalline flakes, which may be purified by crystallisation from boiling water containing a little alcohol.

Caïncic acid is inodorous; tasteless at first, afterwards very bitter; sparingly soluble in water and ether, very soluble in alcohol. Reddens litmus perceptibly. The crystals give off 9 per cent. water at 100° C. (Liebig). When heated it softens, chars, and yields a crystalline sublimate which is not bitter. Dilute acids and strong alkalis convert it into quinovatic acid.

The *caïncates* are but little known; they have a bitter taste. The neutral caïncates of *ammonium*, *potassium*, *barium*, and *calcium* are soluble in water, deliquescent, and uncrystallisable. Lime-water, added to the solution of neutral caïncate of calcium, produces a copious precipitate of a basic salt, soluble in boiling alcohol, whence it separates in white flakes, which are strongly alkaline. The *normal lead-salt*, $C^{16}H^{24}Pb^2O^7 + H^2O$, is precipitated on mixing strong alcoholic solutions of caïncic acid and acetate of lead. There are also basic lead-salts.

CAIRNGORM STONE. Smoky quartz. See QUARTZ.

CAJEPUT, OIL OF. This oil is prepared in India by distilling the leaves of *Melaleuca Leucodendron* (*L.*) with water. It was formerly employed to a great extent in medicine, both internally and externally, but is now but little used, and is seldom met with in a pure or unchanged state, except in the hands of wholesale druggists. As introduced into Europe, it possesses a light green colour, resembling that of a dilute solution of chloride of chromium, which is caused by a resinous colouring matter dissolved in it in very small quantity.

The colour of the crude oil is also partly due to copper, the presence of which may be accounted for, either by the use of a copper head in the distilling apparatus of the Hindoos, or by intentional adulteration, resorted to for preserving the green colour of the oil, which otherwise changes gradually by oxidation to a reddish-brown, the oil then becoming unsaleable for medicinal purposes. That the oil possesses a green colour of its own is proved by the fact that the colour remains after the complete removal of the copper by sulphuretted hydrogen.

Oil of cajeput consists mainly of the dihydrate of a hydrocarbon called **cajputene**, isomeric with oil of turpentine. Its specific gravity is 0·926 at 10° C. On submitting it to fractional distillation, dihydrate of cajputene, which constitutes about two-thirds of the crude oil, passes over between 175° and 178° C.; smaller fractions, perhaps products of decomposition, are obtained from 178° to 240° and from 240° to 250°; and at

250° only a small residue is left, consisting of carbonaceous matter mixed with metallic copper. On treating this residue with ether, a green solution is obtained, which, when evaporated, leaves a green resin, soluble in the portion which boils between 175° and 178°, and capable of restoring the original colour. (M. Schmidl, Trans. Roy. Soc. Ed. xxii. [6] 360; Chem. Soc. Qu. J. xiv. 63.)

CAJPUTENE. $C^{10}H^{16}$. (Schmidl, *loc. cit.*)—This compound is obtained, together with two isomeric hydrocarbons, isocajputene and paracajputene, by cohobating dihydrate of cajputene with phosphoric anhydride for half an hour, and then distilling off the liquid, whereupon cajputene passes over at 160°—165° C.; isocajputene at 176°—178°, and paracajputene at 310°—316°.

Cajputene is permanent in the *air*. It is not affected by *iodine* at ordinary temperatures, but at a higher temperature, hydrogen is evolved and a black liquid is formed. *Bromine* acts quickly on it, producing a dark viscid oil. With *gaseous hydrochloric* acid, it forms a beautiful violet liquid, but no crystalline compound, even at −10° C. A mixture of ordinary *nitric* and *sulphuric acids* acts upon it with violence, forming a yellow bitter resin.

Cajputene is insoluble in *alcohol*, but dissolves in *ether* and in *oil of turpentine.*

Isocajputene, $C^{10}H^{16}$.—Obtained: 1, as above.—2, by distilling the dihydrate of cajputene with oil of vitriol. It is an oil boiling between 176° and 178° C. Its odour is less agreeable than that of cajputene, and becomes more pungent and aromatic by exposure to the air, the oil at the same time acquiring a yellow colour. Specific gravity = 0·857 at 16° C. Vapour-density of (1) = 4·82; of (2) = 4·52.

Iodine, bromine, gaseous hydrochloric acid, and a mixture of *nitric* and *sulphuric acids*, act upon isocajputene in the same manner as on cajputene. With *oil of vitriol*, and with *dilute sulphuric, hydrochloric*, or *nitric acid* (neither of which acts upon cajputene), it forms dark viscid liquids.

Isocajputene is insoluble in *water* and in *alcohol*, but mixes in all proportions with *ether* and with *oil of turpentine.*

Paracajputene, $C^{20}H^{32}$, obtained as above mentioned, by distilling dihydrate of cajputene with anhydrous phosphoric acid, passes over between 310° and 316° C. It is very viscous, has a lemon-yellow colour, and in certain directions exhibits deep-blue fluorescence. Vapour-density, by experiment = 7·96; by calculation (2 vol.) = 9·43. The difference between the experimental and calculated vapour-densities is probably due to decomposition, taking place at the high temperature required for the determination.

Paracajputene oxidises rapidly in contact with the *air*, acquiring a red colour and resinous consistence. A mixture of *nitric* and *sulphuric acids* does not act so violently on it as on cajputene and isocajputene. With *hydrochloric acid gas*, it forms a dark viscid liquid, which does not yield crystals, even at −10° C. It is insoluble in *water, alcohol*, and *oil of turpentine*, soluble in *ether.*

BROMIDE OF CAJPUTENE, $C^{10}H^{16}Br^4$.—Obtained by the action of bromine on oil of cajeput. When dry bromine is dropped into the rectified oil, a very brisk action takes place, and the sides of the vessel become covered with yellow needles, which however soon disappear; but if the addition of the bromine be continued till the reaction almost ceases, a dark, thick, viscous oil is formed, which, after several weeks, deposits a granular substance. By boiling the mixture with alcohol, the granular substance is extracted; a heavy oil is left behind; and the alcoholic solution, on cooling, deposits bromide of cajputene as a soft crystalline substance having a fatty lustre and much resembling cholesterin.

Bromide of cajputene melts at 60° C. and solidifies again at 32°. By dry distillation, it yields a liquid which crystallises again in the cooler parts of the retort. It is not altered by boiling with aqueous potash. It dissolves in ether and in boiling alcohol.

Rectified oil of cajeput shaken up with bromine-water, forms a red resin, from which a solid substance separates in small white prisms, extremely deliquescent and rapidly decomposing.

Another crystallised bromine-compound (probably a hydrobromate analogous to the hydriodate) is formed in the same manner as that compound (p. 713).

CHLORIDE OF CAJPUTENE, $C^{10}H^{16}Cl^2$, is produced by the action of nascent chlorine on the dihydrate (rectified cajeput oil). When the portion of the oil distilling between 175° and 178° C. is mixed with very dilute nitric acid, and hydrochloric acid gas is passed into the liquid, a violent action takes place in a few minutes, chlorine and nitrous gas being evolved; and, if the passage of the gas be continued, chloride of cajputene ultimately sinks to the bottom, as a limpid brown oil, which may be freed from adhering nitric and nitrous acid by distillation over strong potash-ley. It has a fragrant odour, and may be kept without alteration for any length of time, but is decomposed by distillation. Boiled with nitrate of silver, it detonates in a peculiar manner, and forms chloride of silver.

Hydrates of Cajputene. *Hemi-hydrate*, $C^{20}H^{34}O = (C^{10}H^{16})^2.H^2O$ (or perhaps *monohydrate of paracajputene*, $C^{20}H^{32}.H^2O$.)—Obtained by the action of oil of vitriol on oil of cajeput. When the crude oil is raised to the boiling-point in a deep open vessel, and oil of vitriol continuously dropped into it, violent ebullition takes place, accompanied, after a while, by a peculiar crackling sound. As soon as this is observed, the flame must be lowered and the acid very cautiously added, till the liquid suddenly assumes a dark colour, extending in an instant from the surface throughout the whole depth. The vessel must then be immediately removed from the fire, otherwise further decomposition will take place, attended with evolution of sulphurous anhydride. The upper oily liquid is separated from the acid on which it floats, well washed, and distilled, and the portion which passes over from the 170° to 175° is collected and rectified. It is an oily liquid, whose vapour-density, as found by experiment, is 5·19 to 5·27. Now the formula, $C^{20}H^{34}O$, if supposed to represent 2 volumes of vapour, gives for the calculated vapour-density the number 10·04 ($= \frac{240 + 34 + 16}{2} \times 0·0693$), which is nearly double the experimental number. Consequently, the molecule $C^{20}H^{34}O$ represents 4 volumes of vapour, and probably splits up at high temperatures into $C^{20}H^{32}$ and H^2O, each of which occupies 2 volumes. (See Atomic Weights, p. 469.)

Monohydrate. $C^{10}H^{18}O = C^{10}H^{16}.H^2O$.—This is the chief constituent of oil of cajeput (p. 710), and passes over in the fractional distillation between 175° and 178° C. After rectification, it is a colourless oil which boils constantly at 175°, has a specific gravity of 0·903 at 17° C., and vapour-density, by experiment = 5·43; by calculation (2 vol.) = 5·338. It dissolves in all proportions in *alcohol*, *ether*, and *oil of turpentine*.

Exposed to the *air* for a considerable time, in the moist state, it changes to a reddish liquid, which ultimately exhibits a rather strong acid reaction with litmus. *Iodine* dissolves in the oil, and under certain circumstances forms crystalline compounds (p. 712). *Bromine* acts quickly upon it, and under similar circumstances forms crystalline compounds (p. 711). *Chlorine gas* passed into the oil raises the temperature, but does not appear to act upon it further; but *nascent* chlorine (evolved by passing hydrochloric acid gas into the oil mixed with dilute nitric acid) converts it into dichloride of cajputene, $C^{10}H^{16}Cl^2$. *Phosphoric anhydride* heated with the monohydrate takes away the whole of its water, converting it into cajputene, isocajputene, and paracajputene (p. 711). *Chloride of zinc* likewise dehydrates it, but less completely. *Strong sulphuric acid* acts but very slowly on the oil at low temperatures; but if the temperature be allowed to rise, sulphurous anhydride is given off, and the oil blackens and ultimately suffers complete decomposition. If the action be checked at a certain point, a sulpho-acid is formed, which yields a soluble barium-salt. Oil of vitriol dropped into the oil at the boiling heat, in the manner above described takes away half the water, forming monohydrate of cajputene. *Dilute sulphuric acid*, on the contrary, causes the monohydrate to take up 2 at. more water, converting it into $C^{10}H^{16}.3H^2O$. *Fuming sulphuric acid* converts the monohydrate into a thick brown liquid, which boils above 360°. *Fuming nitric acid* rapidly oxidises the oil, even at ordinary temperatures, forming a large quantity of oxalic acid. Ordinary nitric acid produces the same effect at the boiling heat, but at ordinary temperatures it acts very slowly, converting the oil into a red liquid. Distilled over *permanganate* or *acid chromate of potassium* in presence of sulphuric acid, it forms a thick resinous liquid. It does not appear to be altered by digestion with *peroxide of lead*. In contact with aqueous *potash*, or when dropped into melting potash, it forms a soluble salt, the acid of which is precipitated as a resin by hydrochloric or sulphuric acid. Heated with *sodium*, it forms a crystalline mass, soluble in water and alcohol, and consisting of soda and an organic substance, which is separated by strong acids in the form of a fragrant resin. When the vapour of the monohydrate is passed over red-hot *soda-lime*, a yellow oil distils over, having a peculiar odour quite different from that of the monohydrate; at the same time the soda-lime becomes blackened by deposited charcoal, and when treated with acids, gives off a large quantity of carbonic anhydride. The yellow oil thus formed yielded by distillation, a fraction boiling between 180° and 185° C. which gave in two analyses, 79·76 and 80·03 per cent. C, 12·20 and 12·07 H, agreeing nearly with the formula $C^{26}H^{24}O^{2}$, which requires 79·59 per cent. C, 12·24 H, and 7·97 O.

Trihydrate of Cajputene, $C^{10}H^{22}O^3 = C^{10}H^{16}.3H^2O$.—Produced by the action of dilute sulphuric acid on the monohydrate, or on crude oil of cajeput. Two pts. of dilute sulphuric acid are added to 1 pt. of the crude oil; and the mixture is well shaken for several days till the watery liquid acquires a yellowish colour, and then left to itself for about ten days, whereupon it deposits crystalline tufts of the trihydrate, adhering to the sides of the vessel. The crystals melt at 120° C. and solidify again at

85°. On submitting them to dry distillation, an oily liquid passes over and condenses again in the colder parts of the apparatus, apparently as the unaltered trihydrate. The crystals dissolve sparingly in cold, easily in boiling alcohol.

Crystals having the same composition were deposited from a secondary fraction of crude cajeput-oil, which distilled at 210°—230° C., and was left for a very long time moist and exposed to the air. The crude oil mixed with nitric acid and alcohol, changes, in the course of seven or eight months, into a black heavy liquid in which crystals are suspended, perhaps consisting of the trihydrate. The same compound appears likewise to be formed in beautiful long prisms, when the crystalline mass produced by passing hydrochloric acid gas into rectified oil of cajeput is thrown into water or alcohol.

HYDROCHLORATES OF CAJPUTENE.—The *monohydrochlorate*, $C^{10}H^{16}.HCl$, is obtained by distilling the dihydrochlorate, and collecting apart the fraction which boils at 160° C. —A product having the same composition is obtained by treating the dihydrochlorate for several days with aqueous or alcoholic potash; but its odour is different from that of the product obtained by simple distillation of the hydrochlorate, and resembles that of pelargonic ether.

The *dihydrochlorate*, $C^{10}H^{16}.2HCl$, is obtained by passing hydrochloric acid gas through rectified cajeput-oil, mixed with a third of its volume of alcohol or strong aqueous hydrochloric acid. It crystallises from alcohol in beautiful radiating tufts; melts at 55° C. and solidifies again at 30°. It has no taste or smell. By dry distillation, it gives off hydrochloric gas at 60°, and splits into several fractions, one of which is the monohydrochlorate. It is also deprived of half its chlorine by heating with aqueous or alcoholic potash. It dissolves sparingly in cold, easily in boiling alcohol or ether.

HYDRIODATE OF CAJPUTENE. *a. Anhydrous.* $C^{10}H^{16}.HI$.—Obtained by adding a solution of phosphorus in sulphide of carbon to a solution of iodine and oil of cajeput in the same liquid. The liquid becomes hot, assumes a reddish colour, deposits red oxide of phosphorus, and gives off vapours, probably containing phosphoretted hydrogen, and after ten or twelve days deposits crystals of the hydriodate. The reaction is perhaps:

$$6(C^{10}H^{16}.H^2O) + 6PI = 6C^{10}H^{17}I + 2PH^3 + P^2O + P^2O^5.$$

The crystals are deposited in cells like those of beehives, and possess a black metallic lustre. They are soluble in alcohol and ether, and are very stable, not being altered even by boiling with potash.

b. Hydrated, $C^{20}H^{36}I^2O = 2(C^{10}H^{16}.HI).H^2O$, or *Hydriodate of Hemihydrated Cajputene*, $C^{20}H^{34}O.2HI$.—If iodine be added by small quantities, and with constant stirring, to cajeput-oil till the temperature rises from 10° to 40° C., and the vessel be then immersed in cold water, a black crystalline compound soon separates from it, and on filtering, pressing the black substance between paper, and then dissolving it in alcohol or ether, a solution is obtained, from which the hydrated hydriodate crystallises in prisms having a fine yellow-green colour and metallic lustre, and melting at 80° C. to a compound which does not recrystallise on cooling. Potash dissolves the crystals, abstracting part of the iodine in the cold, and the whole when heated. The crystals are insoluble in water, and are not decomposed thereby; they dissolve readily in alcohol and ether.

CALAITE. Syn. of TURQUOIS.

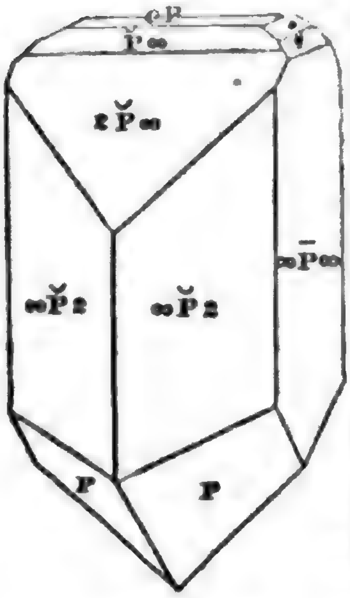
CALAMINE. *Native Carbonate of Zinc. Zinc-spar. Smithsonite. Galmei.* Zn^2CO^3. —This mineral, which is one of the most abundant ores of zinc, occurs crystallised in rhombohedrons with cleavage parallel to the rhombohedral faces. Ratio of principal to secondary axes = 0·8070 : 1. Inclination of terminal faces = 107° 40′. Also reniform, botryoïdal, and stalactitic, and in crystalline incrustations; likewise granular, earthy, and friable. Specific gravity = 4·45; hardness = 5. It is translucent or subtransparent; white when pure, but often tinged more or less with grey, green, or brown, from admixture of the carbonates of iron and manganese. Streak white. Lustre vitreous, inclining to pearly. Brittle, with uneven, imperfectly conchoïdal fracture.

Pure calamine is found in Somersetshire and Derbyshire. A specimen from Somersetshire analysed by Smithson (Nicholson's Journal, vi. 76) gave 35·2 per cent. CO^2, and 64·8 Zn^2O, which is exactly the theoretical composition. Generally, however, a portion of the zinc is isomorphously replaced by iron, manganese, calcium, magnesium, lead, and copper. The following are examples: *a.* From Nertzchinsk in Siberia, analysed by Kobell (J. pr. Chem. xxviii. 480.) *b, c, d.* From Altenberg near Aix-la-Chapelle (Monheim, Rammelsberg's *Mineralchemie*, s. 227.) *e, f.* From Herrenberg near Nirm, Aachen (Monheim, *ibid.*) *g.* A cupriferous variety called Herrerite, from Albarradon in Mexico. (Genth, Sill. Am. J. ii. xx.; J. pr. Chem. lxvi. 475.)

	Zn^2CO^3	Fe^2CO^3	Mn^2CO^3	Ca^2CO^3	Mg^2CO^3	Pb^2Co^3	Cu^2CO^3	SiO^2	Zn^2SiO^4	H^2O	
a . .	96·00	2·03	—	—	—	1·12	—	—	—	—	= 99·15
b . .	60·35	32·31	4·02	1·90	0·14	—	—	—	2·49	—	= 101·11
c . .	55·89	36·46	3·47	2·27	—	—	—	—	0·41	—	= 98·50
d . .	84·92	1·58	6·80	1·58	2·84	—	—	—	1·85	—	= 99·57
e . .	85·78	2·24	7·62	0·98	4·44	—	—	0·09	—	trace	= 101·15
f . .	74·42	3·20	14·98	1·68	3·88	—	—	0·20	—	0·56	= 98·92
g . .	93·74	—	1·50	1·48	0·29	—	3·42	—	—	—	= 100·43

CALAMINE, SILICEOUS. *Siliceous oxide of zinc. Hydrous silicate of zinc. Zinc-glance. Kieselzinkerz. Kieselgalmei.* $Zn^4SiO^4 + H^2O$.—(Dana applies to this mineral the name *calamine*, distinguishing the preceding as *Smithsonite.*) Occurs in crystals of the trimetric system. Ratio of brachydiagonal, macrodiagonal, and principal axis = 0·6385 : 1 : 0·6169. The crystals are short prisms (*fig.* 114) resulting from the predominance of the faces $\infty\breve{P}2$ and $\infty\bar{P}\infty$, and unsymmetrically terminated, viz. at one end by the faces P, and at the other by $2\breve{P}\infty$. $\bar{P}\infty$. 0P . $\frac{1}{3}\bar{P}\infty$ (*y*) and $\frac{1}{3}\breve{P}\infty$ (*x*). Inclination of faces, $\infty\breve{P}2 : \infty\breve{P}2 = 103° 53'$; $\frac{1}{3}\bar{P}\infty : \frac{1}{3}\bar{P}\infty = 51° 34'$; $\breve{P}\infty : \breve{P}\infty = 63° 20'$; $2P : 2P\infty = 101° 56'$. Cleavage perfect parallel to $\infty\breve{P}2$; somewhat less, parallel to $\breve{P}\infty$ (Kopp's *Krystallographie*, pp. 250, 264). The mineral likewise occurs in stalactitic, mammillary, botryoïdal, and fibrous forms; also massive and granular. Specific gravity 3·16—3·9. Hardness = 4·5—5. It is white when pure, sometimes blue, more or less coloured by oxide of iron. Transparent or translucent. Lustre generally vitreous. Streak white. Brittle, with uneven fracture. Like many other unsymmetrical minerals, it is pyroelectric.

Fig. 114.



Before the blowpipe it melts with difficulty at the edges; it is not altered by heating on charcoal, either alone or with carbonate of sodium; but with carbonate of sodium and borax it is completely reduced, with formation of a zinc-deposit. It is easily decomposed by acids, with separation of gelatinous silica; it also dissolves in potash-ley.

Siliceous calamine generally occurs nearly pure. A specimen from Tarnowitz in Upper Silesia, analysed by Rammelsberg, yielded 24·99 SiO^2, 68·66 Zn^2O, and 7·75 H^2O = 101·40; the formula $Zn^4SiO^4 + H^2O$ or $2Zn^2O.SiO^2 + H^2O$, requiring 25·1 SiO^2, 67·4 Zn^2O, and 7·5 H^2O. Sometimes a small portion of the zinc is partly replaced by iron or lead: in a specimen from Nertzschinsk in Siberia, Hermann found 2·70 per cent. oxide of lead.

Siliceous calamine usually occurs, associated with the native carbonate, in calcareous rocks. Large crystals are found at Nertzchinsk. (Dana, ii. 314; Rammelsberg's *Mineralchemie*, s. 549.)

CALAMITE. A variety of tremolite (*q. v.*) having an asparagus-green colour.

CALCAREOUS SPAR. See CALCSPAR.—**CALCEDONY.** See CHALCEDONY.

CALCHANTUM. Pliny's term for copperas.

CALCINATION. The fixed residues of such matters as have undergone combustion are called cinders in common language, and calces, or oxides, by chemists; and the operation, when considered with regard to these residues, is termed calcination. In this general way it has likewise been applied to bodies not really combustible, but only deprived of some of their principles by heat. Thus we hear of the calcination of chalk, to convert it into lime, by driving off its carbonic acid and water: of gypsum or plaster stone, of alum, of borax, and other saline bodies, by which they are deprived of their water of crystallisation; of bones, which lose their volatile parts by this treatment; and of various other bodies. (See COMBUSTION.)

CALCITE. Syn. with CALCSPAR (p. 721).

CALCIUM. *Symbol*, Ca. *Atomic weight*, 20.—Lime, the oxide of calcium, has been known from the earliest times, and was used by the ancients in the composition of mortar. Black, in 1756, first pointed out the difference between burnt and unburnt lime. The metal was first incompletely isolated by Davy in 1808, and has recently been obtained in the pure state by Matthiessen.

Calcium is the most widely diffused of the alkaline-earthy metals. The carbonate occurs in a great variety of forms, and, as limestone, constitutes entire mountain ranges. The sulphate, fluoride, phosphate, and silicate are also abundant natural products. Less frequent are the chloride, nitrate, arsenate, and tungstate. Calcium also exists as carbonate and phosphate in the bones of animals; the shells of molluscs are almost entirely composed of the carbonate. In the bodies of plants, calcium exists in combination with various organic acids.

Preparation of the Metal.—Davy in 1808 obtained calcium in an impure state by electrolysis, similarly to barium (p. 500), and by passing vapour of potassium over red-hot lime (?) Matthiessen (Chem. Soc. Qu. J. viii. 28) prepares the pure metal as follows:—A mixture of 2 at. chloride of calcium and 1 at. chloride of strontium, with a small quantity of chloride of ammonium (this mixture being more fusible than chloride of calcium alone), is melted in a small porcelain crucible, in which a carbon positive pole is placed, while a thin harpsichord wire wound round a thicker one, and dipping only just below the surface of the melted salt, forms the negative pole. The calcium is then reduced in beads, which hang on to the fine wire, and may be separated by withdrawing the negative pole every two or three minutes, together with the small crust which forms round it. A surer method, however, of obtaining the metal, though in very small beads, is to place a pointed wire so as merely to touch the surface of the liquid; the great heat evolved, owing to the resistance of the current, causes the reduced metal to fuse and drop off from the point of the wire, and the bead is taken out of the liquid with a small iron spatula. Or, thirdly, the disposition of the apparatus may be the same as that for the reduction of strontium (*q. v.*)

Liès-Bodart and Gobin (Compt. rend. xlvii. 23) prepare calcium by igniting the iodide with an equivalent quantity of sodium in an iron crucible, having its lid screwed down. According to Dumas (Compt. rend. xlvii. 175) it is essential that the process be conducted in a closed vessel, as, under the ordinary atmospheric pressure, the sodium burns away, and the iodide of calcium remains unaltered.

Properties.—Calcium is a light yellow metal, of the colour of gold alloyed with silver; on a freshly cut surface the lustre somewhat diminishes the yellow colour, which becomes more apparent when the light is reflected several times from two surfaces of calcium, or when the surface is slightly oxidised. It is about as hard as gold, very ductile, and may be cut, filed, or hammered out into plates having the thickness of the finest paper. Its specific gravity is 1·5778. In dry air the metal retains its colour and lustre for a few days, but in damp air the whole mass is slowly oxidised. Heated on platinum-foil over a spirit-lamp, it burns with a very bright flash. It is not quickly acted on by dry chlorine at ordinary temperatures; but when heated, it burns in that gas with a most brilliant light; also in iodine, bromine, oxygen, sulphur, &c. With phosphorus, it combines without ignition, forming phosphide of calcium. Heated mercury dissolves it as a white amalgam. Calcium rapidly decomposes water, and is still more rapidly acted on by dilute nitric, hydrochloric, and sulphuric acids, nitric acid often causing ignition. Strong nitric acid does not act upon it below the boiling heat. In the voltaic circuit, with water as the liquid element, calcium is negative to potassium and sodium, but positive to magnesium. It is not, however, reduced by potassium or sodium from its chloride by electrolysis. On the contrary, a fused mixture of $CaCl$ with KCl or $NaCl$, in certain proportions, yields potassium or sodium, when subjected in a certain manner to electric action; hence it appears that the metal formerly obtained by reducing chloride of calcium with potassium or sodium, could not be calcium, but was probably a mixture of potassium or sodium with aluminium, silicon, &c. (Matthiessen.)

Calcium unites with all the non-metallic elements, forming compounds into which it enters for the most part as a monatomic radicle, *e. g.* the chloride $CaCl$, the oxide Ca^2O, the sulphide Ca^2S, &c. Most of the compounds are colourless; they have an acrid taste, and a lower specific gravity than the corresponding compounds of barium and strontium. Of the compounds of calcium with other metals, little is known, excepting that it forms an amalgam with mercury.

CALCIUM, BROMIDE OF. $CaBr$.—Formed by the direct union of calcium and bromine, or by dissolving lime or the carbonate in hydrobromic acid. The solution yields by evaporation colourless silky needles of the hydrated bromide, from which the anhydrous bromide may be obtained by heating. It is deliquescent and very soluble in alcohol.

CALCIUM, CHLORIDE OF. $CaCl$.—This compound exists in sea-water, river-water, and spring-water, and is produced by passing chlorine over red-hot lime, or better by dissolving lime or the carbonate in hydrochloric acid, and evaporating. It is also produced in large quantity in the preparation of ammonia by heating sal-ammoniac with slaked lime:

$$NH^4Cl + CaHO = CaCl + NH^3 + H^2O.$$

The residue is treated with water; the solution, which is always alkaline, is neutralised with hydrochloric acid, and the residue evaporated to dryness.

The aqueous solution, when highly concentrated, deposits the hydrated chloride,

$CaCl.3H^2O$, in six-sided prisms with pyramidal summits. It has a bitter taste. The crystals give off 2 at. water when dried in vacuo, leaving the hydrate $CaCl.H^2O$, which retains the original form of the crystals, but is opaque, and has the appearance of talc (Graham). At 200° C. they part with the whole of their water, leaving the anhydrous chloride in the form of a white porous mass.

The anhydrous chloride melts at a low red heat. If it be then exposed to the sun's rays, it afterwards appears luminous in the dark; it was formerly called *Homberg's phosphorus*. When ignited in contact with the air, it is partially converted into oxide and carbonate of calcium. Hence the porous chloride dried at about 200° C. is better adapted for absorbing water in organic analysis (p. 228) than the fused chloride; the latter, containing lime, absorbs carbonic acid as well as water.

Anhydrous chloride of calcium is exceedingly greedy of water, and is one of the most deliquescent substances known. 100 pts. of it in powder exposed to an atmosphere saturated with moisture absorb 124 pts. of water in ninety-six days, more, therefore, than is required for complete deliquescence (Brandes, Schw. li. 433). The crystallised chloride also deliquesces rapidly, and dissolves in half its weight of water at 0° C., in one-fourth of its weight at 16°, and in every proportion of hot water. The solution of the anhydrous chloride in water is attended with considerable evolution of heat; but the hydrated chloride in dissolving lowers the temperature of the liquid. A mixture of crystallised chloride of calcium and snow produces a degree of cold sufficient to freeze mercury.

Both the anhydrous and the hydrated chloride dissolve readily in alcohol. 10 pts. of absolute alcohol at 80° C. dissolve 6 pts. of anhydrous chloride of calcium; and the solution when evaporated in vacuo, at the winter temperature, yields rectangular laminæ containing 59 per cent. of alcohol, agreeing with the formula $4CaCl.7C^2H^6O$. The alcohol in this compound appears to take the place of water of crystallisation. It likewise forms similar compounds with methylic and amylic alcohols.

Chloride of calcium combines with *ammonia*, forming the compound $CaCl.4NH^3$, it cannot, therefore, be used for drying gaseous ammonia. It unites also with *chromic acid* and with *acetate* and *oxalate of potassium*.

A solution of chloride of calcium boiled with slaked lime dissolves that substance, and the filtered solution deposits an *oxychloride of calcium*, $2CaCl.3Ca^2O + 15H^2O$, which is decomposed by pure water and by alcohol.

CALCIUM, DETECTION AND ESTIMATION OF. 1. *Reactions in the dry way.*—The hydrated chloride and a few other calcium-compounds, when heated in the blowpipe flame on platinum-wire, impart a red colour to the flame, similar to that produced by strontium-salts, but less intense. The colour disappears as soon as the salts are dehydrated, and is not produced at all if barium is likewise present. Alcohol burned on soluble calcium-salts exhibits a red flame tinged with yellow.

The spectrum of a flame in which a volatile calcium-compound is ignited, according to Bunsen and Kirchhoff's method (p. 214), is distinguished by a broad bright green line situated at about the confines of the green and yellow of the normal solar spectrum, and an intensely bright orange line situated nearer to the red end of the spectrum than the orange band of strontium, and about midway between the lines C and D of the solar spectrum. This reaction is best seen with the chloride, bromide, and iodide of calcium; the sulphate does not produce it till it has become basic, the carbonate exhibits it most distinctly after the carbonic acid has been expelled. Compounds of calcium with the non-volatile acids require to be decomposed, generally by hydrochloric acid. To obtain the reaction with silicates not decomposible by hydrochloric acid, a small quantity of the mineral in fine powder is mixed on a platinum plate with excess of fluoride of ammonium, and gently heated till all the fluoride is volatilised; the residue is then moistened with sulphuric acid, and the excess of that acid driven off. If the remaining substance be ignited in the flame as above, the characteristic spectra of the alkali-metals, if present, are first seen, and afterwards those of strontium and calcium. If only a trace of calcium is present, the bead must be held for a few minutes in the reducing flame of the blowpipe, then moistened with hydrochloric acid, and again ignited in the gas-flame.

2. *Reactions in the wet way.*—The bromide, chloride, iodide, nitrate, acetate, and many other organic salts of calcium are soluble in water; the carbonate, borate, phosphate, arsenate, and oxalate are insoluble, the sulphate sparingly soluble; all of them, however, except the sulphate, dissolve readily in nitric or hydrochloric acid.

In the aqueous solutions of calcium-salts, *potash* or *soda* produces a white gelatinous precipitate of hydrate of calcium, unless the solution is very dilute. *Ammonia:* no precipitate. *Neutral carbonates of alkali-metals:* white precipitate of carbonate of calcium, soluble with effervescence, in nitric, hydrochloric and acetic acids. *Acid carbonates of alkali-metals:* no precipitate in the cold; pulverulent precipitate on boiling, attended with escape of carbonic acid. *Sulphuric acid* and *soluble sulphates:* white precipitate of sulphate of calcium, unless the solution is very dilute; in that case, the precipitate appears on addition of alcohol, in which the sulphate of calcium is quite insoluble. *Oxalic acid* and *oxalate of ammonium:* white precipitate of oxalate of calcium, easily soluble in nitric or hydrochloric acid, but insoluble in acetic acid. *Sulphydric acid, alkaline sulphides, ferrocyanide of potassium, hydrofluosilicic acid:* no precipitate.

By these characters calcium in solution may be immediately distinguished from all other metals, except barium and strontium, and from these it may be distinguished by the greater solubility of its sulphate. A solution of sulphate of calcium gives a white precipitate immediately with a soluble barium-salt, and after a while with a salt of strontium.

3. *Quantitative Estimation.*—Calcium may be estimated either as carbonate or as sulphate. The best method of precipitating it, is in most cases by oxalate of ammonium, the oxalate being the least soluble of all the salts of calcium. If the solution contains an excess of any strong acid, such as nitric or hydrochloric acid, it must be neutralised with ammonia before adding the oxalate of ammonium, because oxalate of calcium is soluble in the stronger acids. The precipitate, after being washed with hot water and dried, is heated over a lamp, care being taken not to allow the heat to rise above low redness. It is thereby converted into carbonate of calcium containing 40·15 per cent. of calcium or 56·12 of lime.

If, however, the solution contains any acid which forms with lime a compound insoluble in water, phosphoric or boracic acid for example, this method of precipitation cannot be adopted; because, on neutralising with ammonia, the lime would be precipitated in combination with that acid, and would not be converted into oxalate on addition of oxalate of ammonium. In such a case, the calcium may be precipitated as sulphate by adding pure dilute sulphuric acid and alcohol. The sulphate, when dried, contains 41·25 per cent. of lime. From acid solutions of phosphate of calcium the metal may, however, be precipitated by oxalate of ammonium, with addition of acetate of ammonium, because oxalate of calcium is insoluble in acetic acid, which dissolves the phosphate with facility.

4. *Separation from other Elements.*—From the metals of the first group (p. 217) calcium is easily separated by sulphydric acid, from those of the second, by sulphide of ammonium.

From the *alkali-metals*, calcium is easily separated either by oxalate of ammonium, or by sulphuric acid and alcohol.

Calcium is separated from *barium* by precipitating both the earths as carbonates, dissolving the carbonates in nitric acid, evaporating to dryness, and digesting the residue in absolute alcohol, which dissolves nitrate of calcium, but not nitrate of barium. They may also be separated in this manner in the form of chlorides, but the separation is less complete, because chloride of barium is not quite insoluble in absolute alcohol.

From *strontium*, calcium is separated in the same manner, nitrate of strontium being likewise insoluble in absolute alcohol.

When baryta, strontia, and lime occur together, the baryta is first separated by hydro-fluosilicic acid; the strontia and lime in the filtrate are then converted into sulphates; these sulphates, after being weighed, are converted into carbonates, either by fusion with carbonate of sodium or by boiling with the aqueous solution of that salt; the carbonates weighed; and the quantities of strontium and calcium determined, as follows:—Let x be the weight of the strontium, y that of the calcium, s that of the sulphates and c that of the carbonates; then we have the equations:

$$\frac{Sr^2SO^4}{Sr^2}x + \frac{Ca^2SO^4}{Ca^2}y = s; \qquad \frac{Sr^2CO^3}{Sr^2}x + \frac{Ca^2CO^3}{Ca^2}y = c.$$

$$\text{or } \frac{183\cdot8}{97\cdot8}x + \frac{136}{40}y = s; \qquad \frac{157\cdot8}{97\cdot8}x + \frac{100}{40}y = c.$$

Or, the carbonates may be dissolved in nitric acid, and the nitrates separated by absolute alcohol, as above.

5. *Atomic Weight of Calcium.*—Dumas found that 100 pts. of Iceland spar, $Ca^2O.CO^2$, yielded by calcination 56 pts. lime, Ca^2O, whence (since $CO^2 = 44$) the atomic weight of lime = 56, and that of calcium 20. Erdmann and Marchand, and likewise Berzelius, in repeating this mode of estimation, found for calcium the number 20·03. Berzelius (Traité, iv. 538) by converting pure lime into the sulphate, found Ca = 20·13. Lastly, Dumas (Ann. Ch. Pharm. cxiii. 33) has determined this number by decomposing pure chloride of calcium with nitrate of silver. White marble was treated with dilute hydrochloric acid; the solution mixed with excess of lime (prepared from the same marble); the filtrate evaporated; the residue again treated with hydrochloric

acid, and ignited in hydrochloric acid gas; and the pure chloride of calcium thus obtained was decomposed by nitrate of silver. Three experiments thus made gave respectively $Ca = 20{\cdot}00$, $20{\cdot}03$, $20{\cdot}00$. The number 20 is generally adopted.

CALCIUM, FLUORIDE OF. CaF.—This compound occurs abundantly in nature, sometimes massive, sometimes crystallised in octahedrons, cubes, and other forms of the regular system (see FLUOR-SPAR). It is peculiarly a constituent of metalliferous veins. In minute quantity it is very generally diffused, being associated, to the amount of a few thousandths, with phosphate of calcium, in the bones of animals, and in somewhat larger quantity in the enamel of the teeth; minute quantities of it also found in plant-ashes and in the earthy deposit formed in sea-water by boiling. It may be prepared artificially as a gelatinous mass, by precipitating a soluble calcium-salt with fluoride of potassium or sodium, or in the granular state, by neutralising hydrofluoric acid with carbonate of calcium.

Fluoride of calcium dissolves in about 2000 pts. of water at 15° C. (G. Wilson), and somewhat more abundantly in water containing carbonic acid; hence its occurrence in sea-water. It dissolves in free hydrofluoric acid and in strong hydrochloric acid, and is precipitated as a transparent jelly by ammonia. It melts at a high temperature, and crystallises on cooling. It is decomposed at a high temperature by vapour of water, yielding lime and hydrofluoric acid. Fused with hydrate or carbonate of potassium, or sodium, it yields oxide or carbonate of calcium and an alkaline fluoride. Strong sulphuric acid does not decompose it at ordinary temperatures, but on heating the mass, hydrofluoric acid is given off, and sulphate of calcium remains. Vapour of sulphide of carbon passed over a red-hot mixture of fluor-spar and charcoal at a red heat, decomposes the fluoride completely, forming sulphide of calcium and volatile fluorine-compounds. It is also decomposed at a red heat by chlorine. (Frémy.) (See FLUORINE.)

Fluor-spar is much used as a flux in metallurgic operations, especially in the treatment of copper ores; also in the reduction of aluminium (p. 151).

CALCIUM, IODIDE OF. CaI.—Prepared by heating calcium in iodine vapour or by dissolving lime or the carbonate in hydriodic acid, evaporating and fusing the residue in a closed vessel. Resembles the chloride, melts below a red heat, and if in contact with the air, is decomposed, with formation of lime and separation of iodine. Very soluble and deliquescent. Decomposed by sodium at a red heat. The hydrate crystallises in long needles.

CALCIUM, OXIDE OF. *Lime*, Ca^2O, or CaO.—Anhydrous or quick lime is obtained by heating to redness the carbonate, nitrate, or any salt of calcium containing an acid easily expelled by heat; but for actual preparation, the carbonate is the only salt employed. In a closed vessel capable of resisting pressure, carbonate of calcium may be melted without undergoing decomposition; but when heated to redness under the ordinary atmospheric pressure, it gives off carbonic anhydride and leaves lime ($Ca^2CO^3 = Ca^2O + CO^2$). On the small scale, the decomposition may be performed in a crucible heated in a furnace; to obtain perfectly pure lime, the crystallised carbonate or the finest Carrara marble should be used. On the large scale, masses of limestone are burned in kilns, the mineral being mixed up with the coal or other combustible matter. In general, one bushel of coal is sufficient to make five or six bushels of lime; magnesian limestones require less fuel than pure limestone. When a limestone containing much aluminous or siliceous earth is to be burnt, great care should be taken to prevent the fire from becoming too intense; for such lime easily vitrifies. The kilns for burning these argillaceous or siliceous limestones should be provided with a damper. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 729.)

Pure lime forms white hard porous masses of specific gravity 2·3 to 3·08. It bears the strongest heat without decomposition, and melts only in the flame of the oxyhydrogen blowpipe or in the voltaic arc. Its most remarkable property is the avidity with which it takes up water. When water is poured upon pure lime, it is instantly absorbed, and in a few seconds the lime becomes hot, gives off a large quantity of steam, and crumbles to powder: this is called the *slaking* of lime; with large masses the evolution of heat and escape of vapour are very violent. Lime which slakes easily, is called *fat lime*. Impure lime, especially that which contains clay, takes up water but slowly: such lime is said to be *poor*.

The product of the action of water on lime, is *hydrate of calcium* or *hydrate of lime*, $CaHO$ or $Ca^2O.H^2O$. It is a white soft powder, which gives off its water at a red heat, and is reconverted into quicklime. It is sparingly soluble in water, more in cold than in hot water: hence, water saturated with lime in the cold, deposits the hydrate when boiled. A solution evaporated in vacuo over oil of vitriol, deposits the hydrate in hexagonal prisms (Gay-Lussac). According to Dalton, lime-water formed at 60° 130°, and 212° (Fahr.) contains 1 grain of lime (anhydrous) in 778, 972, and 1270 grs.

of water. The solution, called *lime-water*, is alkaline, and has a caustic taste. It precipitates most metallic oxides from their solutions, all those in fact which are insoluble in water; also carbonic, boracic, silicic, and phosphoric acids when added to their neutral or alkaline solutions, or in excess to their acid solutions. When exposed to the air, it soon becomes covered with a pellicle of carbonate of calcium. The solid hydrate also absorbs carbonic acid from water, forming, according to Fuchs, the hydrocarbonate $Ca^2CO^3.HCaO$.

Lime dissolves readily in nitric, hydrochloric, and acetic acid. The hydrate exposed to the action of chlorine gas, forms a mixture of chloride and hypochlorite of calcium, commonly called *chloride of lime* or *bleaching powder:*

$$Ca^2O + Cl^2 = CaCl + CaClO.$$

Chlorine does not act upon anhydrous lime or on the carbonate.

Lime is applied to a variety of useful purposes: —1. For making mortar. The lime in the state of hydrate, is mixed with 2 pts. of coarse or 3 pts. of fine sand, and made with water into a paste, which as it dries, absorbs carbonic acid slowly from the air, and is converted into a hard mass of hydrate and carbonate, which binds the stones or bricks firmly together. The chief use of the sand is to prevent by its mass the too great contraction of the mortar in drying. — 2. In tanning, to promote the separation of the hair or wool from the skins, and of the fat and fleshy parts.—3. In the preparation of caustic alkalis from their carbonates. —4. In the saponification of fatty bodies intended for the preparation of stearine candles.—5. In the defecation of sugar (see SUGAR).—6. As a manure. Soils containing too much clay, are often mixed with lime, which, by absorbing water and carbonic acid, swells and disintegrates, and thus renders the soil lighter. It also exerts a decomposing action on the clay, rendering the silicate of potassium soluble.

Peroxide of Calcium, CaO, is known only as a hydrate, which falls down in very fine crystalline scales when lime-water is mixed with an aqueous solution of peroxide of hydrogen. (Thénard.)

CALCIUM, OXYCHLORIDE OF. (See page 716.)

CALCIUM, OXYGEN-SALTS OF. See the several ACIDS.

CALCIUM, OXYSULPHIDE OF. When sulphide of calcium prepared by reducing the sulphate with charcoal, is boiled with a large quantity of water, the solution filtered hot, and evaporated in a retort containing air, a large quantity of sulphuretted hydrogen escapes with the watery vapours: the cooled liquid deposits sulphite of calcium, and on further concentrating the mother-liquor, gold-coloured needles are obtained consisting of an oxysulphide $Ca^{12}S^5O + 20 aq$. When heated out of contact with the air, they give off water and sulphur, without alteration of form, and leave a white residue, which, when treated with hydrochloric acid, deposits sulphur, gives off sulphuretted hydrogen, and forms a product containing sulphate of calcium. (H. Rose, Pogg. Ann. xv. 433.)

CALCIUM, PHOSPHIDE OF. CaP or Ca^2P? — Prepared by passing vapour of phosphorus over red-hot lime. A good mode of proceeding is to place a few pieces of phosphorus at the closed end of a combustion-tube, fill the tube with small lumps of quick lime (made by forming slaked lime into pellets and calcining them), then heat the part of the tube containing the lime to redness, and pass the vapour of phosphorus over it by cautiously surrounding the closed end of the tube with hot fuel. To prepare larger quantities, a crucible having a hole at the bottom is filled with pellets of lime, and placed on the grate of a furnace, and a flask containing phosphorus is placed below the grating with its neck passing upwards through the hole in the crucible. The fire is then lighted, and as soon as the crucible is red-hot, the phosphorus in the flask is gradually heated, so that its vapour may pass upwards through the lime. The product is a brown mass consisting, according to Thénard, of hemiphosphide and pyrophosphate of calcium:

$$7Ca^2O + P^7 = 5Ca^2P + Ca^4P^2O^7.$$

According to Gmelin (Handb. iii. 188), it is a mixture of monophosphide and tribasic phosphate of calcium:

$$4Ca^2O + P^6 = 5CaP + Ca^3PO^4$$

Possibly both these reactions may take place together. The product, when thrown into water, is immediately decomposed, with evolution of spontaneously inflammable phosphoretted hydrogen:

$$3CaP + 3H^2O = PH^3 + 3CaHO + P^2;\ \text{or}\ 3Ca^2P + 3H^2O = 2PH^3 + 3Ca^2O + P.$$

Part of the diphosphide may also be decomposed in the manner represented by the equation:

$$Ca^2P + H^2O = PH^2 + Ca^2O.$$

The formation of the compound PH^2, may account for the spontaneous inflammability of the gas. (See PHOSPHORETTED HYDROGEN, under PHOSPHORUS.)

CALCIUM, SELENIDES OF. A *monoselenide* is formed by precipitating chloride of calcium with monoselenide of potassium; it is a flesh-coloured precipitate.

A *polyselenide*, mixed however with selenite of calcium, is produced by heating lime with selenium to a temperature just below redness. Lime-water saturated with seleniuretted hydrogen, deposits crystals of [mono ?] selenide of calcium when exposed to the air.

CALCIUM, SULPHIDES OF. The *monosulphide*, Ca^2S, is prepared: 1. By decomposing the sulphate with charcoal or coal.—2. By decomposing the sulphate at a red heat with carbonic oxide: $Ca^2SO^4 + 4CO = Ca^2S + 4CO^2$. — 3. By passing sulphuretted hydrogen over red-hot lime, water being formed at the same time. It is white, amorphous, with hepatic taste and alkaline reaction. It is but sparingly soluble in water: boiling water decomposes it, yielding sulphydrate and hydrate of calcium:

$$Ca^2S + H^2O = CaHS + CaHO.$$

Mixed with water, it is easily decomposed by carbonic acid, yielding carbonate of calcium and sulphydric acid:

$$Ca^2S + H^2O + CO^2 = Ca^2CO^3 + H^2S.$$

The monosulphide, after being heated, shines in the dark; it was formerly called *Canton's Phosphorus.*

Disulphide of Calcium, Ca^2S^2, is formed by boiling milk of lime with sulphur and water, but not long enough to allow the lime to be completely saturated. The filtered liquid on cooling, deposits crystals, whose composition agrees with the formula $Ca^2S^2.3H^2O$. (Herschell.)

Pentasulphide of Calcium, Ca^2S^5, is produced when the monosulphide or hydrate of calcium is boiled for a considerable time with excess of sulphur. It absorbs oxygen with avidity. When hydrate of calcium is used, there is also formed an oxysulphide represented by the formula $Ca^{12}S^5O.20H^2O$, or $5Ca^2S.Ca^2O.20H^2O$. (H. Rose.)

SULPHYDRATE OF CALCIUM, $CaHS$ or $Ca^2S.H^2S$, is formed, together with the hydrate, when the monosulphide is repeatedly boiled with water. The best mode of preparing it is to pass sulphuretted hydrogen through hydrate or sulphide of calcium suspended in a considerable quantity of water, as long as it is absorbed, stirring well all the while. The solution thus formed has a sharp, bitter, hepatic taste, an alkaline reaction, and slight causticity. The compound cannot be separated from it in the solid state, even by evaporation in vacuo or in hydrogen gas, being resolved, as soon as crystallisation begins, into sulphydric acid which escapes, and sulphide of calcium which separates in silky prisms. If the solution be boiled down in a retort containing air, sulphydric acid escapes and oxysulphide of calcium is deposited (p. 715).

Sulphydrate of calcium may be used as a depilatory, and is recommended for this application by Böttger (Ann. Ch. Pharm. xxix. 79), in place of sulphide of arsenic. It may be prepared for the purpose by passing sulphuretted hydrogen into thin milk of lime till the mass acquires a bluish-grey colour (from admixed sulphide of iron). The paste thus formed, is laid, to the thickness of a line, on the surface from which the hair is to be removed, and scraped off after a minute or two with a blunt knife, the hair then coming away with it. If it could be produced cheaply enough, it might be used for removing the hair from hides in the tan-yard.

CALC-SINTER. *Stalactitic carbonate of lime.* It is found in pendulous conical rods or tubes, mammelated, massive, and in many imitative shapes. Fracture lamellar, or divergent fibrous. Lustre silky or pearly. Colours, white of various shades, yellow, brown; rarely green, passing into blue or red. Translucent, semi-hard, very brittle. Large stalactites are found in the grotto of Antiparos, the Woodman's cave in the Harz, the cave of Auxelle in France, in the cave of Castleton in Derbyshire, and Macalister cave in Skye. They are continually forming by the infiltration of carbonated lime water, through the crevices of the roofs of caverns. Solid masses of stalactite have been called oriental alabaster. The irregular masses on the bottoms of caves are called stalagmites. U.

CALCOFERRITE. A yellow laminar mineral, from Battenberg in Rhenish Bavaria, containing, according to Reissig, 34·01 per cent. P^2O^5; 24·34 Fe^4O^3, 2·96 Al^4O^3, 14·81 Ca^2O, 2·65 Mg^2O, and 20·56 water (= 99·27), a composition agreeing nearly with the formula $2(2Ca^2O.P^2O^5).2Fe^4O^3.P^2O^5 + 12aq$. It exhibits perfect cleavage in one direction, and traces in two other directions, oblique to each other but perpendicular to the first, and is therefore probably orthorhombic. Specific gravity 2·52—2·53. Hardness = 2·5. Fuses readily before the blowpipe to a black, shining, magnetic globule. Dissolves easily in hydrochloric acid. (Handw. d. Chem. ii. [2] 671.)

CALCSPAR. *Calcareous Spar. Calcite.*—The rhombohedral form of carbonate of calcium. The primary form is an obtuse rhombohedron (*fig.* 116), in which the length of the principal axis to that of the secondary axis as 0·8543 to 1, and the angle of the terminal edges is 105° 5′. Of this, there are numerous modifications, among which are many acute and obtuse rhombohedrons, and likewise scalenohedrons, but all distinctly cleavable parallel to the faces of the primary rhombohedron. The primary form, + R, seldom occurs as an unbroken crystal in pure calcspar, but is the prevailing form of bitter-spar ($CaMgCO^3$). Most of the forms occur only in combination. The dimensions of the most frequently occurring rhombohedrons are given in the following table, each of them being the *next acuter* rhombohedron with relation to the one above, and *next obtuser* with relation to that next below it. (See CRYSTALLOGRAPHY, HEXAGONAL SYSTEM.)

	Principal axis.	Inclination of faces at terminal edges.	Inclination of faces at lateral edges.
+ $\frac{1}{4}$R	0·2136	156° 2′	23° 58′
− $\frac{1}{2}$R	0·4271	134° 57′	45° 3′
+ R	0·8543	105° 5′	74° 55′
− 2R	1·7086	78° 51′	101° 9′
+ 4R	3·4172	65° 50′	114° 10′

These forms, and combinations of them, are shown in figures 115, 116, 117, 118, 119, 120, 121. *Fig.* 115 is one of the most common of the rhombohedrons, and is frequently found alone, but still more frequently in combination with the hexagonal prism, producing the form seen in *fig.* 122. It occurs abundantly at Andreasberg in the Harz, and in the mines of Derbyshire. Among the scalenohedrons, is the variety called *Dog's-tooth spar*, + R^3 (*fig.* 123), in which the inclinations of the faces in the terminal edges are 104° 38′ and 144° 24′. It is found in Derbyshire and other localities. It frequently occurs also in hemitropic twin-crystals (*fig.* 124), which may be supposed to be formed by cutting the crystal (*fig.* 123), in halves by a horizontal plane, and turning one of the halves through an angle of 180°.

Fig. 115.

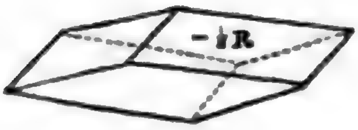


Fig. 116.

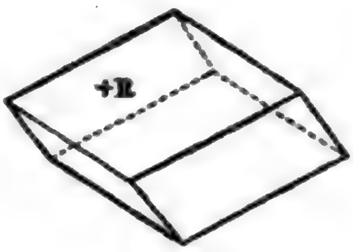

Fig. 117.

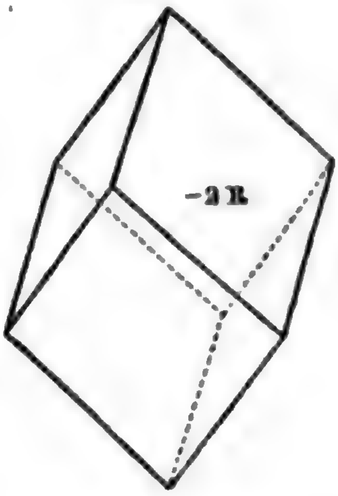

Fig. 118.

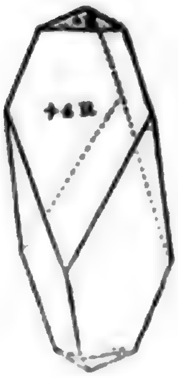

Fig. 119.

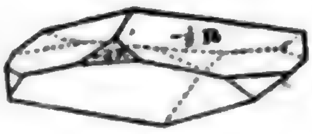

Fig. 120.

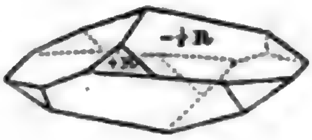

Fig. 121.

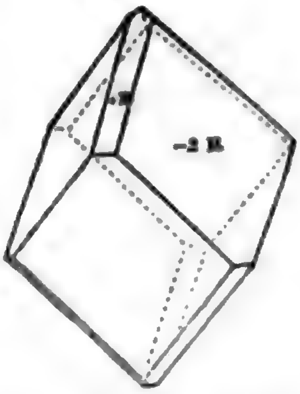

The specific gravity of the purest crystals of calcspar is 2·721. Hardness = 3, being intermediate between gypsum and fluorspar. Calcspar when pure is colourless, but often exhibits various tints of yellow, green, red, brown, and even black, arising from impurities. Lustre vitreous. Translucent more or less, and when transparent, exhibits in a remarkable degree, the double refraction of light. This property is best seen in the beautiful crystals obtained from Iceland, hence known as Iceland spar. These crystals exhibit the ground-form R, being in fact merely fragments of larger crystals.

Fig. 122.

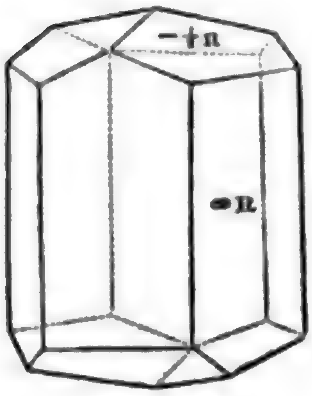

Fig. 123.

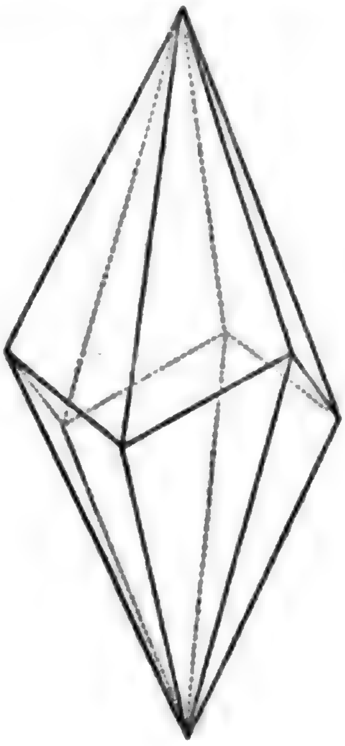

Fig. 124.

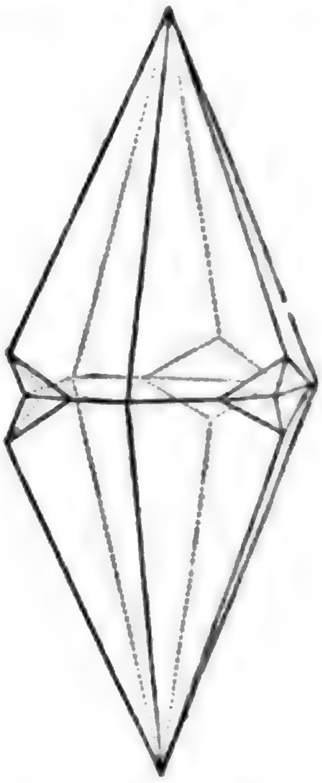

Calcspar occurs in all parts of the world, and is one of the most abundant of minerals. The lead-mines of Derbyshire and Cumberland, and of Andreasberg in the Harz, are noted as affording the most beautiful crystals and the greatest variety of form. [Respecting the circumstances under which carbonate of calcium assumes the forms of calcspar and of arragonite, see ARRAGONITE, p. 358.]

CALCTUFF. An alluvial form of carbonate of calcium, probably deposited from calcareous springs. It has a yellowish-grey colour, a dull lustre internally; a fine-grained earthy fracture; is opaque, and usually marked with impressions of vegetable matter. Its density is nearly the same as that of water. It is soft and easily cut or broken. U.

CALCULUS, or **STONE.** The name generally given to all hard concretions, not bony, formed in the bodies of animals. (See BEZOARS, BILIARY CALCULI, URINARY CALCULI.)

CALDERITE. A mineral from Nepal, said by Söchting (Deutsche geolog. Gesellschaft, ix. 4) to be a kind of garnet.

CALEDONITE. *Cupreous Sulphocarbonate of Lead*, from Leadhills in Scotland, consists, according to analyses by Brooke (Ed. Phil. J. iii. 117), and Thomson (Phil. Mag. 1840, p. 402), of $3Pb^2SO^4.2Pb^2CO^3.Cu^2CO^3$. It occurs in prismatic crystals of the trimetric system, with numerous secondary faces, sometimes large, but usually minute, and occasionally in branches diverging from a point. Specific gravity = 6·4. Hardness = 2·5—3. Colour verdigris- or bluish-green. Streak greenish-white. Lustre resinous. Translucent. Fracture uneven. Rather brittle. It is easily reduced before the blowpipe, and dissolves partially in nitric acid, with separation of sulphate of lead.

CALENDULIN. A mucilaginous substance extracted from the leaves and flowers of the common marigold, *Calendula officinalis*. (Geiger, *Diss. de Cal. off.*, Heidelberg, 1848.)

CALICO-PRINTING. The art of dyeing cloth (chiefly cotton and linen), topically; that is, impressing figures in one or more colours on certain parts of the cloth, while the rest of the surface is left in its original state. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 491.)

CALIFORNIN. A bitter principle extracted from *Chica Californica*. (Winckler, Buchn. Repert. xxxii. 20.)

CALISAYA BARK. See CINCHONA BARK.—**CALLAIS.** See TURQUOIS.

CALLUNA VULGARIS. An ericaceous plant, commonly called *Ling*. It contains, according to Rochleder, a peculiar tannic acid; the leaves and branches contain a trace of volatile oil, an acid, probably citric acid, and a small quantity of ericolin. 100 pts. of the air-dried plant yield, according to Sprengel, 1·95 ash (I.) Röthe found in the plant collected at the end of August, 5·55 per cent. water, and the dried plant yielded 6·35 per cent. ash (II.) Nutzinger found in the air-dried plant growing on moor-land, 2·87 per cent. ash (III.); and Thielau found in the flowering plant growing on the lias sand-stone, 3·32 per cent. ash (IV.) The ash contained in 100 pts:

	K^2O	Na^2O	Ca^2O	Mg^2O	Al^4O^3	Fe^4O^3	Mn^4O^3	Cl	SO^3	P^2O^5	SiO^2
I. . .	4·8	10·2	26·5	8·4	2·3	2·7	4·6	4·9	5·2	0·6	29·7
II. . .	10·6	0·8	12·0	6·7	—	4·9	4·1	—	1·7	10·9	48·1
III. . .	6·4	5·4	33·5	8·0	0·8	2·0	3·8	1·8	1·4	4·0	32·7
IV. . .	29·6		15·5	6·6	0·5	1·5	4·7	4·1	1·0	5·3	30·9

CALLUTANNIC ACID. $C^{14}H^{14}O^9$ or $C^{14}H^7C^9$ (Rochleder, Ann. Ch. Pharm. lxxxiv. 354).—The tannic acid of *Calluna vulgaris*. To obtain it, the alcoholic extract of the green parts of the plant (without the root) is mixed with water; the liquid filtered from a green precipitate of fat, chlorophyll, &c., is precipitated with acetate of lead; the washed precipitate treated with very dilute acetic acid, in which it is but partially soluble; the filtrate mixed with excess of sub-acetate of lead; the resulting yellow precipitate decomposed by sulphuretted hydrogen; and the filtered liquid evaporated on a chloride of calcium bath, in an atmosphere of carbonic anhydride. Callutannic acid then remains as an inodorous amber-coloured mass. This acid does not form any definite salts with the alkali-metals, alkaline-earth-metals or silver: for its solutions in alkalis or alkaline earths quickly absorb oxygen from the air, and oxide of silver is immediately reduced by it. Rochleder has obtained two lead-salts to which he assigns the formula $5PbO.HO.2C^{14}H^6O^8$ and $8PbO.2HO.3C^{14}H^6O^8$, and a stannic salt said to contain $7SnO^2.2HO.2C^{14}H^6O^8$.

Callutannic acid may be used to dye wool. The aqueous solution mixed with stannic chloride and a few drops of hydrochloric acid, and heated to the boiling point, imparts to wool mordanted with alum, a sulphur-yellow to chrome-yellow colour, according to the strength of the solution and the time of immersion.

CALLUXANTHIN. $C^{14}H^{10}O^7$.—A yellow flocculent substance obtained by boiling callutannic acid with dilute mineral acids. It is sparingly soluble in cold water, easily in hot water and in alcohol. It dissolves also in alkaline liquids, but the solution quickly absorbs oxygen, and is then precipitated by dilute acids in red-brown flocks. (Rochleder.)

CALOMEL. Hemichloride of mercury or mercurous chloride. See MERCURY.

CALOPHYLLUM RESIN. *Maynas resin*, $C^{14}H^{18}O^4$.—A resin from Maynas in South America, obtained from *Calophyllum Caloba* or *C. longifolium*. It has the aspect of common resin, dissolves in alcohol, ether, and oils, both fixed and volatile, and crystallises from boiling alcohol in small transparent colourless prisms of specific gravity 1·12. It melts at 105° C., but does not resolidify till cooled to 90°. It is decomposed by dry distillation; dissolves with red-brown colour in sulphuric acid, but is precipitated unaltered by water; and when heated with nitric acid of specific gravity 1·32, is said to yield butyric and oxalic acids, together with another acid which does not precipitate calcium-salts. With chromic acid, it is said to yield carbonic and formic acids. It dissolves in alkalis. (Levy, Compt. rend. xviii. 242.)

CALORIMETER. An instrument for the estimation of latent heat, specific heat, heat of combustion, &c. (See HEAT.)

CALORIMOTOR. A voltaic arrangement consisting of one pair or a few pairs of very large plates, used chiefly for producing considerable heat effects. (See ELECTRICITY.)

CALSTRONBARYTE. Shepard's name for a variety of heavy spar from Shoharie in New York, mixed with carbonate of strontium and calcium. (Sill. Am. J. xxxiv. 161.)

CALYPTOLITE. A mineral from Haddam and Mittletown in Connecticut, crystallised in square prisms of specific gravity 4·34, hardness 6·5. Probably an altered zircon. (Shepard, Sill. Am. J. [2] xii. 210.)

CAMBOLEY RESIN. A resin from *Morus indica*.

CAMELLIA JAPONICA. The leaves contain tannin, which is sparingly precipitated by gelatin, abundantly by lead and iron salts: they do not contain theine. (Stenhouse.)

CAMPEACHY WOOD. See LOGWOOD.

CAMPHAMIC ACID and **CAMPHAMIDE.** See CAMPHORAMIC ACID and CAMPHORAMIDE.

CAMPHENE. This term is used in various ways; sometimes as a generic name for the hydrocarbons isomeric or polymeric with oil of turpentine, sometimes as the name of the radicle of camphor ($C^{10}H^{16}$) and its allied compounds. By Dumas and Berthelot, it has been applied especially to the hydrocarbon, also containing $C^{10}H^{16}$, obtained by the action of alkalis on hydrochlorate of turpentine-oil. Laurent applied the same appellation to the radicle of oil of cloves, eugenin, &c.

Chlorinated and brominated derivatives of camphene, *e. g.* $C^{10}H^{14}Cl^2$ and $C^{10}H^{12}Br^4$ are obtained by the action of chlorine or bromine on oil turpentine and its isomers. A *monochlorocamphene*, $C^{10}H^{15}Cl$, and a *dichloride of camphene*, $C^{10}H^{16}Cl^2$, are produced by the action of pentachloride of phosphorus on camphor (see p. 728).

CAMPHENES or *Terebenes.* The generic name for the volatile oils or hydrocarbons $C^{5n}H^{8n}$, isomeric or polymeric with oil of turpentine. Most of them are isomeric and consist of $C^{10}H^{16}$, *e. g.* oil of turpentine, oil of lemons, oil of juniper, caoutchin, &c.; some, as colophene, appear to consist of $C^{20}H^{32}$.

Many camphenes exist ready formed in plants, as the oils of juniper, lemon, and turpentine; they are often contained in the natural oils associated with oxygenated compounds, and may be separated therefrom by fractional distillation, as carvene from oil of caraway, borneene or valerene from oil of valerian, &c. Many are produced from oxygenated compounds containing $C^{5n}H^{8n}$ + water, by the action of phosphoric anhydride (*e. g.* borneene from borneol, cinæbene from wormseed-oil, &c.) Others are formed from oxygenated oils by the action of hydrate of potassium (oil of sage and others); some by dry distillation, as oil of amber, caoutchin, &c.

All the camphenes are liquid at ordinary temperatures (except Berthelot's camphene, which is a solid melting at 46° C.); they have for the most part a density of 0·8 to 0·9 (oil of parsley is the only one heavier than water, specific gravity = 1·0 to 1·1), and boil between 155° and 165° C.; their observed vapour-density varies from 4·6 to 4·8, the formula $C^{10}H^{16}$ calculated for 2 vol. giving a thoretical density of 4·7. A few only boil at higher points, viz. oil of copaiba at 250° C.; petrolene at 280°; colophene at about 310°; cinæphene at nearly 320°, metaterebene about 360°. The observed vapour density of carvene is 5·1, of tolene 5·7, of petrolene 9·4, of colophene 11·1; the formula $C^{20}H^{32}$ calculated for 2 vol. requires 9·4.

Camphenes are distinguished one from the other by their odours, which in some, as oil of lemon, are very fragrant, in others, as in oil of copaiba, extremely disagreeable; also by their action on polarised light. All natural camphenes possess the optical rotatory power in a greater or less degree, some turning the plane of polarisation to the right, others to the left; but even in the same oil, the strength and direction of the rotatory power vary according to the temperature and other circumstances.

Camphenes readily absorb *oxygen* and convert it into ozone. *Iodine* for the most part decomposes them readily and with evolution of heat, sometimes even with slight explosion, the iodine taking the place of a portion of the hydrogen; this reaction serves to detect the admixture of camphenes, oil of turpentine, for example, with other volatile oils. *Chlorine* and *bromine* act in a similar manner.

Camphenes treated with *bromine* and *water* are easily converted into brominated oils (Gr. Williams, Phil. Mag. [4] v. 536). According to Chautard (Compt. rend. xxxiii. 671; xxxiv. 485), camphenes distilled with *water* and *bromide* or *chloride of lime*, yield, amongst other products, bromoform or chloroform.

Most camphenes unite with *hydrochloric acid*, forming either liquid or crystallised compounds, frequently having the composition $C^{10}H^{16}.HCl$ or $C^{10}H^{16}.2HCl$; these compounds, called artificial camphors, have the same rotatory power as the oils from which they are produced. Similar compounds are formed with *hydrobromic* and *hydriodic* acid.

Natural camphenes treated with *acids*, especially with *strong sulphuric acid*, generally undergo an alteration of molecular arrangement without change of chemical constitution, the odour being for the most part greatly altered, sometimes also the density and boiling point; but the most characteristic alteration is the loss of optical rotatory power. A camphene often yields several isomeric modifications by treatment with different acids, or by repeated treatment with the same acid. The new camphenes thus produced are called camphenes of the second order, or sometimes campherenes. Another class, called camphenes of the third order, or sometimes camphilenes, are obtained by the action of lime or baryta at high temperatures on the hydrochlorates of other camphenes; these are also optically inactive; and generally differ greatly in odour from the original camphenes, but often exhibit nearly the same specific gravity and boiling point. The camphenes of the second and third orders are decomposed by chlorine, bromine, and iodine, and form liquid or crystallised compounds with hydrochloric, hydrobromic, and hydriodic acids.

The camphenes are a very numerous class of bodies; the principal of them are:

Oil of bergamot
Borneene
Carvene
Caoutchin
Cinæbene
Neutral oil of cloves
Oil of copaiba
Oil of elemi
Gaultherilene
Oil of gomart
Oil of hops
Oil of juniper
Oil of lemon
Oil of orange
Oil of parsley
Oil of pepper
Petrolene
Oil of savin
Thymene
Tolene
Oil of turpentine

For details relating to specific gravity, boiling point, vapour-density, and rotatory power, see the several oils. (Handw. d. Chem. ii. [2] 691; Gm. xiv. 271—322 and 356—404.)

CAMPHERENES. Camphenes of the second order (p. 724).

CAMPHERYL or **CAMPHERILE.** A name applied by Laurent to the impure camphorone (*q. v.*) which he obtained from camphorate of calcium.

CAMPHIC ACID. $C^{10}H^{16}O^2$?—A product obtained, together with borneol, by heating camphor with alcoholic soda-solution in sealed tubes to 170°—190° C.

$$\underset{\text{Camphor.}}{2C^{10}H^{16}O} + H^2O = \underset{\text{Borneol.}}{C^{10}H^{18}O} + \underset{\text{Camphic acid.}}{C^{10}H^{16}O^2}.$$

On neutralising the product with sulphuric acid, dissolving out the camphate of sodium with alcohol, evaporating and again adding sulphuric acid, the camphic acid separates as a nearly solid, coloured mass, heavier than water, sparingly soluble therein, easily soluble in alcohol. It is decomposed by nitric acid. The potassium and sodium-salts are nearly insoluble in strong alkaline leys; they precipitate the salts of copper, iron, lead, silver, and zinc, not those of the alkaline-earth metals; all the precipitates are soluble in a large quantity of water. (Berthelot, Ann. Ch. Phys. [3] lvi. 94.)

CAMPHIDES. This term was applied by Laurent to nuclei in which the combustible hydrogen is replaced by oxygen.

CAMPHILENE. Deville's name for the camphene obtained by treating hydrochlorate of turpentine-oil with lime. Camphenes of the third order (p. 724) are sometimes called camphilenes.

CAMPHIMIDE. See CAMPHORIMIDE.

CAMPHIN. $C^{10}H^{18}$ or C^9H^{16}? (Claus, J. pr. Chem. xxv. 262; Gm. xiv. 448.)—Formed, together with campho-creosote, colophene, and campho-resin, by triturating camphor with an equal weight of iodine, and distilling. A black mass then remains containing campho-resin, and the distillate separates on standing, into a watery layer containing hydriodic acid, and an upper oily layer containing camphin, campho-creosote, and colophene. To obtain the camphin, the mixture is agitated with mercury, to remove iodine, then rectified *per se*, and the most volatile portion shaken up with potash-ley, and repeatedly rectified over potash-lime to remove iodine; it may also be freed from the last traces of iodine by setting it aside with potassium and rectifying.

Camphin is a thin colourless oil of specific gravity 0·827 at 25° C., and boiling at 167—170° under a pressure of 28 inches. It has a pleasant odour, like that of oil of mace, somewhat also like turpentine. It gave by analysis 86·06 per cent. C and 12·79 H; the formula $C^{10}H^{18}$ requires 86·96 C and 13·04 H, while C^9H^{16} requires 87·10 C and 12·90 H. Gerhardt regarded it as impure cymene, $C^{10}H^{14}$ (89·5 C and 10·5 H).

Camphin burns with a bright but very smoky flame. It dissolves in *alcohol*, *ether*, *oil of turpentine*, and *rock-oil;* but not in water, weak alcohol, potash, or dilute acids, or even in strong hydrochloric acid. It absorbs a small quantity of *hydrochloric acid gas*. It is but slightly attacked by *sulphuric acid*. *Nitric acid*, with aid of heat, converts it into a yellow nitrogenised oil, smelling like cinnamon, or by prolonged heating, into a red oil soluble in potash. *Pentachloride of antimony* converts it into a resin.

Camphin is readily decomposed by *chlorine* and *bromine*, yielding *substitution-products*. The chlorocamphins are transparent, colourless, oily bodies, which, when treated with alcoholic potash, yield chloride of potassium and a chlorinated oil having an agreeable odour. Claus obtained two compounds, which he regarded as $C^9H^{13}Cl^3$ and $C^9H^{10}Cl^6$.

CAMPHINE. This term is applied in commerce to purified oil of turpentine, obtained by carefully distilling the oil over quick lime, sometimes also rectifying it over dry chloride of lime; in this manner it is obtained quite free from resin. In some cases, the oil is treated with sulphuric acid previous to rectification. This purified turpentine-oil is much used for burning in lamps, giving a very brilliant light. It is however very apt to smoke, and must therefore be burnt in lamps of peculiar construction, with very strong draught. A solution of camphine in three times its volume of alcohol of specific gravity 0·820, sometimes with addition of a little ether to ensure more complete solution, is also used as an illuminating material, and may be burned in ordinary lamps with argand burners.

CAMPHOCREOSOTE. A product of the decomposition of camphor by iodine at high temperatures; according to Schweizer, it is probably identical with carvacrol (*q. v.*)

CAMPHOGEN. Dumas' name for the hydrocarbon $C^{10}H^{14}$, obtained from camphor by the action of phosphoric anhydride; it is identical with cymene (*q. v.*)

CAMPHOL. This name was applied by Gerhardt to the camphor of the Lauraceæ; but Berthelot has recently applied it (Ann. Ch. Phys. [3] lvi. 78), to Borneol or Borneo-camphor, which he regards as the alcohol of a series in which common camphor is the aldehyde, thus:

Ethyl-series.		Camphyl-series.	
Ethyl-alcohol,	C^2H^6O	Camphol,	$C^{10}H^{18}O$
Aldehyde,	C^2H^4O	Camphor,	$C^{10}H^{16}O$
Acetic acid,	$C^2H^4O^2$	Camphic acid,	$C^{10}H^{16}O^2$
Chloride of ethyl,	C^2H^5Cl	Chloride of camphyl,	$C^{10}H^{17}Cl$
Ethylene,	C^2H^4	Camphene,	$C^{10}H^{16}$

Camphol is produced by treating camphor with alcoholic potash (p. 626), just as benzylic alcohol is produced from benzoic aldehyde (p. 578). It is also formed by distilling amber with ¼ of its weight of potash and a large quantity of water.

From later experiments by Berthelot and Buignet (Compt. rend. l. 606), it appears that the several bodies to which the name camphol has been applied, are isomeric but not identical, being especially distinguished by their different rotatory power, which in camphol from common camphor = +44·9°; in natural camphor or borneol, = +33·4°; in camphol from amber = +4·5°; while in lævo-rotatory borneol, or camphol obtained from madder-camphor (p. 626), it is −33·4°.

According to Berthelot, camphol heated with acids unites with them, like all alcohols, with elimination of water. The resulting compound ethers may be purified by removing the excess of acid with slaked lime and ether, and distilling off the excess of camphol by prolonged heating at 150°C. They are colourless, neutral, soluble in alcohol and ether; some are liquids, others crystalline; the latter melt at a lower temperature than camphol. Alkalis decompose them into acid and camphol, the latter exhibiting its original properties. *Benzoate of camphol*, $C^{17}H^{22}O^2 = C^7H^5(C^{10}H^{17})O^2$, is a neutral, colourless, inodorous oil.—*Stearate of camphol*, $C^{28}H^{52}O^2 = C^{18}H^{35}(C^{10}H^{17})O^2$, is colourless, inodorous, viscid, solidifying after a while in a crystalline mass.—*Chloride of camphyl*, $C^{10}H^{17}Cl$, obtained by heating camphol (borneol) with strong hydrochloric acid to 100° C. in a sealed tube for 8 or 10 hours, and purified by washing with dilute potash and crystallisation from alcohol, has the aspect, odour, and empirical composition of hydrochlorate of turpentine-oil or artificial camphor ($C^{10}H^{16}.HCl$), but turns the plane of polarisation to the left, somewhat less strongly than borneol. Heated to 180° C. with alcoholic soda-solution, it yields chloride of sodium and borneol. By this and by its rotatory power, it is sufficiently distinguished from hydrochlorate of turpentine-oil. (Handw. d. Chem. 2te Aufl. ii. [2] 695.)

CAMPHOLENE. C^9H^{16}. A liquid hydrocarbon obtained by distilling campholic acid with phosphoric anhydride. Vapour-density 4·353. (Delalande.)

CAMPHOLIC ACID. *Bornenic acid.* $C^{10}H^{18}O^2 = C^{10}H^{17}O.H.O.$—Produced by the action of hydrate of potassium on camphor. The quantity found under the ordinary atmospheric pressure is but small: but if the camphor be enclosed, together with potash-lime, in a sealed combustion tube of the ordinary dimensions, and its vapour made to pass several times over the heated potash-lime, about 5 or 6 grammes of purified acid may be obtained from each tube. To isolate the acid, the contents of the tube are digested in water, and the solution decomposed by a stronger acid. The campholic acid is then deposited as a crystalline mass, which may be purified by distillation. It is white, and crystallises well from a mixture of alcohol and ether; melts at 50° C.; boils without alteration towards 250°. Insoluble in water, but imparts to it an aromatic odour. Vapour-density 6·058. Distilled with phosphoric anhydride, it yields campholene, carbonic oxide being probably evolved at the same time:

$$C^{10}H^{18}O^2 = CO + H^2O + C^9H^{16}.$$

It is monobasic. The *calcium-salt*, $C^{10}H^{17}CaO^2$, is a snow-white crystalline powder obtained by pouring chloride of calcium into a nearly boiling solution of the acid in excess of ammonia. By dry distillation, it yields an oily body called *campholone*, $C^{19}H^{34}O$:

$$2C^{10}H^{17}CaO^2 = Ca^2CO^3 + C^{19}H^{34}O.$$

Campholate of silver, obtained by decomposing the neutral ammonium-salt with nitrate of silver, forms curdy flakes. (Delalande, Ann. Ch. Phys. [3] i. 120.)

CAMPHONE. Syn. of CYMENE.

CAMPHOMETHYLIC ACID. Camphorate of methyl and hydrogen. (See CAMPHORIC ACID, p. 733.)

CAMPHOR. $C^{10}H^{16}O$. (Gm. xiv. 358; Gerh. iii. 621).—A crystalline substance obtained from the *Laurus camphora* and other plants in which it exists ready formed. There are three modifications of it, identical in composition and chemical properties, but differing in their action on polarised light, viz. *dextro-camphor*, which turns the plane of polarisation to the right, *lævo-camphor*, which turns it to the left, and *inactive camphor*, which has no action on polarised light.

a. *Dextro-camphor. Laurel* or *common camphor*. This variety exists in the wood and bark of several trees of the Lauraceous order, chiefly in the *Laurus camphora*, a tree indigenous in Japan, Java, Sumatra, and Borneo. The process of extraction is very simple. In China and Japan, the wood, sawn into billets, is distilled with water in a kettle covered with an earthen capital lined with rice-straw, on which the crystals of camphor are deposited, being carried up by the aqueous vapour. The crude camphor thus obtained is exported to Europe, where it is purified by sublimation. In Sumatra and Borneo, the wood is split with wedges, and the camphor, which is found between the fibres in tears and crystals, is extracted; a single tree sometimes yields as much as twenty pounds.

Dextro-camphor is also produced artificially by the action of nitric acid on borneol or camphor of Borneo, $C^{10}H^{18}O$ (pp. 626, 726).

Camphor crystallises by sublimation, or by slow deposition from an alcoholic solution, in octahedrons or segments of octahedrons. It is white and semi-transparent, like ice, rather tough, sectile, and not easily reduced to powder without the aid of a little alcohol. It melts at 175° C. and boils at 204° C. evaporating completely away without alteration. Its specific gravity varies from 0·986 to 0·996. Vapour-density = 5·317 (Dumas). Water dissolves $\frac{1}{1000}$ pt. of camphor, and thereby acquires its peculiar smell and taste. When small bits of camphor are thrown into water in a broad basin, they revolve and move about with more or less velocity, in proportion to their smallness. These rotations are attributed to the force exerted by the vapours rapidly exhaled from the camphor on the surface of the water; but the explanation is not very satisfactory. If a pin-point slightly smeared with oil be dipped into the water, all the motions cease instantly, and the particles of camphor are repelled from the pin-spot by the spreading film of oil. The dispersion of the camphor-vapour is made very striking by the repulsion of the water on a moistened saucer from the points on which bits of this substance are laid.

Laurel-camphor is soluble in alcohol, ether, acetone, acetic acid, wood-spirit, sulphide of carbon, and oils. 100 pts. of alcohol of specific gravity 0·806 dissolve 120 pts. of camphor. It is thrown down almost entirely in flocks by the addition of water. Camphor augments in a remarkable degree the solubility of corrosive sublimate in spirit of wine.

The optical rotatory power of the alcoholic solution of camphor, is 47·4 for a length of 100 millimetres. According to Arndtsen (Ann. Ch. Phys. [2] liv. 403), it increases with the refrangibility of the rays much more quickly than is observed in any other substance. Solid camphor does not exhibit any rotatory power.

Reactions.—1. Camphor, when set on fire in the *air*, burns with a smoky flame, producing water and carbonic acid. Spongy *platinum*, or a coil of fine platinum wire laid on camphor, begins to glow when the camphor is set on fire, and continues glowing after the flame is blown out. Camphor is set on fire by *chlorochromic acid*.—2. By prolonged boiling with *nitric acid* or *permanganate of potassium*, it is converted into camphoric acid (p. 730).—3. Heated with *strong sulphuric acid* to 100° C. for 12—13 hours, it is converted into camphrene, $C^9H^{12}O$, with evolution of sulphurous anhydride and separation of charcoal (Chautard, Compt. rend. xliv. 66). According to Delalande (Instit. 1839, p. 399), camphor heated with excess of strong sulphuric acid, is converted into a volatile oil, which has the chemical properties and composition of common camphor, but less rotatory power, and when heated with potash to nearly 200° C. is converted into a solid camphor, whose rotatory power is intermediate between that of common camphor and that of the oily camphor. Gerhardt supposed that the oil obtained by Delalande was cymene; according to Chautard, it is camphrene containing camphor.—4. Camphor-vapour passed through a *red-hot glass* or *porcelain tube*, yields a combustible gas and an oil soluble in alcohol (Saussure).—5. When the vapour of camphor is passed over *red-hot iron*, an oily liquid is produced, containing naphthalene and a hydrocarbon boiling at 140° C. and having the composition of benzene (D'Arcet, Ann. Ch. Phys. [2] lxvi. 110).—6. Camphor distilled with

2 pts. *alumina* or *clay*, is resolved into carbonic anhydride, carburetted hydrogen, empyreumatic oil, and a residue of charcoal.—7. Distilled with *phosphoric anhydride*, it is resolved into water and cymene, $C^{10}H^{14}$ (Delalande, Ann. Ch. Phys. [3] i. 368). Heated with concentrated phosphoric acid, it volatilises for the most part undecomposed. It is also resolved into water and cymene by distillation with *chloride of zinc*. —8. Camphor-vapour passed over *red-hot lime*, yields camphrone, $C^{30}H^{44}O$, an oily liquid boiling at 75° C. At a very bright red heat, this product is resolved into carbonic oxide, carburetted hydrogen, and naphthalene (Frémy, Ann. Ch. Phys. lix. 16).—9. When the vapour is passed over heated *potash-lime*, under pressure, campholate of potassium, $C^{10}H^{17}KO^2$ is produced (Delalande, p. 726).—10. Camphor heated to 180°—200° C. with *alcoholic potash* or *soda*, is converted into borneol (Berthelot, pp. 626, 726).—11. When camphor is triturated with *iodine*, and the mixture is distilled, a dark-coloured oily liquid passes over, containing camphin, camphocreosote, and colophene, and a blackish residue is left, containing campho-resin (Clauss, p. 725).—12. *Bromine* unites with camphor, forming an instable bromide of camphor, $C^{10}H^{16}O.Br$, which is crystalline, and is decomposed by heat, by contact with air, and by the action of ammonia.—13. *Chlorine* exerts but little action on camphor, even in sunshine.—14. With *pentachloride of phosphorus*, camphor yields oxychloride of phosphorus, and a crystalline substance, $C^{10}H^{16}Cl^2$, having the aspect of artificial camphor (hydrochlorate of turpentine-oil). It remains dissolved in the oxychloride, and may be precipitated by water (Gerhardt):

$$C^{10}H^{16}O + PCl^5 = POCl^3 + C^{10}H^{16}Cl^2.$$

This compound yields by repeated dry distillation, a chlorinated oil consisting of $C^{10}H^{15}Cl$. (Gerhardt.)

According to Pfaundler (Ann. Ch. Pharm. cxv. 29), 1 at. camphor heated to about 110° C. with 1 at. PCl^5, yields hydrochloric acid, oxychloride of phosphorus, and chlorocamphene, $C^{10}H^{15}Cl$, which is a white, soft, crystalline substance, having an odour of camphor. Its index of refraction is 1·49327. It is insoluble in water, but dissolves in 3·5 pts. of 87 per cent. alcohol at 14° C., forming an optically inactive solution. The crystals volatilise rather quickly at ordinary temperatures, melt at about 60° C., and then sublime, decomposing at higher temperatures. With 2 at. pentachloride of phosphorus to 1 at. camphor, chloride of camphene, $C^{10}H^{16}Cl^2$, is obtained in white crystals, resembling the preceding in aspect and in odour, but softer, and having an index of refraction = 1·50553. It dissolves in 4·95 pts. of 87 per cent. alcohol, at 14° C., forming a solution possessing lævo-rotatory power. The crystals volatilise rather quickly at ordinary temperatures, and melt with partial sublimation near 70°. —15. If *chlorine* be passed through the solution of camphor in *trichloride of phosphorus*, various substitution-products are formed, according to the time for which the action of the chlorine is continued. *Tetrachlorocamphor*, $C^{10}H^{12}Cl^4O^2$, has been isolated, though not quite pure. If the action be continued for a long time, and assisted by heat, a colourless product is at length obtained, having the aspect of white wax, and consisting of *sexchloro-camphor*, $C^{10}H^{10}Cl^6O$ (Claus, J. pr. Chem. xxv. 259). —16. When camphor is heated with *mercuric chloride*, hydrochloric acid is evolved, together with an odour of turpentine, and a carbonaceous mass containing calomel remains.—17. *Pentachloride of antimony* attacks camphor strongly, giving off hydrochloric acid, and forming a resinous substance.—18. *Hydrochloric acid gas* is absorbed by camphor in quantities varying according to pressure and temperature, as shown by the following table, which gives the quantity of the gas (HCl) absorbed by 100 pts. camphor, at the temperature *t* and barometric pressure *b*:

t	24°	20°	18·5°	18·5°	13°	9°	7°	7°	3°	3° C.
b	747	740	735	744	320	288	270	740	232	738 mm.
HCl	19·0	20·0	20·4	20·5	15·3	15·8	16·3	240	17·0	26·0

At a certain low pressure, camphor no longer absorbs hydrochloric acid gas. This pressure varies with the temperature, being 220 mm. at 12°; 340 mm. at 15·0; 300 mm, at 20°; and 423 mm. at 24° (Bineau, Ann. Ch. Phys. [3] xxiv. 328).—19. *Sulphurous anhydride* is quickly absorbed by camphor, forming a colourless liquid, which is heavier than water, dissolves iodine and camphor, and when saturated with camphor, contains 4 pts. camphor to 1 pt. SO^2. It gives off sulphurous anhydride even at ordinary temperatures. The quantities absorbed by 100 pts. camphor at various pressures and temperatures, are given in the following tables (Bineau, *loc. cit.*):

t	24°	24°	15·5°	15·5°	12·5°	12·5°	2°	8°	4°	4°	2°	2° C.
b	524	745	355	744	529	727	304	682	490	720	649	650 mm.
SO^2	25·5	35·4	28·0	47·6	37·3	50·5	33·0	57·4	46·0	73·6	48·4	72·0

At 700 mm. pressure, 100 pts. camphor absorb of SO^2:

at	24°	20°	15·5°	14°	12·5°	10°	8°	4° C.
	33·1	37·7	44·3	46·8	48·9	54·0	58·6	70·5

—20. Camphor absorbs the vapour of *peroxide of nitrogen* (or nitric oxide in presence of air), forming a liquid which is decomposed by water, dissolves camphor, and when saturated therewith at 18° C., contains 100 camphor to 26—27 peroxide of nitrogen. (Bineau.)

β. Lævo-camphor.—When the essential oil of feverfew (*Pyrethrum parthenium*) is fractionally distilled, and the portion which distils between 200° and 220° C. is collected apart, it deposits on cooling a large quantity of camphor, similar in all respects to common camphor, excepting in its optical rotatory power, which is equal and opposite, viz. $[\alpha] = -47{\cdot}4$ for a length of 100 millimetres. The camphor treated with nitric acid yields lævo-camphoric acid. (Dessaignes and Chautard, J. Pharm. [3] xiii. 241; Chautard, Compt. rend. xxxvii. 166.)

γ. Inactive Camphor.—According to Proust, the essential oils of several labiate plants, viz. rosemary, marjoram, lavender, and sage, often deposit a substance like camphor. Lavender camphor has the same composition as laurel camphor, but is without action on prolonged light. (Dumas, Ann. Ch. Phys. xiii. 275; Biot, Compt. rend. xv. 710.)

Bodies resembling camphor but of undetermined modification, have been obtained by the action of nitric acid on the essential oils of tansy, semen-contra, valerian, and sage. Lastly, when amber is treated with nitric acid, it yields a distillate containing camphor, which may be extracted by saturating with carbonate of potassium and igniting with ether.

CAMPHOR, ARTIFICIAL. Syn. with HYDROCHLORATE OF TURPENTINE-OIL. (See TURPENTINE.)

CAMPHOR OF BORNEO. See BORNEOL.

CAMPHOR, OIL OF. When the branches of the camphor-tree (*Laurus camphora*) are distilled with water, a volatile oil passes over together with camphor. This oil is mobile, colourless, has a strong odour of camphor and considerable dextrorotatory power, and is resolved by fractional distillation into an oil boiling at 180° C. and a portion boiling at 205°; the latter appears to be essentially the same as common camphor. The oil boiling at 180° is very much like oil of lemon, possesses strong dextro-rotatory power, and forms with hydrochloric acid a crystalline compound, which melts at 42°, and gives by analysis 57·34 per cent. C, 8·6 H, and 33·83 Cl, agreeing with the formula $C^{10}H^{16}.2HCl$. (Lallemand, Ann. Ch. Phys. lvii. 404.)

The wood of *Dryabalanops Camphora*, from which borneol is obtained, likewise yields by boiling with water, a camphor oil, separable by fractional distillation into two volatile oils, having the composition $C^{10}H^{16}$, one boiling between 180° and 190° C., the other at about 260°, and a resin, $C^{30}H^{46}O^2$ (?), which melts at a temperature a little above 100° (Lallemand). It is remarkable that the oil of Dryabalanops examined by Lallemand, did not contain borneol, and that even the most volatile portion of it had a boiling point much higher than that of borneene (p. 626). The subject requires further examination. (See DRYABALANOPS.)

CAMPHORAMIC ACID. $C^{10}H^{17}NO^3 = \left.\begin{matrix} N.H^2.(C^{10}H^{14}O^2)'' \\ H \end{matrix}\right\} O.$ (Laurent, Compt. chim. 1845, p. 147.)—Derived from acid camphorate of ammonium by elimination of 1 at. water:

$$C^{10}H^{15}(NH^4)O^3 - H^2O = C^{10}H^{17}NO^3.$$

The ammonium-salt of this acid is produced by the action of ammonia on a boiling saturated solution of camphoric anhydride ($C^{10}H^{14}O^3 + 2NH^3 = C^{10}H^{16}(NH^4)NO^3$), and on treating the solution of this salt with hydrochloric acid and evaporating, camphoramic acid is deposited in crystals, which may be purified by solution in dilute alcohol and spontaneous evaporation. It is then obtained in splendid crystals, belonging to the trimetric system, $\infty\breve{P}\infty \,.\, \infty\bar{P}\infty \,.\, \breve{P}\infty$, with ∞P and P subordinate. Inclination of the faces: $P\infty : P\infty = 114° 30'$; $\breve{P}\infty : \infty\breve{P}\infty = 122° 45'$; $\breve{P}\infty : P = 155°$; $\infty\breve{P}\infty : \infty P = 131° 40'$. It is colourless, moderately soluble in hot water, less in cold; more easily in alcohol. A small quantity melted on a plate of glass, partly crystallises in rhombs, while the rest solidifies slowly into a transparent vitreous mass.

The acid is monobasic. Its *ammonium-salt*, $C^{10}H^{16}(NH^4)NO^3 + H^2O$, crystallises well, has a slightly acid, bitter, transient taste, and melts at 100° C. It differs from neutral camphorate of ammonium, with which, in the hydrated state, it agrees in composition, by not precipitating the salts of lead, copper, or silver. The *lead-salt*, $C^{10}H^{16}PbNO^3$, is deposited in small crystals, on mixing the concentrated boiling alcoholic solutions of camphoramate of ammonium and acetate of lead, the former in excess, and leaving the liquid to cool. The *silver-salt*, $C^{10}H^{16}AgNO^3$, is obtained as a transparent jelly, composed of minute crystals, on mixing the boiling concentrated solutions of camphoramate of ammonium and nitrate of silver, and leaving the liquid to cool.

CAMPHORANILIC ACID. See Phenyl-Camphoramic Acid.

CAMPHORAMIDE. $C^{10}H^{18}N^2O^2 = N^2.H^4.(C^{10}H^{14}O^2)''$.—When a current of ammonia-gas is passed into the middle of a solution of camphoric anhydride in absolute alcohol, the liquid becomes heated, and yields by evaporation a syrupy mass, insoluble in water, which is probably camphoramide. It is not decomposed in the cold by hydrochloric acid; but when treated with potash, it gives off ammonia, and forms camphorate of potassium. (Laurent, Rev. scient. x. 123.)

CAMPHORESIN. The name given by Claus to the non-volatile product of the action of iodine on camphor (p. 728).

CAMPHORIC ACID. $C^{10}H^{16}O^4 = C^{10}H^{14}O^2.H^2.O^2$. (Gm. xiv. 455; Gerh. iii. 700.)—There are three modifications of this acid, corresponding to those of camphor, viz. *dextro-rotatory*, *lævo-rotatory*, and *inactive*.

Dextro-camphoric or *ordinary Camphoric acid.*—This acid was discovered by Kosegarten (*Diss. de camphora et partibus quæ eam constituant*, Göttingen, 1785), and particularly studied by Laurent (Ann. Ch. Phys. lxiii. 207; Compt. Chim. 1845, p. 141), Malaguti (Ann. Ch. Phys. lxiv. 151), and Liebig (Ann. Ch. Pharm. xxii. 60). To prepare it, common camphor is heated in a retort with ten times its weight of strong nitric acid, the liquid being cohobated several times, and the acid renewed. On evaporating and cooling the residual liquid, the camphoric acid crystallises out, and may be purified by dissolving it in carbonate of potassium, precipitating with nitric acid, and recrystallising several times.

Camphoric acid forms colourless transparent scales or needles, which melt at 70° C., and taste sour and bitter at the same time. It is sparingly soluble in cold water, more readily in boiling water; easily also in alcohol, ether, and fatty oils. According to Brandes, it requires for solution, 88·8 pts. of water at 12·5° C., and 8·6 pts. at 96·25°. Molecular rotatory power of the solution $[\alpha] = + 38{\cdot}875$; this power diminishes considerably on saturating the acid with an alkali.

It gives an abundant precipitate with neutral acetate of lead. By dry distillation it is resolved into water and camphoric anhydride, leaving only a small film of charcoal. It dissolves without alteration in strong nitric and sulphuric acid.

β. *Lævo-camphoric Acid.*—Obtained by the action of nitric acid on the camphor of feverfew (p. 729), has the same composition and chemical properties as dextro-camphoric acid, and rotates the plane of polarisation, by exactly the same amount, to the left. (Chautard, Compt. rend. xxxvii. 166.)

γ. *Inactive Camphoric Acid*, or *Paracamphoric Acid*, is produced by mixing equal weights of dextro- and lævo-camphoric acid. It agrees with ordinary camphoric acid in most of its properties, but has no action on polarised light. (Chautard.)

Camphorates.—Camphoric acid is dibasic, the formula of a neutral camphorate being $C^{10}H^{14}M^2O^4$. The camphorates are odourless, and have a slightly bitter taste. Most of them are sparingly soluble in water. They are decomposed by sulphuric, hydrochloric, and nitric acid.

Camphorates of Ammonium.—The neutral salt, $C^{10}H^{14}(NH^4)^2O^4$, is obtained by passing a current of dry ammonia-gas over camphoric acid, and exposing the product to a current of dry air. It is very soluble in water, and has a slight acid reaction, but no decided taste. An *acid ammonium-salt* is obtained in small prisms, melting above 100° C. by throwing crystals of acid carbonate of ammonium into a boiling solution of camphoric acid. When dried at 100° in a current of air, they lose 19 per cent. of water. They contain, according to Malaguti, 53·57 per cent. carbon, 8·97 hydrogen, and 8·5 nitrogen, whence he deduces the formula $3C^{10}H^{16}O^4.4NH^3 + 9H^2O$, that is to say, a compound of 1 at. neutral camphorate and 2 at. acid camphorate of ammonium; but, according to Gerhardt, the salt is an *acid camphorate*, $C^{10}H^{15}(NH^4)O + 3H^2O$, the formula of which requires 55·3 C, 8·7 H, 6·6 N, and 19·9 per cent. water.

Camphorate of Potassium. $C^{10}H^{14}K^2O^4$.—Crystallises in large nacreous scales when prepared with hydrated camphoric acid, and in small delicate needles when prepared by dissolving camphoric anhydride in potash. According to Bucholz and Bouillon-Lagrange, it is but sparingly soluble in water, whereas Brandes states that it is very deliquescent, and dissolves in a very small quantity of water (probably the sparingly soluble salt was an acid salt). Camphorate of sodium forms limpid, confused, slightly efflorescent crystals, soluble in 200 pts. of cold and 8 pts. of boiling water; also in alcohol.

The *barium-salt* forms laminæ or needles soluble in 600 pts. of boiling water; according to Brandes, in 1·8 pts. water at 19·9° C.

The *strontium-salt* forms colourless laminæ much more soluble than the barium-salt.

Calcium-salt.—The neutral salt forms a non-crystalline mass, neutral to test-paper, nearly insoluble in cold water, soluble in 200 pts. of boiling water, insoluble in alcohol, and containing 7 per cent. water of crystallisation. It falls to powder in contact with the air. By treating carbonate of calcium with camphoric acid, a salt is obtained having an acid reaction, and crystallising in rhomboïdal prisms, containing 37·5 per cent. water, and soluble in 5 pts. of cold water (Bucholz, Brandes). Neutral camphorate of calcium yields, by dry distillation, carbonate of calcium and camphorone:

$$C^{10}H^{14}.Ca^2O^4 = CO^3Ca^2 + C^9H^{14}O.$$

Camphorate of Copper, $C^{10}H^{14}Cu^2O^4$ (at 100°), is obtained by double decomposition as a light green precipitate, nearly insoluble in water. It forms a crystallisable compound with ammonia.

Camphorate of Manganese is very soluble in water. Manganous salts are not precipitated by alkaline camphorates.

Mercurous Camphorate is a white precipitate, nearly insoluble in water.

Camphorate of Silver is a white fusible precipitate, which becomes coloured by exposure to light.

CAMPHORIC ANHYDRIDE. *Anhydrous camphoric acid.* $C^{10}H^{14}O^2.O.$ (Bouillon-Lagrange (1799), Ann. Chim. xxiii. 153.—Laurent, Ann. Ch. Phys. lxiii. 207.—Malaguti, *ibid.* lxiv. 151.)—Obtained by distilling camphoric or ethyl-camphoric acid, and crystallising the product from boiling alcohol. It forms fine prisms without acid reaction, and having no perceptible taste at first, but afterwards irritating to the throat. It dissolves very sparingly in cold water, a little more in boiling water, very abundantly in alcohol, still more in ether. At 130° C. it begins to sublime in beautiful white needles, melts to a colourless liquid at 217°, begins to boil above 270°, and distils without residue. Specific gravity of the crystals 1·194 at 20°·5. They become electric by friction, like resins. Their solution does not precipitate neutral acetate of lead.

Camphoric anhydride boiled with water dissolves very slowly as camphoric acid. The transformation is effected much more quickly by alkalis. It does not absorb dry ammonia gas, but aqueous or alcoholic ammonia converts it into camphoramate of ammonium. Heated with phenlyamine, it yields phenylcamphoramate of phenylammonium and phenylcamphorimide. Heated with strong sulphuric acid, it gives off carbonic oxide, and is converted into sulphocamphoric acid (*q. v.*)

$$\underset{\substack{\text{Camphoric}\\\text{anhydride.}}}{C^{10}H^{14}O^3} + H^2SO^4 = \underset{\substack{\text{Sulpho-}\\\text{camphoric}\\\text{acid.}}}{C^9H^{16}SO^6} + CO$$

CAMPHORIC ETHERS. *Camphorate of Ethyl.* $C^{14}H^{24}O^4 = C^{10}H^{14}(C^2H^5)^2.O^4$.—This body is formed in the dry distillation of ethyl-camphoric acid, and is obtained by pouring water into the alcoholic mother-liquors from which the latter has been precipitated. It is purified by boiling with alkalised water, drying in vacuo, then washing, distilling, and again drying in vacuo. It is an oil having a faint amber colour, a very disagreeable bitter taste, and a powerful odour. Specific gravity 1·029 at 16° C. Begins to boil at 285° or 287°; turns brown a few degrees higher, and leaves a black residue, but the distillate is very pure after being washed. It is perfectly neutral and insoluble in water. Potash decomposes it like other ethers; sulphuric acid dissolves it in the cold without decomposition; at higher temperatures, decomposition takes place, but without blackening or evolution of sulphurous acid. It is not altered by hydrochloric or nitric acid, either cold or hot. (Malaguti, Ann. Ch. Phys. lxiv. 151.)

Tetrachlorinated Camphorate of ethyl, $C^{14}H^{20}Cl^4O^4$, is produced by the action of chlorine on camphorate of ethyl. Neutral; has a bitter persistent taste. Soluble in alcohol and ether. Specific gravity 1·386 at 14° C. When heated it becomes very fluid, and decomposes before boiling. Aqueous potash scarcely attacks it, but alcoholic potash converts it into camphorate, acetate, and chloride of potassium:

$$C^{14}H^{20}Cl^4O^4 + 8KHO = C^{10}H^{14}K^2O^4 + 2C^2H^3KO^2 + 4KCl + 4H^2O.$$

(Malaguti, Ann. Ch. Phys. lxx. 360.)

Camphorate of Ethyl and Hydrogen. Ethyl-camphoric or *Camphovinic acid.* $C^{12}H^{20}O^4 = C^{10}H^{14}(C^2H^5.H)O^4$.—When a mixture of 2 pts. camphoric acid, 4 pts. absolute alcohol, and 1 pt. sulphuric acid is boiled and cohobated several times, a residue is obtained, which, when diluted with water, yields an oily deposit of ethyl-camphoric acid. This acid has, at ordinary temperatures, the consistence of treacle. It is transparent and colourless, has a peculiar odour and a very agreeable taste, not acid, but bitter. It dissolves very sparingly in alcohol and ether. Specific gravity 1·095 at 20·5° C; reddens litmus paper after a while only; dissolves in alkaline solutions, but is decomposed when boiled with them. Water effects the same decomposition after long contact or continued ebullition. By dry distillation it yields water, camphoric anhydride, and camphorate of ethyl, together with very small quantities of alcohol and carburetted hydrogen gas, resulting from secondary decomposition:

$$\underset{\substack{\text{Ethyl-camphoric}\\\text{acid.}}}{2C^{12}H^{20}O^4} = H^2O + \underset{\substack{\text{Camphoric}\\\text{anhydride.}}}{C^{10}H^{14}O^3} + \underset{\substack{\text{Camphoric}\\\text{ether.}}}{C^{14}H^{24}O^4}$$

The alcoholic solution gives a copious precipitate with neutral acetate of lead. (Malaguti.)

Ethyl-camphoric acid is monobasic, the formula of its salts being $C^{10}H^{14}(C^2H^5.M)O^4$. The *ammonium*, *potassium*, *sodium*, *barium*, *strontium*, *calcium*, and *magnesium*-salts are soluble in water. The *zinc*, *copper*, *lead*, *mercury*, and *silver*-salts are insoluble or sparingly soluble. The copper-salt, obtained by precipitating sulphate of copper with ethyl-camphorate of ammonia, is probably a sesquibasic salt. (Malaguti, Ann. Ch. Phys. lxiv. 151.)

Camphorate of Methyl and Hydrogen. Methyl-camphoric or *Camphomethylic acid.* $C^{11}H^{18}O^4 = C^{10}H^{14}(CH^3.H)O^4$.—Obtained in the same manner as ethyl-camphoric acid, substituting wood-spirit for alcohol. The residue of the third distillation yields, when washed with water and left at rest, a crystalline mass, which is to be pressed between paper and boiled with water. It then forms an acid liquid, at the bottom of which some drops of oil collect, changing after a few days into well-defined, colourless, shining crystals of methyl-camphoric acid. These crystals are either needles arranged in radiating groups, or small four-sided or six-sided laminæ; but on dissolving them in ether and leaving the solution to evaporate very slowly, well formed prisms are obtained belonging to the trimetric system, and exhibiting the combination, $P \,.\, \infty P \,.\, \infty \breve{P} \infty$. Inclination of the faces, $\infty P : \infty P = 106° 30'$; $\infty \breve{P} \infty : \infty P = 126° 45'$; $\infty P \infty : P = 115° 25'$ and $66° 4'$; $P : P = 160° 30'$. The four-sided laminæ are hemihedral, and exhibit only the combination $\frac{P}{2} \,.\, 8\breve{P}\infty$, with cleavage perpendicular to $\infty \breve{P} \infty$.

Methylcamphoric acid is very little soluble in water, very soluble in alcohol, ether, and chloroform. The solutions are strongly acid, and turn the plane of polarisation of a ray of light to the right: $[\alpha] = +51° 4'$. The acid melts at about 68° C., and remains viscid a long time after cooling. By distillation it yields camphoric anhydride, a viscid liquid, and a slight residue of carbon. Boiled with caustic potash, it gives off wood-spirit and is converted into camphorate of potassium.

The aqueous and alcoholic solutions of the acid form a white crystalline precipitate with acetate of lead, soluble in excess of the acetate; with acetate of copper, a greenish crystalline precipitate; with baryta-water, they form a cloud, which disappears on adding a drop of nitric acid. They have no action on lime-water or on soluble barium-salts, but form a slight cloud with nitrate of silver. Oxide of silver is reduced by them, producing a blackish deposit. (Low, Ann. Ch. Phys. xxxviii. 483.)

CAMPHORIMIDE. $C^{10}H^{15}NO^2 = N.H.(C^{10}H^{14}O^2)''$.—Obtained by heating neutral camphoramate of ammonium to 150° or 160° C., or by melting or distilling camphoramic acid:

$$\underset{\substack{\text{Camphoramic}\\\text{acid.}}}{C^{10}H^{17}NO^3} = \underset{\text{Camphorimide.}}{C^{10}H^{15}NO^2} + H^2O$$

and:

$$\underset{\substack{\text{Camphoramate of}\\\text{ammonium.}}}{C^{10}H^{16}(NH^4)NO^3} = \underset{\text{Camphorimide.}}{C^{10}H^{15}NO^2} + NH^3 + H^2O.$$

It is purified by solution in boiling alcohol and crystallises on cooling. It is colourless, volatilises at a high temperature without decomposition, and dissolves easily in boiling alcohol, crystallising, on cooling, in tufts like fern leaves, beautifully divided; or by very slow cooling in hexagonal tables, oblique and much elongated. From a solution in weak alcohol, it is gradually deposited in the form of a gummy, transparent substance, which solidifies after some hours in opaque tubercles. The alcoholic solution gives off ammonia when boiled with potash. It dissolves at a gentle heat in strong sulphuric acid, and, on pouring a few drops of water into the solution, a white crystalline deposit is formed. (Laurent, Compt. chim. 1845, p. 147.)

CAMPHORIN. *Camphorate of Glyceryl.*—Produced by heating camphoric acid with glycerin. Viscid; soluble in ether; decomposed by oxide of lead, yielding glycerin and camphorate of lead. (Berthelot.)

CAMPHORONE. *Phorone* (Gerhardt); *Camphoryl* (Laurent). $C^9H^{14}O$. — This compound, the acetone of camphoric acid, was first obtained in an impure state, as a product of the decomposition of that acid, by Laurent (Ann. Ch. Phys. [2] lxv. 329), afterwards prepared pure and more thoroughly examined by Gerhardt and Liès-Bodart (Compt. chim. 1849, p. 385).

Camphorone is produced, like other acetones, by the dry distillation of the calcium-salt of the acid:

$$\underset{\text{Camphorate of calcium.}}{C^{10}H^{14}O.Ca^2.O^2} = \underset{\text{Carbonate of calcium.}}{CO.Ca^2.O^2} + \underset{\text{Camphorone.}}{C^9H^{14}O}$$

It is best to operate only on small quantities at a time. The brown or yellow oil which passes over is purified by fractional distillation, a small quantity of tar remaining behind.

Camphorone is likewise obtained, together with other products, by distilling with lime either of the following substances: 1. *Acetic acetone*, which differs from it only by the elements of water ($3C^3H^6O - 2H^2O = C^9H^{14}O$). On rectifying the distillate, oxide of mesityl, $C^6H^{10}O$, passes over at about 131° C., and camphorone between 200° and 205° (Fittig, Ann. Ch. Pharm. cx. 33).—2. *Grape-sugar.* The distillate yields on rectification, an oil boiling at 86° C., having the composition of metacetone, $C^{18}H^{30}O^3$ (and converted into camphorone, or a body isomeric with it, by distillation with phosphoric anhydride), while camphorone passes over at 208° (Liès-Bodart, Compt. rend. xliii. 394).—3. The juice of *ripe mountain-ash berries*, which contains a small quantity of malic acid: this method, however, does not always yield it. (Liès-Bodart, *loc. cit.*)

Camphorone is a colourless or yellowish oil, very mobile, lighter than water: and having a strong odour like that of peppermint. It boils at 208° C. (Gerhardt), and volatilises undecomposed, yielding a vapour whose density = 4·982 (Gerhardt and Liès-Bodart), by calculation for 2 vol. = 4·784. It is insoluble in water, but dissolves in alcohol and very readily in ether. It does not unite either with acids or with alkalis, and according to Limpricht (Ann. Ch. Pharm. xciv. 246), differs from other acetones in not combining with acid-sulphites of alkali-metals.

Camphorone becomes darker in colour when exposed to the air. It dissolves with blood-red colour, in strong sulphuric acid, and is for the most part precipitated therefrom by water. It is resinised by nitric acid. Phosphoric anhydride acts quickly upon it at a high temperature, converting it, by abstraction of water, into cumene, C^9H^{12} (not mesitylene), which passes over in fractional distillation at 170° C., a carbonaceous mass being left behind. Pentachloride of phosphorus converts it into a chlorinated oil, $C^9H^{13}Cl$, boiling at 175° C., lighter than water, insoluble therein, easily soluble in alcohol. The alcoholic solution, saturated with ammonia-gas, yielded a crystalline substance, probably $C^9H^{15}N.HCl$ (Liès-Bodart). Camphorone heated with *potassium*, gives off hydrogen, and appears to form the compound $C^9H^{13}KO$ (Liès-Bodart). With *potash-lime* it becomes heated, and appears to enter into combination; the mixture heated to 240° C. gives off a colourless oil, apparently different from camphorone, while a resinous substance remains with the alkali. (Gerhardt and Liès-Bodart.)

CAMPHORYL. $C^{10}H^{14}O^2$. The diatomic radicle of camphoric acid, &c. The same term was applied by Laurent to camphorone.

CAMPHOSULPHURIC ACID. See Sulphocamphoric Acid.

CAMPHOVINIC ACID. Camphorate of Ethyl and Hydrogen. (See Camphoric Ethers, p. 732.)

CAMPHRENE. A product of the decompsition of camphor by sulphuric acid (p. 728).

CAMPHRONE. $C^{30}H^{44}O$.—A liquid produced by passing camphor over red-hot lime. It is a light oil, having a strong and peculiar odour, quite different from that of camphor. It boils at 75° C., is insoluble in water, soluble in alcohol and in ether. It is produced from camphor by abstraction of water ($3C^{10}H^{16}O - 2H^2O = C^{30}H^{44}O$), and is perhaps identical with the product obtained by heating camphor with clay, or by passing the vapour of camphor through a red-hot porcelain tube. (Frémy, Ann. Ch. Phys. [2] lix. 16.)

CAMWOOD. See Barwood (p. 517).

CANAANITE. A greyish scapolite rock, from Canaan, Connecticut, containing 53·37 per cent. SiO^2, 4·10 Fe^4O^3, 10·38 Al^4O^3, 25·80 Ca^2O, 1·62 Mg^2O, and 4·00 CO^2. (Dana, ii. 203.)

CANADA BALSAM. See Balsams (p. 492).

CANCERIN. An artificial guano from Newfoundland.

CANCHA-LAGUA. See CACHA-LAGUA (p. 701).

CANCRINITE. A massive mineral found near Miask in the Ural, in the Mariinskaja mine in the Tunskinsk mountains, Siberia, and in Litchfield in the State of Maine. It cleaves parallel to the faces of a hexagonal prism, has an uneven fracture, light rose-red colour and waxy lustre, nacreous on the cleavage faces; transparent or strongly translucent. Specific gravity 2·45 to 2·46. Hardness 5·0—5·5. It melts to a white tumefied glass. Hydrochloric acid dissolves it readily, with efflorescence and separation of gelatinous silica.

The following are analyses of cancrinite: 1. From Miask; light red: *a.* Specific gravity 2·453 (G. Rose, Pogg. Ann. xlvii. 375); *b.* Specific gravity 2·489 (Pusirewsky, Kokscharow's *Materialen zur Mineralogie Russlands*, i. 81).—2. From the Tunskinsk Mountains, yellow; *a.* Specific gravity 2·449 (Struve, Pogg. Ann. xc. 613); *b.* Specific gravity 2·448 (Pusirewsky).—3. From Litchfield. *a.* Yellow. Specific gravity 2·448; *b.* Greenish. Specific gravity 2·461. (Whitney, *ibid.* lxx. 431.)

	From Miask.			From the Tunskinsk Mts.		From Maine.	
	G. Rose.		Pusirewsky.	Struve.	Pusirewsky.	Whitney.	Whitney.
Silica	6·38		5·55	8·51*	5·61	5·95	5·92
Carbonic anhydride	40·43		35·96	38·33	37·72	37·72	37·20
Alumina	28·227		29·57	28·55	27·27	27·55	27·59
Ferric and Manganic oxides	—		0·19	—	—	0·75	0·27
Lime	6·70		5·68	4·24	3·11	3·67	5·26
Soda	17·52		18·53	20·37	21·60	20·27	20·46
Potash	0·70		—	—	—	0·67	0·50

		SO^3	0·32				
	100·00		99·49	100·00	99·86	99·60	100·48

From these results, Rammelsberg concludes that the mineral is a mixture of carbonate of calcium with elæolite, containing a smaller proportion of potash and more water than the usual amount. (Rammelsberg's *Mineralchemie*, p. 653; Dana, ii. 232.)

CANDITE. See SPINEL.

CANELLA ALBA. *Costus dulcis. White Cinnamon.*—These names are applied to the bass or inner bark of *Canella alba*, a canellaceous tree growing in the West Indies, especially in Jamaica. It forms reddish-yellow tubes, three feet long and an inch thick, having a pleasant aromatic taste and odour: it contains about 8 per cent. of manna (formerly mistaken for a peculiar kind of sugar called *canellin*), besides starch and the other usual constituents of vegetable structures. By distillation with water, it yields two volatile oils, one lighter than water, the other heavier. If these oils be left in contact with potash-ley, the liquid then diluted with water and distilled, the first portion of the distillate is again lighter than water, and at last a heavy oil is obtained, of very peculiar odour. The potash-ley from which the oils have been distilled, yields by neutralisation with acid and distillation, a heavy oil, smelling like oil of cloves. The light oil of white cinnamon smells very much like oil of cajeput. It may be separated by fractional distillation into several oils, differing greatly in boiling point. White cinnamon contains about 6 per cent. of ash, consisting mainly of carbonate of calcium. (Handw. d. Chem. ii. [2] 927.)

CANNAMINE. Syn. of BRUCINE.

CANNABIN. A poisonous resin extracted from hemp, by exhausting the bruised plant (*Gunjah*) with alcohol, after the greater part of the brown colouring matter has been removed by digestion, first in tepid water, afterwards in solution of carbonate of sodium, then precipitating the chlorophyll with lime, decolorising with animal charcoal, and evaporating. (T. and H. Smith, Pharm. J. Trans. vi. 127, 171.)

From the *Extract. hb. canab. ind. spirituos.* G. Martius has prepared a resin, by treating it with cold alcohol of 83 per cent., mixing the dark green filtrate with water till turbidity ensues, agitating with animal charcoal, filtering and distilling off the alcohol: the resin then separates. It is a light brown, shining substance, becoming glutinous and ductile, has a peculiar narcotic odour, like that of the extract, and an intensely bitter taste. It melts at 68° C., burns with a bright smoky flame, is insoluble in potash and ammonia, but dissolves in alcohol and ether, sparingly also in acids. Volatile oils dissolve it in the cold; fixed oils, with aid of heat.

The narcotic effects of haschish (*q. v.*) are due to hemp-resin. (Handw. d. Chem. ii. [2] 727.)

---

* Carbonic anhydride and water.

CANNABIS INDICA. *Indian Hemp.*—This plant, which is indigenous in India and Asia Minor, is much used in the East as an intoxicating agent; the narcotic action appears to reside essentially in a resinous exudation (see Cannabin and Haschish). According to Martius (Chem. Centr. 1856, 225), the herb contains a small quantity of essential oil. The herb dried at 100° C. yielded 18·1 per cent. ash, which, after deduction of carbonic anhydride and sand, contained in 100 pts.: 13·6 potash, 1·4 soda, 32·0 lime, 10·4 magnesia, 8·8 phosphate of iron, 10·1 phosphoric anhydride, 0·3 sulphuric anhydride, 1·2 chlorine, and 22·1 silica.

CANNABIS SATIVA. *Common hemp.*—The leaves of this plant contain 40·5 per cent. carbon, 5·9 hydrogen, 1·8 nitrogen, and 22·0 ash; the stems: 39·9 per cent. C, 5·0 H, 1·7 N, and 4·5 ash. (Kane, J. pr. Chem. xxxii. 354.)

Reich (Jahresber. d. Chem. 1850, Tafel C. p. 661), found in the hemp-plant 4·6 per cent. ash; in the seed 6·3 per cent. The analyses of the ash of the entire plant and of the seed, are given in the following table:

	K^2O	Na^2O	Ca^2O	Mg^2O	Al^4O^3	Fe^4O^3	SO^3	SiO^2	P^2O^5	Cl	CO^2
Plant (Kane)	7·5	0·7	42·0	4·9	0·4	—	1·0	6·7	3·2	1·5	31·9
„ (Reich)	15·8	3·4	35·5	7·7	—	1·1	2·7	7·7	14·2	3·4	8·4
Seed (Reich)	18·5	0·8	20·2	10·2	—	1·2	0·2	9·6	37·6	0·1	1·3

According to Leuchtweiss (Ann. Ch. Pharm. l. 416), hempseed yields 5·6 per cent. ash, containing 20·8 K^2O, 0·6 Na^2O, 25·6 Ca^2O, 1·0 Mg^2O, 33·5 P^2O^5, 13·5 SiO^2, 6·2 sand and charcoal, and small quantities of sulphuric acid, chloride of sodium, and ferric oxide.

Hempseed yields 31·8 per cent. oil, 22·6 albumin, and 6·37 ash, of which 2·47 consists of phosphates (Anderson, Highland Agr. Soc. Journal [new series] No. 50). The oil is $C^{11}H^{22}O^2$, and yields with chlorine and bromine, the substitution-products $C^{11}H^{20}Cl^2O^2$, and $C^{11}H^{20}Br\,O^2$. (Lefort, Compt. rend. xxxv. 134.)

The leaves, flowers, and pollen of hemp have been examined by Schlesinger, (Rep. Pharm. lxxi. 190). The ash of the leaves contains 8·0 per cent. soluble, and 9·2 per cent. insoluble salts. (Kane.)

CANNEL COAL. See Coal.

CANNON METAL. See Copper, Alloys of.

CANTHARIDES. *Spanish Flies* (*Lytta vesicatoria.*)—These coleopterous insects, so well known for their vesicating properties, are much used in medicine in the form of tincture, plasters, &c. Their vesicating power is due to a peculiar acrid principle called cantharidin. Taken internally, they act as a powerful aphrodisiac, and may even destroy life. According to Thoury (J. Pharm. Jan. 1858, p. 65), their poisonous effects may be counteracted by the administration of animal charcoal.

When the aqueous extract of cantharides is treated with alcohol, cantharidin is dissolved, together with other substances, and a brown nitrogenous substance remains. On evaporating the alcoholic extract and treating the residue with ether, the cantharidin dissolves, together with a yellow substance, and an extractive matter remains, which reddens litmus and contains lactic acid, together with a nitrogenous substance. The aqueous decoction of cantharides reddens litmus strongly, and gives with ammonia a precipitate of ammonio-magnesian phosphate (Robiquet, Ann. Ch. lxxvi. 302). When the insects, after being exhausted with boiling water, are treated with boiling alcohol, a greenish fatty oil dissolves, destitute of vesicating power, and consisting, according to Gössmann (Ann. Ch. Pharm. lxxxvi. 317), of olein, stearin, and palmitin.

CANTHARIDIN. $C^5H^{12}O^2$. Isomeric with picrotoxin. (Robiquet, *loc. cit.*; Regnault, Ann. Ch. Phys. [2] lxviii. 151; Thierry, J. Pharm. xxi. 44; Warner, Amer. J. Pharm. xxviii. 193; Procter, Pharm. J. Trans. xxi. 44.)—This substance, which is the active principle of the Spanish fly, is likewise found in the following coleopterous insects:—*Lytta vittata*, *L. ruficollis*, *L. gigas*; *Mylabris cichorii* (Chinese cantharides), *M. pustulata*, *M. punctum*, *M. Sidæ*, *M. Schoenherri*; *Meloe violaceus*, *M. autumnalis*, *M. Furca*, *M. punctatus*, *M. variegatus*, *M. scabrosus*, *M. majalis*. According to Warner, *Lytta vesicatoria*, *L. vittata*, and *Mylabris cichorii* contain about 0·4 per cent. of cantharidin. According to Ferrer, *Mylabris punctatus* contains 0·33 per cent., *M. punctum* 0·19, *M. cichorii* 0·10, *M. Sidæ* 0·12, *M. Schoenherrii* 0·15 per cent.

Cantharidin is prepared from Spanish flies, or better from *Mylabris cichorii*, inasmuch as this insect contains less fat, by digesting the pulverised insects for some days with ether, ether-alcohol, or alcohol alone; completing the extraction in a displacement apparatus, the ether or alcohol being ultimately displaced by water; and distilling off the ether or alcohol. The cantharidin, which crystallises out on cooling, is redissolved and purified with animal charcoal. Ether is preferable to alcohol for the preparation, since it dissolves less of a green oil, which adheres obstinately to the cantharidin (Thierry). According to Procter, cantharidin is best extracted by chloroform. The pulverised cantharides are left in contact for some time with twice their weight of chloroform in a displacement apparatus; the chloroform is then drained off, and finally displaced by alcohol, and the solution is left to evaporate, whereupon the cantharidin crystallises out, saturated with the green oil. It is laid on bibulous paper, which absorbs the greater part of the oil, then crystallised from chloroform mixed with alcohol.

Pure cantharidin forms colourless right-angled four-sided prisms of the dimetric system, acuminated with four faces resting on the lateral faces. According to Procter, it crystallises from ether in oblique four-sided prisms, with dihedral summits, having the aspect of micaceous laminæ. It melts at 200° C., and volatilises in white fumes, which strongly irritate the eyes, nose, and throat, and condense in rectangular prisms, having a strong lustre, and sometimes iridescent.

Cantharidin *per se* is insoluble in *water*, but it is rendered soluble by the presence of other substances (see the last article). It volatilises in small quantity at 104° C., and more quickly at 182°; not with vapour of water. It dissolves readily in *alcohol*, in 34 pts. of cold *ether*, and rather less of hot ether; *acetic ether*, *wood-spirit*, and *acetone* also dissolve it readily when hot, and deposit it on cooling. But its best solvent is *chloroform*, which extracts it even from the aqueous infusion of cantharides. It likewise dissolves in *oils*, both fixed and volatile. Its solution in any of the liquids abovementioned possesses the vesicating power, which, however, is not exhibited by cantharidin in the solid state. A grain of cantharidin mixed with an ounce of lard produces very strong vesication. Cantharidin dissolves in *sulphuric acid*, and is reprecipitated by water; also in hot *hydrochloric* and *nitric acids*, whence it crystallises on cooling; *phosphoric*, *acetic*, and *formic acids* dissolve but little of it at ordinary temperatures. It dissolves in *potash-ley*, and is precipitated by acetic acid. *Ammonia* has no action upon it.

CANTONITE. A variety of sulphide of copper, Cu^2S, from the Canton mine in Georgia, having hexahedral cleavage, bluish-black colour, and semi-metallic lustre. Specific gravity = 4·18. Hardness = 2·0 (N. A. Pratt, Sill. Am. J. [2] xxiii. 409). Genth (*ibid.* 417) regards it as a pseudomorph of covellin after galena.

CANTON'S PHOSPHORUS. A phosphorescent substance prepared by calcining for an hour, at a red heat in a crucible, a mixture of 3 pts. of finely ground oyster-shells with 1 pt. of flowers of sulphur. A better phosphorescence is obtained by calcining the entire shell in a closed crucible, after dusting it over with sulphur. Exposure to bright light is necessary to its luminosity in the dark. The magnesia in the shells is said to be essential to the effect. Gypsum mixed with flour becomes phosphorescent when calcined.

CAOUTCHENE. A hydrocarbon, isomeric with tetrylene, C^4H^8, said by Bouchardat (J. Pharm. Sept. 1837, p. 454), to be produced, together with others, by the dry distillation of caoutchouc (*q. v.*) It has a density of 0·65, boils at 14·5° C., and solidifies in brilliant needles at −10°.

CAOUTCHIN. $C^{10}H^{16}$. (Himly, Ann. Ch. Pharm. xxvii. 41; Gr. Williams, Proceedings of the Royal Society, x. 517; Gm. xiv. 326.)—A hydrocarbon contained, together with many other substances, in the oils produced by distillation of caoutchouc and gutta percha. To separate it, rectified oil of caoutchouc boiling between 140° and 280° C., is repeatedly shaken up with dilute sulphuric acid, then washed alternately with water and potash-ley, and distilled with water several times. The distillate is dehydrated with chloride of calcium and rectified *per se*, the portion which distils between 160° and 175°, being collected apart; from this, by repeated rectification and removal of the portions which pass over below 166° and above 174°, caoutchin is at length obtained, boiling between 168° and 171°; and this product, by repeated fractional distillation, may be brought to boil at 171°. The purification may also be effected by passing dry hydrochloric acid gas into the cooled oil, previously dried over chloride of calcium, whereby hydrochlorate of caoutchin is produced; decanting this liquid from the resin, after it has stood for some days; dissolving it in absolute alcohol; precipitating with water; dehydrating it, and decomposing it by distillation over caustic lime or baryta, and finally over potassium. The product thus obtained is pure caoutchin. (Himly.)

Caoutchin is a transparent, colourless, mobile liquid, having an odour like that of oil of orange, but not quite so agreeable, and a peculiar aromatic taste. It makes transient grease spots on paper. Specific gravity 0·8423 at 0° C. Boils at 175·5° at 0·75 met. pressure. Does not solidify at −39°. Vapour-density 4·461 (Himly), 4·65 (Williams), by calculation (2 vols.) = 4·714. It has but little electric conducting power.

Caoutchin dissolves in 2000 pts. of *water*. It likewise takes up a small quantity of water in the cold, and at higher temperatures a larger quantity, which separates on cooling. It dissolves in all proportions of *alcohol*, *ether*, and *acetate of ethyl;* water separates it from the alcoholic, but not from the ethereal solution, unless alcohol be afterwards added. The alcoholic solution burns with a bright flame, which does not smoke if the caoutchin and alcohol have been mixed in the right proportion. It dissolves slightly in concentrated *acetic* and *formic* acids; also in *oils* both fixed and volatile.

Caoutchin absorbs *oxygen* from the air (45 vols. in fourteen days), and is converted into a resin, part of it, however, volatilising. It is likewise resinised by various *oxidising agents*, *e. g.* by *peroxide of hydrogen*, *nitric oxide*, *nitrous acid*, *strong nitric acid*, and *crystallised chromic acid;* it reduces *cupric oxide* to cuprous oxide and *permanganate of potassium* to peroxide of manganese, but exerts no deoxidising action, even at the boiling heat, on the oxides of lead, mercuric oxide, or chromate of potassium. It is likewise unaffected by sodium, potash, baryta, or lime. With *potassium* it evolves a few gas-bubbles, and covers the metal with a grey film, then remains unaltered.

Of *hydrogen*, caoutchin absorbs 2 vols. in three weeks at 20° C.; of *carbonic anhydride* 11 vols.; carbonic oxide, marsh-gas, and olefiant-gas are not absorbed by it. Of *nitrogen*, it absorbs 5 vols. in five weeks; of *nitrous oxide* a small quantity; *nitric oxide* colours it yellow after a while. It absorbs 3 vols. *ammonia-gas*, but does not mix with aqueous ammonia. It does not absorb cyanogen gas, but *hydrocyanic acid* and *chloride of cyanogen* are absorbed by it in any quantity. It dissolves *phosphorus* and *sulphur* sparingly in the cold, rather more freely when heated; does not absorb sulphydric acid gas, but mixes in all proportions with *sulphide of carbon* and *xanthic acid*. It absorbs *hydrochloric*, *hydrobromic*, and *hydriodic acid gases*, forming the compounds $C^{10}H^{16}.HCl$, &c. It easily dissolves the *chlorides of sulphur*, *phosphorus*, and *carbon*, small quantities of *iodide of sulphur*, and *iodide of phosphorus*. It dissolves a large quantity of *benzoic*, and a small quantity of *oxalic acid;* but not malic, citric, tartrate, tannic, mucic, or succinic acid.

Caoutchin dropped into strong *sulphuric acid*, becomes heated, eliminates sulphurous anhydride, and forms a brown unctuous acid, $C^{10}H^{16}SO^3$, which forms soluble barium and calcium-salts, the latter having, according to Williams, the formula $C^{10}H^{15}CaSO^3$. Boiled with strong *selenic acid*, it turns brown and gradually decomposes. It is not decomposed by *phosphoric* or *phosphorous acid*.

With *chlorine*, caoutchin gives off hydrochloric acid and forms chlorocaoutchin, which, after washing with soda-ley, then with water, and dehydration over chloride of calcium, forms a transparent, colourless, neutral, viscid liquid, of specific gravity 1·433, having a strong ethereal odour and extremely sharp burning taste. It dissolves sparingly in water, easily in alcohol and ether, gives off irritating vapours of hydrochloric acid when distilled *per se*, and yields a variety of oily products by distillation with alkalis.

With *bromine*, caoutchin gives off hydrobromic acid, but remains colourless and transparent; it easily separates bromine from its solution in water, alcohol, or ether, forming heavy drops of oil. Caoutchin mixed with ½ vol. water decolorises bromine till 231·7 pts. bromine have been added to 100 pts. caoutchin, which is in the ratio of 4 at. bromine to 1 at. caoutchin.

By the alternate action of *bromine* and *sodium* on caoutchin, 2 at. hydrogen are removed, and cymene, $C^{10}H^{14}$, is produced. (Williams.)

With *iodine*, caoutchin turns black, and gives off hydriodic acid. It abstracts iodine from solution in water, alcohol, or ether, forming iodocaoutchin, which is a black-brown oil, giving off hydriodic acid when distilled, easily decomposed by heating with oil of vitriol, bromine, chlorine, fuming nitric acid, or potash, nearly insoluble in water, but soluble in alcohol or ether. Caoutchin distilled with excess of iodine, forms a colourless fragrant oil.

Hydrochlorate of Caoutchin, $C^{10}H^{16}.HCl$.—This compound is prepared by passing dry chlorine gas into caoutchin cooled with ice, the delivery-tube terminating a little above the surface of the liquid,—washing the product first with soda-ley, then with water, and drying over chloride of calcium. It is also produced, though in an impure state, by treating caoutchin with trichloride of antimony or mercuric chloride. It is a transparent, colourless, neutral, viscid liquid, having a strong ethereal odour and a very sharp burning taste. Specific gravity 1·433. It gives off very irritating vapours of hydrochloric acid when distilled; is decomposed by boiling with sulphuric acid, with elimination of hydrochloric acid; and yields a variety of oily products by distillation with potash, lime, or baryta. It dissolves sparingly in water, easily in alcohol and ether; also in hot nitric acid and sulphuric acid, separating out unchanged on cooling; but by long boiling with the latter, it becomes carbonised and gives off hydrochloric acid.

CAOUTCHOUC. *Gum elastic*, or *India Rubber*. *Gomme élastique*. *Federharz.*—A product of several genera of arboraceous plants, in which it occurs in the form of a milky sap, and exudes from incisions made in their trunks. Among these trees are the *Siphonia elastica*, *S. Cahuchu*, *Hevea caoutchouc*, *H. Guianensis*, *Jatropha elastica*, *Ficus elastica*, *F. indica*, *F. religiosa*. Formerly the greater part of the good caoutchouc was imported from Para in South America, but an excellent article has of late years been brought from Assam and other districts of India, in which the trees that yield it greatly abound. The juice drawn from the old trees and in the cold season is preferable to that from the young trees and in the hot season, the quantity being greater the higher the incision is made across and through the bark of the tree. The fluid is of a creamy consistence and colour. Its specific gravity, as imported into this country in well-closed vessels, used to vary from 1·0175 to 1·04125 (Ure); the lighter juice yielded 37 per cent. of solid caoutchouc; the denser only 20, though it was the thicker of the two. Some samples of juice have a brownish tinge, which proceeds from a little aloetic matter secreted along with it, which, if dried up in it, gives the caoutchouc a certain degree of viscidity, and by its decomposition eventually destroys its firm texture. Such juice ought to be mixed with its own bulk of water and boiled, whereby the aloes are separated and the caoutchouc concretes into a white elastic mass, free from offensive smell.

Much of the caoutchouc is imported in coarse rough masses. These are cleaned by washing in a trough, with a stream of water, and afterwards kneaded together by the strong pressure of iron-arms in an iron box. The masses thus obtained are next moulded into the forms of square or round cheeses in a press, and finally sliced by knives driven by machinery into thin cakes or ribbands. U.

Faraday recommends for the purification of caoutchouc, to dilute the natural juice with four times its weight of water, and leave it at rest for twenty-four hours. The caoutchouc then separates and rises to the surface in the form of a cream. This is removed, diffused through a fresh quantity of water, and again left to settle at the surface. By repeating this operation till the wash-water is perfectly limpid, the caoutchouc may be obtained very nearly pure. It is then to be spread upon a plate of unglazed earthenware to absorb the water, and afterwards pressed.

Pure caoutchouc is colourless and transparent, but the best found in commerce has a more or less dingy colour from having been dried from the juice in a smoky atmosphere. It is a bad conductor of heat, and a non-conductor of electricity. It is very combustible, and burns without residue, emitting a white light. At ordinary temperatures, it is soft, flexible, and highly elastic. Freshly cut surfaces adhere easily and firmly when pressed together, a property which is made available in forming tubes and vessels out of sheet-caoutchouc. Below 0° C. it becomes hard and rigid. When heated, it gradually softens, and at 120° C. (248° F.) begins to melt; when it is fused, it remains greasy and semi-fluid after cooling, but if exposed to the air in thin layers, gradually dries up and recovers its original properties, provided it has not been heated much above its melting point. If, however, it be heated to 200° C. (398° F.) it begins to fume, and is converted into a viscid mass which no longer dries up. If mixed in this state with half its weight of lime slaked to powder, it forms a tenacious non-drying cement, which serves admirably for attaching glass-plates to vessels with ground lips, such as are used for preserving anatomical preparations, as it forms an air-tight, but easily-loosened joint; if a drying cement be required, a quantity of red lead may be added equal in weight to the lime.

According to the experiments of Ure (Phil. Trans. 1822), confirmed by those of Faraday (Quart. Journal of Sc. Lit. and Art, xi. 19), caoutchouc is composed wholly of carbon and hydrogen, containing 87·5 per cent. of carbon, and 12·5 hydrogen. It is not, however, a simple proximate principle, but chiefly a mixture of two substances, one much more soluble in ether, benzene, and other liquids than the other.

On examining with the microscope a thin sheet of caoutchouc, it is seen to be filled with irregularly rounded pores, partly communicating with each other, and dilating under the influence of liquids. It is perfectly insoluble in water and alcohol; but ether, benzene, rock-oil, and sulphide of carbon, penetrate it rapidly, causing it to swell up and apparently dissolving it.

The liquid thus formed, is not, however, a complete solution, but a mixture formed by the interposition of the dissolved portion between the pores of the insoluble substance, which is considerably swelled up, and has thus become easy to disintegrate. By employing a sufficient quantity of these solvents, renewed from time to time, without agitation, so as not to break the tumefied portion, the caoutchouc may be completely separated into two parts, viz. a substance perfectly soluble, ductile, and adhering strongly to the surface of bodies to which it is applied; and another substance, elastic, tenacious, and sparingly soluble. The proportions of these two principles vary with the quantity of the caoutchouc and the nature of the solvent employed. Anhydrous ether extracts from amber-coloured caoutchouc 66 per cent. of white soluble matter; oil of turpentine separates from common caoutchouc 49 per cent. of soluble matter having a yellow colour.

The best solvent for caoutchouc is a mixture of 6 to 8 pts. of absolute alcohol and 100 pts. of sulphide of carbon. (Payen.)

Caoutchouc is not altered by dilute acids. Strong sulphuric acid acts slowly, and fuming nitric acid rapidly on it, the latter with complete decomposition. It resists strong alkaline-leys, even at the boiling heat.

Caoutchouc yields by *dry distillation*, an empyreumatic oil called oil of caoutchouc or caoutchoucin, which forms an excellent solvent for caoutchouc and other resins. It is a mixture of a considerable number of hydrocarbons. Ordinary impure caoutchouc likewise yields small quantities of carbonic anhydride, carbonic oxide, water, and ammonia.

Respecting the nature of the hydrocarbons contained in caoutchouc-oil, different experimenters have arrived at somewhat different results. According to Bouchardat (J. Pharm. xxiii. 457), the most volatile of the hydrocarbons has a density of 0·63 at −4° C.; boils at a temperature above 0° C., is not solidified by cold, and is perhaps identical with tetrylene, C^4H^8. The next, caoutchene, isomeric with the first, has a density of 0·65, boils at 14·5° C., and solidifies at −15° in brilliant needles which melt at −10°.

The less volatile portion of the oil, which does not distil till the temperature is raised to 315° C. and does not solidify at the lowest temperatures, is called heveene. It is a clear yellow oil of specific gravity 0·921 at 19° C. and belonging to the camphene group, C^nH^{2n}. It mixes with alcohol and ether, absorbs chlorine quickly, and solidifies to a waxy mass. By repeated treatment with strong sulphuric acid and potash-ley, it is converted into an oil, boiling at 228° C., having a sweeter and more agreeable taste than heveene, and similar in many respects to eupione. (Bouchardat.)

Himly (Phil. Mag. [3] lvi. 579), by subjecting caoutchouc-oil to repeated fractional distillation, obtained: 1. An oil called *Faradayin*, boiling at 33° C., of specific gravity 0·654, and dissolved by strong sulphuric acid without evolution of sulphurous anhydride. According to Liebig, water separates from this solution a colourless oil boiling at 220° C. According to Gregory, both this and the more volatile oils belong to the group of camphenes, C^nH^{2n}. The oil unites with chlorine and bromine, forming brown liquids.—2. A mixture of oils distilling at 96° C. from which potash extracts creosote, and dilute sulphuric acid separates a brown resin, destroying the odour at the same time. According to Himly, the percentage of carbon in these oils increases as the boiling point rises.—3. Caoutchin (p. 736).

Another hydrocarbon, isoprene, polymeric with caoutchin, and boiling at 37—38° C., has been obtained by Gr. Williams (Proc. Roy. Soc. x. 56), from the distillation of caoutchouc. From the composition of these several hydrocarbons, it appears that the decomposition of caoutchouc by heat is merely the disruption of a hydrocarbon into other compounds polymeric with it.

The residue left in the retort, after the volatile oil of caoutchouc has distilled off, forms, when dissolved in the oil, a varnish much used by shipwrights, being impervious to moisture and very elastic. An exceedingly tenacious glue is also made by dissolving 1 pt. of caoutchouc, cut up into small pieces, in 4 pts. of coal-tar, adding 2 pts. of shellac when the solution is complete, and heating the whole in an iron vessel.

VULCANISED CAOUTCHOUC.—When caoutchouc is kneaded in an iron box with flowers of sulphur heated to about 112° C. (234° F.), it takes up a certain portion of sulphur, and acquires new properties which greatly increase its utility for various purposes in the arts. It remains perfectly flexible at temperatures below 0° C. and does not soften at 50° C. (122 F.), whereas ordinary caoutchouc becomes perfectly rigid at temperatures several degrees above the freezing point, while a moderate heat renders it so soft and adhesive as to be useless. This sulphured or *vulcanised* caoutchouc, is an excellent material for tubes for conveying water or gases, or for bags to hold gases under pressure.

The vulcanisation of caoutchouc requires a temperature of about 150° C. (304° F.), maintained for a few minutes only. A longer contact with sulphur at that temperature causes the caoutchouc to absorb too much, which renders it hard and brittle. Vulcanised caoutchouc appears to retain only one or two-hundredths of its weight of sulphur in the state of combination; a larger quantity, 15 or 20 per cent., remains simply interposed between the pores, and may be extracted either by the action of solvents, such as ether, benzene, and sulphide of carbon, or by friction, or alternate extension and contraction. If the vulcanised caoutchouc be heated to 120° C., this mechanically interposed sulphur enters into combination with the caoutchouc and renders it brittle. The same combination takes place slowly at ordinary temperatures, so that the caoutchouc after some time, loses its elasticity and becomes brittle. By contact with certain metals, such as lead or silver, the free sulphur in the pores of the caoutchouc is abstracted, and thus again the quality is deteriorated.

The vulcanisation of caoutchouc is effected in various ways: 1. By immersing the sheet-caoutchouc in flowers of sulphur heated to 112° C. till it has absorbed about $\frac{1}{13}$ of its weight, and then heating it for a short time to 150° C., or by immersing the caoutchouc in flowers of sulphur heated to 150°, and keeping up that temperature till the sulphuration is complete.—2. By immersing the caoutchouc in a mixture of 100 pts. sulphide of carbon, and 2·5 protochloride of sulphur, and then plunging it into water to decompose the excess of chloride of sulphur.—3. By immersing articles of caoutchouc already manufactured, in a solution of polysulphide of calcium marking 25° Baumé, keeping them in it for three hours in a closed vessel at 140° C., and then washing them with weak alkaline-ley of 60° Bm. This process always yields the right amount of sulphuration.—4. By powdering 100 pts. of the caoutchouc in rough laminæ, with a mixture of 4 pts. flowers of sulphur and 50 pts. slaked lime, pressing it between rollers so as to incorporate it thoroughly with the powder, then working it into various fabrics by the usual processes, and exposing the finished articles for an hour to the action of vapour of water. By this last treatment, the surface of the caoutchouc experiences a kind of washing, which removes the excess of sulphide of calcium, and brings it to the exact degree of sulphuration required.

Hardened Caoutchouc. Ebonite. — Caoutchouc may be hardened and rendered susceptible of polish by mixing it in the kneading machine or between rollers, with half its weight of sulphur, rolling the mass into sheets, and heating it for two hours to 100° C., and then for four hours to 150°. At the latter temperature, the mass may be rolled; when cold it may be cut like ivory. It serves for the manufacture of combs, knife-handles, buttons, &c. It is also preeminently distinguished by the large quantity of electricity which it evolves when rubbed, and is therefore admirably adapted for the plates of electrical machines. It resists the action of solvents even more obstinately than elastic vulcanised caoutchouc, scarcely even swelling up when immersed in sulphide of carbon. (For a full account of the manufacture and use of caoutchouc, both ordinary and vulcanised, see *Ure's Dictionary of Arts, Manufactures and Mines*, i. 581—604. *Muspratt's Chemistry*, p. 441—451. Payen, *Précis de Chimie Industrielle*, 4^{me} éd. i. 139—184. *Handw. d. Chem.* 2^{te} Aufl. ii. [2] 836—853.)

CAOUTCHOUC, MINERAL. See ELATERITE.

CAOUTCHOUCIN. Empyreumatic oil of caoutchouc (p. 739).

CAPERS. See CAPPARIS.

CAPHOPICRITE. Syn. of RHEIN or RHABARBARIN.

CAPILLARITY. The surface of a liquid at rest is horizontal, excepting where it comes in contact with the sides of the vessel; there it is curved, being concave if the liquid wets the vessel, convex in the contrary case. Moreover, if one end of a narrow tube be dropped into the liquid, the level of the liquid within the tube is not the same as that without, but higher if the liquid wets the vessel and assumes a concave surface, lower if it does not wet the vessel and forms a convex surface; thus water, alcohol, ether, oils, &c., rise in narrow tubes of glass, metal, or wood, having the inner surface clean; but if the surface is greased so that the liquid cannot wet it, depression takes place instead of elevation: mercury is also depressed in tubes of glass, but rises in a tin tube, to which it can adhere. The phenomenon is called capillarity (from *capilla*, a hair), because it is most conspicuous in tubes of very fine bore. The term is, however, extended to all the alterations of level and form of surface which take place at the contact of liquids and solids. The curved surface of the liquid within the tube is called a meniscus.

The amount of elevation of a liquid in capillary tubes is measured by reading off with the cathetometer (a telescope moving up and down a vertical scale, p. 274), first the height of the lowest point of the meniscus, then the height of a fine metallic point brought exactly in contact with the surface of the liquid. In making this last observation, the point is brought down to the surface of the liquid, till it exactly coincides with its reflected image therein, and a small quantity of the liquid is then removed with a pipette so as to leave the extremity free. Another mode of observation, adopted chiefly for measuring the depression of mercury in glass tubes, is to place the liquid in a syphon-tube one arm of which is of capillary bore, while the other is wide enough to render the alteration of level due to capillarity imperceptible. The difference of level in the two arms is then read off with the cathetometer.

By these methods it has been found that the elevation or depression of liquids in capillary tubes is regulated by the following laws:

1. In a tube of given diameter, the amount of elevation or depression depends upon the nature of the liquid, and not at all upon the nature or the thickness of the material of the tube, the nature of the tube merely determining whether the liquid shall be elevated

or depressed, according as the tube is or is not wetted by it, but not affecting the amount.

2. The amount of elevation or depression varies with the temperature, but not according to the same law as the density. Thus Gay-Lussac found that in a tube of 1 millimetre diameter, the heights to which alcohol rose varied with the temperature and density, as follows:

Density.	Temperature.	Height of Column.
0·8196	8° C.	12·18 mm.
0·8135	16 „	9·15 „
0·8595	10 „	12·01 „
0·9415	8 „	12·91 „

3. In very narrow cylindrical tubes, the amount of elevation or depression of a given liquid varies inversely as the diameter of the tube.

4. In the annular space enclosed between a wide cylindrical tube, and a solid cylinder which nearly fills it, the height to which a liquid rises is *half* that to which it would rise in a cylindrical tube whose diameter is equal to the thickness of the annular space. Hence also between two parallel flat plates, which may be regarded as cylinders of infinite radius, the height to which a liquid rises is half that in a cylindrical tube whose diameter is equal to the width between the plates.

The following table shows the height, as determined by Frankenheim (Pogg. Ann. lxx. 515), to which different liquids rise in cylindrical tubes of 1 millimetre radius at 25° C.

	Specific Gravity.	Height in millim.		Specific Gravity.	Height in millim.
Benzene	0·840	6·60	Water	0·997	14·67
Oil of turpentine	0 871	6·33	Sulphide of carbon	1·253	4·84
Oil of lemon	0·820	6·63	Trichloride of phosphorus	1·45	3·75
Rock-oil	0·827	6·52	Disulphide of chlorine	1·687	4·95
Oil of cloves	1·030	6·69	Trichloride of arsenic	2·18	4·07
Eupione	0·655	5·72	Dichloride of tin	—	2·50
Alcohol	0·800	5·73	Chloride of nitrogen	1·34	3·9
Ether	0·716	4·77	Bromine	3·0	4·5
Oxalic ether	1·093	6·05	Sulphur	2·14	5·8
Acetic ether	0·749	5·61	Mercury	13·59	—4·6

For the theory of capillary phenomena, we must refer to works on physics (*vid.* Müller, *Lehrbuch der Physik und Meteorologie*, 1853, i. 97).

CAPNOMOR. One of the constituents of beech-tar, first separated by Reichenbach (J. pr. Chem. i. 1). According to Völckel (Ann. Ch. Pharm. lxxxvi. 99), capnomor is contained, together with creosote and another oil, in the portion of wood-tar which is soluble in potash, and on distilling the alkaline-liquid, capnomor passes over with the vapour of water. It is perhaps partly formed by the decomposition of the creosote.

It is a colourless oil, having a peculiar odour, rather lighter than water; boils between 180° and 208° C. Insoluble in pure water and in potash, but dissolves partially when creosote is likewise present. Contains 81·2 carbon and 7·8 hydrogen; perhaps $C^{20}H^{22}O^{2}$. It dissolves in strong sulphuric acid with red-purple colour; the solution is decolorised by water and then contains a conjugated acid. Nitric acid converts it into prussic and oxalic acid and another crystalline substance.

CAPORCIANITE. A silicate of calcium and aluminium found in several localities in Tuscany, both in radiated laminæ and in crystals belonging to the monoclinic system; cleavage perfectly parallel to $0P$ and $\infty P \infty$, easy also parallel to ∞P. It has a flesh-red colour with nacreous lustre; transparent only in thin laminæ. Specific gravity 2·470. Hardness = 3·5. It splits easily into thin acicular fragments. It gives off water when heated in a tube; and melts with intumescence to a white enamel before the blowpipe. Dissolves easily in acids, with separation of gelatinous silica. According to Anderson's analysis (N. Edinb. Phil. J. xxxiv. 21), it contains 52·8 SiO^2, 21·7 Al^4O^3, 0·1 Fe^4O^3, 11·3 Ca^2O, 1·1 K^2O, 0·2 Na^2O, 0·4 Mg^2O and 13·1 H^2O (= 100·7), agreeing nearly with the formula $Ca^2O.Al^4O^3.4SiO^2 + 3\,aq$. It appears to be a variety of Laumontite formed by weathering.

CAPPARIS SPINOSA. A shrub growing in the south of Europe, the root-bark of which is said to contain a neutral bitter principle of sharp irritating taste, and resembling senegin. The flower-buds pickled in salt and vinegar form capers. Distilled with water they yield a distillate having an alliaceous odour. After they have been washed with cold water, hot water extracts from them capric acid and a gelatinous substance of the pectin group. Capric acid is sometimes found deposited on the calices of the buds in white specks having the appearance of wax. (Rochleder and Blas.)

CAPRAL. A term applied sometimes to caproic, sometimes to capric aldehyde (see those compounds).

CAPRAMIDE. *Caprinamide.* $C^{10}H^{21}NO = N.C^{10}H^{19}O.H^{2}$.—The primary amide of capric acid, produced by the action of strong ammonia, on an alcoholic solution of caprate of ethyl. When purified by crystallisation from alcohol, it forms colourless shining crystalline scales, which have a silky lustre when dry, are insoluble in water and in aqueous ammonia, but dissolve readily in alcohol. (Rowney, Ann. Ch. Pharm. lxxix. 231.)

CAPRIC ACID. *Rutic Acid.* $C^{10}H^{20}O^{2}$. (Gm. xiv. 485.)—This acid was first discovered by Chevreul in the butter of cow's milk. It is contained in cocoa-nut oil, and in several kinds of fusel oil; it occurs among the products of the distillation of oleic acid and of choloïdic acid, and is also formed by the oxidation of oleic acid and of oil of rue.

According to Rowney, it is obtained pure and in tolerable quantity from the residue which remains in the distillation of fusel oil, after the amylic alcohol has distilled off at 132° C. The caproic acid is present as caprate of amyl. When this residue is decomposed by boiling with caustic potash, the amylic alcohol distils over, and the residue contains caprate of potassium. On the addition of hydrochloric acid, capric acid is liberated as an oily mass, which is washed with water and dissolved in dilute ammonia. The caprate of ammonium is mixed with chloride of barium, and the insoluble barium-salt which precipitates is filtered off, washed with cold, and dissolved in boiling water: on cooling, caprate of barium is deposited almost pure. To obtain the acid, this salt is treated with carbonate of sodium, and the solution of caprate of sodium is filtered from the carbonate of barium, then decomposed with sulphuric acid, which throws down capric acid almost colourless, and in the solid form. It is purified by solution in alcohol and reprecipitation by water.

The CAPRATES are mostly difficultly soluble in water.

Caprate of Barium, $C^{10}H^{19}BaO^{2}$, is almost insoluble in cold, but soluble in boiling water, from which it separates in needle-shaped or large prismatic crystals, which float on water if not moistened.

Caprate of Calcium, $C^{10}H^{19}CaO^{2}$, falls as a white insoluble powder when caprate of ammonium is mixed with chloride of calcium. It is more difficultly soluble in boiling water than the barium-salt, and crystallises in beautiful lustrous laminæ.

Caprate of Magnesium resembles the calcium-salt.

Caprate of Lead is precipitated as a white amorphous powder when caprate of sodium is mixed with acetate of lead. It is very little soluble in boiling alcohol.

Caprate of Silver is precipitated on the addition of nitrate of silver to caprate of ammonium. It is but slightly soluble in boiling water, and is deposited on cooling in needle-shaped crystals. When moist, it is readily changed by exposure to light.

Caprate of Sodium is readily soluble in water and alcohol. On evaporation it is obtained as a horny mass, presenting traces of crystallisation. It is easily soluble in hot absolute alcohol, forming an opalescent mass.

Caprate of Ethyl. Capric ether, $C^{10}H^{19}(C^{2}H^{5})O^{2}$, is formed by dissolving capric acid in absolute alcohol, saturating the solution with dry hydrochloric acid gas, and then mixing with water. It separates as an oily layer, which, when washed with water, forms a colourless liquid of specific gravity 0·862. E. A.

CAPRIC ALDEHYDE. $C^{10}H^{20}O$.—The aldehyde of capric acid has not yet been obtained with certainty. It was formerly supposed, according to the results of Gerhardt (Ann. Ch. Phys. [3] xxiv. 96) and Wagner (J. pr. Chem. xlvi. 155; lii. 48), to be the chief constituent of oil of rue, but according to Gr. Williams (Phil. Trans. 1858, p. 199), this oil consists mainly of *euodic aldehyde*, $C^{11}H^{22}O$. This result, so far as regards the quantitative constitution, has been confirmed by Hallwachs (Ann. Ch. Pharm. cxiii. 107), who, however, maintains that the body $C^{11}H^{22}O$ is not an aldehyde. According to more recent statements by Wagner, on the contrary, oil of rue is really capric aldehyde, and forms with ammonia a compound which, when treated with sulphydric acid, yields *thiocapric aldehyde*, $C^{30}H^{61}S^{2}N$, and with hydrochloric and hydrocyanic acid a compound homologous with alanine. (See RUE, OIL OF.) (Handw. d. Chem. 2^te Aufl. ii. [2] 741.)

CAPRINAMIDE. See CAPRAMIDE.

CAPROCIANITE. Syn. with CAPORCIANITE.

CAPROENE. Syn. with HEXYLENE, $C^{6}H^{12}$.

CAPROIC ACID. $C^6H^{12}O^2$. (Gm. xi. 414.)—This acid, the sixth in the series of fatty acids, was first discovered by Chevreul in the butter of cow's milk, in which it exists in combination with glycerin. It exists in considerable quantity in cocoa-nut oil, and in cheese, and is a not unfrequent product of the oxidation of the fatty acids of higher atomic weight; it is also obtained by the oxidation of poppy oil and of casein.

From cocoa-nut oil it is readily obtained by saponification with soda-ley of specific gravity 1·12. The soap is decomposed by sulphuric acid, and rapidly distilled from a copper retort. The distillate, which consists essentially of caproic and caprylic acids, is neutralised with baryta, and the solution evaporated to crystallisation. The crystals which first form are caprylate of barium; when the solution is further evaporated and allowed to stand, caproate of barium is obtained in verrucose crystals. The salt purified by crystallisation and decomposed by a stronger acid, yields caproic acid in an oily form.

The best method of preparation is that of Frankland of Kolbe, viz. the decomposition of cyanide of amyl by potash:

$$\underset{\substack{\text{Cyanide}\\ \text{of amyl.}}}{C^6H^{11}N} + KHO + H^2O = \underset{\substack{\text{Caproate of}\\ \text{potassium.}}}{C^6H^{11}KO^2} + \underset{\text{Ammonia.}}{NH^3}.$$

The process as modified by Wurtz, is as follows:—To prepare cyanide of amyl, the black mass obtained by calcining ferrocyanide of potassium in a covered crucible, is placed in a retort connected with the lower part of a Liebig's condenser, together with four or five times its weight of alcohol, and the mixture is heated to boiling. A quantity of iodide of amyl, not quite sufficient to decompose the cyanide, is then gradually introduced through a funnel-tube, and the boiling is continued till the decomposition is complete. This point is ascertained by allowing a drop of the oil which separates on the addition of water, to evaporate on the end of a glass rod held in a flame: the presence of the smallest quantity of iodide is perceptible by the brown vapours of iodine produced. When the conversion of the iodide is effected, the alcoholic liquor is mixed with excess of water, and the oil which separates is boiled with alcoholic solution of potash in a retort connected with the lower end of a Liebig's condenser, until it is completely decomposed into ammonia and caproic acid. The caproate of potassium is then decomposed by a stronger acid, and the oily layer removed and distilled.

Caproic acid is a clear mobile oil of specific gravity 0·931 at 15° C. It has a sudorific odour and penetrating acid taste. Sparingly soluble in water, but dissolves completely in absolute alcohol. The acid prepared from cyanide of amyl solidifies at −9° C., and boils at 198°, and according to Wurtz, has the property of circular polarisation. That from cocoa-nut oil boils between 202° and 209° (probably owing to an admixture of caprylic acid), and does not affect the plane of polarisation.

Caproic acid is dissolved by sulphuric acid without change in the cold, and is again liberated on the addition of water. A concentrated solution of caproate of potassium, when subjected to a current from six of Bunsen's elements, is electrolysed in a manner analogous to valerate of potassium. The oil which separates on the surface contains amyl, $C^{10}H^{22}$, together with another body, which is probably caproate of amyl, resulting from a secondary decomposition:

$$\underset{\substack{\text{Caproate of}\\ \text{potassium.}}}{2C^6H^{11}KO^2} + O = \underset{\text{Amyl.}}{C^{10}H^{22}} + \underset{\substack{\text{Carbonate}\\ \text{of potassium.}}}{K^2CO^3} + CO^2.$$

$$\text{or } \underset{\substack{\text{Caproate of}\\ \text{potassium.}}}{2C^6H^{11}KO^2} + O + H^2O = \underset{\text{Amyl.}}{C^{10}H^{22}} + \underset{\substack{\text{Acid carbonate}\\ \text{of potassium.}}}{2KHCO^3}.$$

CAPROATES.—The salts of capric acid resemble the valerates, and are obtained in a similar manner.

Caproate of Ammonium, obtained by saturating caproic acid with ammoniacal gas, is a crystalline salt, which, by absorbing more ammonia, again deliquesces.

Caproate of Barium is obtained by saturating the acid with carbonate of barium. By spontaneous evaporation of the solution below 18° C. it crystallises in lustrous hexagonal laminæ, which become milky in the air. Crystallised above 30° C. it forms needles often of some length. It dissolves in 12·5 pts. of water at 20° C. In moist air it smells of caproic acid, and its aqueous solution deposits a basic salt when boiled. When distilled it yields combustible gases, among which propylene, C^3H^6, is present in greatest quantity, and an oil passes over which contains propione, $C^{11}H^{22}O$. The residue consists of carbonate of barium and charcoal.

Caproate of Calcium forms lustrous square laminæ, which are soluble in 49 pts. of water at 14° C., and fuse on being heated, emitting an odour like that of the *Labiatæ*.

Caproate of Magnesium, $C^6H^{11}MgO^2 + aq.$, crystallises in small aggregated needles, which retain 1 at. of water when heated above 100° C.

Caproate of Potassium, $C^6H^{11}KO^2$, is obtained by the spontaneous evaporation of its solution, as a transparent jelly, which becomes opaque when warmed.

Caproate of Silver, $C^6H^{11}AgO^2$, is obtained by precipitating an aqueous solution of the barium-salt with nitrate of silver, as a white precipitate, sparingly soluble in cold water. After being washed out with cold, and then dissolved in boiling water, it separates on cooling in magnificent crystalline laminæ, which are unaltered by light.

Caproate of Sodium, $C^6H^{11}NaO^2$, resembles the potassium-compound. Its aqueous solution forms a white uncrystalline mass on evaporation.

Caproate of Strontium, $C^6H^{11}SrO^2$, crystallises in transparent laminæ, which effloresce in the air. E. A.

CAPROIC ALCOHOL. See HEXYLIC ALCOHOL.

CAPROIC ALDEHYDE. *Hydride of Caproyl.* $C^6H^{12}O = C^6H^{11}O.H.$—This compound appears to be produced in small quantity in the dry distillation of caproate of calcium or barium, being found chiefly in the first portion of the distillate obtained by the rectification of crude caprone. (Brazier and Gossleth, Ann. Ch. Pharm. lxx. 256.)

CAPROIC ANHYDRIDE or *Anhydrous Caproic Acid.* $C^{12}H^{22}O^3 = (C^6H^{11}O)^2O.$—According to Chiozza, this body is prepared by placing 6 at. caproate of barium in a retort, and gradually adding 1 at. oxychloride of phosphorus. The mass becomes warm and pasty; on cooling it is extracted with pure ether; the ethereal solution is agitated with weak potash, then dried over chloride of calcium; and finally the ether is evaporated in the water-bath.

Caproic anhydride is a neutral oil, lighter than water, and with an odour resembling caproic acid. When heated it volatilises, emitting an aromatic odour, and leaving a slight carbonaceous residue. E. A.

CAPROIC ETHERS. *Caproate of Methyl*, $C^6H^{11}(CH^3)O^2$, is obtained, according to Fehling, by mixing 2 pts. each of caproic acid and of wood-spirit with 1 pt. of sulphuric acid, and gently heating the mixture. The liquid is mixed with water, and the supernatant oil is washed with water and dried over chloride of calcium. It is a colourless liquid of specific gravity 0·8977 at 18° C.; boils at 150° C. Its vapour-density is 4·623.

Caproate of Ethyl, $C^6H^{11}(C^2H^5)O^2$, is obtained like the preceding compound. It is a transparent liquid, with a pine-apple odour, somewhat resembling butyric ether, but not so delicate. Its specific gravity is 0·882 at 18° C., and it boils at 162° C. Its vapour-density is 4·97.

Caproate of Amyl. $C^6H^{11}(C^5H^{11})O^2$.—Crude caproic acid (prepared by Frankland and Kolbe's method), the greater part of which passes over at 198° C., contains an admixture of caproate of amyl. On continuing the distillation, it passes over at 212° C. It may also be obtained by neutralising the crude acid with carbonate of potassium, whereupon it remains undissolved as an oily layer. Removed, dried over chloride of calcium, and rectified, it is obtained pure, and of constant boiling point at 211° C. It is insoluble in water, but soluble in all proportions in alcohol and ether. It is decomposed by potash into caproate of potassium and amylic alcohol. E. A.

CAPRONE. $C^{11}H^{22}O$? When caproate of barium is submitted to destructive distillation, tritylene and other gases are given off, and a colourless oil passes over. If this oil be dried and rectified, it begins to boil at 120° C., and the thermometer ultimately rises to 160°—170° C. By rectification, a product is obtained, boiling constantly at 165° C. It is a colourless oil, lighter than and insoluble in water, and having a peculiar odour. It is readily soluble in alcohol and ether, becomes brown in the air, and is attacked by nitric acid even in the cold, *nitrovaleric acid*, $C^5H^9(NO^2)O^2$, being apparently formed.

The boiling-point of this compound (164° C.), differs widely from that calculated for caprone, 232°, and it is hence doubtful whether it is the true caprone.

CAPRONITRILE. $C^6H^{11}N$. This compound, which contains the elements of caproate of ammonium *minus* water $[C^6H^{11}(NH^4)O^2 - 2H^2O]$, has not been obtained directly from that salt. The isomeric (or identical) compound, cyanide of amyl, $C^5H^{11}.CN$, is obtained by heating an alcoholic solution of iodide of amyl to the boiling point, with excess of cyanide of potassium. (See CYANIDES OF ALCOHOL-RADICLES.)

CAPRONOYL. A name applied by Weltzien to the radicle C^6H^{11}, which may be supposed to exist in caproic aldehyde, $C^6H^{11}.H.O$, and in caprone, $C^6H^{11}.C^5H^{11}.O$.

CAPROYL (or *Capronyl*, according to Weltzien), $C^6H^{11}O$.—The radicle of caproic acid and its derivatives: *e. g.* caproic acid = $C^6H^{11}O.H.O$; caproic aldehyde, $C^6H^{11}O.H$;

caprone, $C^6H^{11}O.C^5H^{11}$, &c. The same term is also sometimes applied to the corresponding alcohol-radicle C^6H^{13}; but it is much better to designate this radicle by the name Hexyl, as proposed by Gerhardt. (See Hexyl.)

CAPROYLAMINE. See Hexylamine.

CAPROYLENE. See Hexylene.

CAPRYL or **RUTYL,** $C^{10}H^{19}O$. — The radicle of capric or rutic acid, $C^{10}H^{19}O.H.O$, and its derivatives. The same term is applied to $C^8H^{15}O$, the radicle of caprylic acid: it is better however to call the latter caprylyl, unless indeed the term capric acid be altogether abandoned, and rutic acid substituted for it. $C\,^0H^{19}O$ would then be called rutyl, and $C^8H^{15}O$, capryl. There is at present great confusion between the names of these radicles, which is further increased by the application of the same name, *capryl*, to C^8H^{17}, the radicle of the 8-carbon alcohol. For this last-mentioned radicle we shall use Gerhardt's name Octyl (*q. v.*)

CAPRYLAMINE. See Octylamine.

CAPRYLENE. See Octylene.

CAPRYLIC ACID. $C^8H^{16}O^2 = C^8H^{15}O.H.O$ (Gm. xiii. 190).—Caprylic acid was discovered by Lerch, in the butter of cow's milk. It is also contained in cocoa-nut oil and in Limburg cheese; in several kinds of fusel oil it occurs partly free and partly in combination with ethyl and amyl.

The best source for this acid is cocoa-nut oil: from the difficult solubility of its barium salt, it is easily separated from caproic acid, with which it is associated (see Caproic Acid). The caprylate of barium is purified by recrystallisation; its aqueous solution decomposed by sulphuric acid; and the oily liquid which rises to the surface is washed and distilled: the distillate between 230 and 238° C. is pure caprylic acid.

Caprylic acid has a feeble but unpleasant odour, which is more perceptible when the acid is warm. It solidifies at 12° C., melts at 15°, and as the liquid slowly cools, laminæ resembling cholesterin form in it. At 20°, its specific gravity is 0·911. It boils at 236°—238°; its observed vapour density is 5·31 (calculated 4·98).

Caprylic acid is monobasic, the general formula of its salts being $C^8H^{15}MO^2$. *Caprylate of Barium*, $C^8H^{15}BaO^2$, crystallises from a hot aqueous solution, in fine, white, fatty laminæ; by spontaneous evaporation, in small white grains. It dissolves in 50 pts. water at 100° C., and in 126 pts. at 10°. It is quite insoluble in alcohol and ether. It contains no water of crystallisation, and can be heated to 100° without change.

Caprylate of Lead, $C^8H^{15}PbO^2$, is obtained on mixing caprylate of barium with nitrate of lead. Is a sparingly soluble precipitate, which melts at 100° C.

Caprylate of Silver, prepared in the same manner, is white and insoluble. E. A.

Substitution-derivative of Caprylic Acid.

Nitrocaprylic Acid. $C^8H^{15}NO^4 = C^8H^{14}(NO^2)O^2$ (Wirz, Ann. Ch. Pharm. civ. 289).—This acid is produced by the continued action of nitric acid at the boiling heat on the mixture of non-volatile fatty acids which is obtained from cocoa-nut oil by saponifying the oil with soda, decomposing the soap with sulphuric acid, and distilling off the volatile acids. After washing the product with hot water, till the grains of suberic acid mixed with it are removed, there remains a heavy oil, containing nothing but nitrocaprylic and nitrocapric acids. The acid thus obtained is a yellowish-red, syrupy oil, having a peculiar odour and bitter taste, of specific gravity 1·093, at 18° C.; it dissolves sparingly in water, more easily in strong nitric acid. When heated, it becomes dark-coloured, and decomposes, with evolution of nitrous acid, and at a higher temperature, detonates slightly.

Nitrocaprylic acid neutralises alkalis completely. With ammonia, it forms a yellowish-red, and with potash a deep red solution, leaving an uncrystallisable mass when evaporated. The ammonia-salt yields with salts of calcium, barium, lead, and copper, flaky precipitates, which form a viscid mass when stirred. The silver-salt, $C^8H^{14}Ag(NO^2)O^2$ is precipitated in yellowish-white flakes, which dry up to a yellowish-grey mass.

CAPRYLIC ALCOHOL. See Octylic Alcohol.

CAPRYLIC ALDEHYDE. *Hydride of Caprylyl*, $C^8H^{16}O = C^8H^{15}O.H$.—A body having this composition and capable of uniting with the acid sulphites of alkali-metals, is obtained, among other products, by the dry distillation of castor-oil soap (ricinoleate of sodium or potassium), either alone or with excess of alkali. It was first obtained by Limpricht (Ann. Ch. Pharm. xciii. 242), who regards it as caprylic aldehyde; afterwards examined by Bouis (Ann. Ch. Phys. [3] xlviii. 99), who takes the same view of its constitution; and further by Städeler (J. pr. Chem. lxxii. 241), and by

Dachauer (Ann. Ch. Pharm. cvi. 270), who regard it as an acetone, viz. methyl-œnanthyl, $CH^3.C^7H^{13}O$. According to Bouis, the aldehyde is formed, together with an acid ($C^{10}H^{18}O^2$), and without evolution of gas, chiefly when castor-oil soap is slowly heated to a temperature not exceeding 225°—230° C., and without excess of alkali:

$$\underset{\text{Ricinoleic acid.}}{C^{18}H^{34}O^3} = \underset{\text{Caprylic aldehyde.}}{C^8H^{16}O} + \underset{\text{New acid.}}{C^{10}H^{18}O^2};$$

whereas if the soap be quickly and strongly heated, especially with excess of alkali, hydrogen is abundantly evolved, and octylic alcohol is produced, together with sebacic acid (see page 98). Malaguti obtained sometimes octylic alcohol, sometimes caprylic aldehyde, but always sebacic acid; he explains the formation of these products by the equations:

$$\underset{\text{Ricinoleic acid.}}{C^{18}H^{34}O^3} + H^2O + O = \underset{\text{Octylic alcohol.}}{C^8H^{18}O} + \underset{\text{Sebacic acid.}}{C^{10}H^{18}O^4}$$

$$C^{18}H^{34}O^3 + O^2 = \underset{\text{Caprylic aldehyde.}}{C^8H^{16}O} + C^{10}H^{18}O^4$$

Städeler and Dachauer likewise obtained sebacic acid in every case (p. 98).

Caprylic aldehyde is also produced by distilling a mixture of caprylate and formate of calcium (Limpricht):

$$\left.\begin{matrix} C^8H^{15}O \\ Ca \end{matrix}\right\} O + \left.\begin{matrix} CHO \\ Ca \end{matrix}\right\} O = Ca^2CO^3 + \left.\begin{matrix} C^8H^{15}O \\ H \end{matrix}\right\}$$

To prepare pure caprylic aldehyde, the crude distillate obtained by heating castor-oil soap with excess of hydrate of potassium, is treated with a strong aqueous solution of acid sulphite of sodium; and the resulting crystalline mass is repeatedly pressed between paper, washed with alcohol, dried over sulphuric acid, and dissolved in hot water, whereby it is decomposed, and caprylic aldehyde set free: it is then dried over chloride of calcium and rectified. According to Bouis, it is better to distil the neutral soap *per se*, or better still, the barium-salt formed from it, because the latter does not froth.

Caprylic aldehyde is a colourless, strongly refracting liquid, having an aromatic odour and caustic taste. Specific gravity 0·818 at 19° C. (Bouis). Boiling point 178° (Limpricht); 171° under ordinary pressure (Bouis). It is insoluble in water. It burns with a bright non-smoking flame; becomes acid when warm air or oxygen is passed through it (Bouis); and is violently oxidised by nitric acid, with formation of caprylic acid and other fatty acids; chromic acid also partly converts it into an acid. Heated with solid potash, it forms a brown spongy mass. With ammoniacal nitrate of silver it forms a metallic mirror. With pentachloride of phosphorus, it forms chloride of octylene, $C^8H^{16}Cl^2$.

Caprylic aldehyde unites with acid sulphites of alkali-metals, without rise of temperature. The compounds are insoluble in excess of the acid sulphite, and are decomposed by water. The sodium-salt contains $2C^8H^{16}O.2NaSO^3.SO^2 + 2\,aq.$

CAPRYLIC ANHYDRIDE. *Anhydrous Caprylic acid*, $C^{16}H^{30}O^3. = (C^8H^{15}O)^2O$. —This body is obtained by treating 6 at. caprylate of barium with 1 at. of oxychloride of phosphorus. Much heat is disengaged, and the mixture is changed into a pasty mass, developing a peculiar and unpleasant odour, which probably arises from chloride of caprylyl. From this pasty mass, the anhydride is extracted by treatment with ether, which must be free from alcohol. The ethereal solution is agitated with dilute potash-ley, in order to remove caprylic acid, and then dried over chloride of calcium. On the evaporation of the ethereal solution, the anhydride is left as a clear mobile oil, lighter than water. When freshly prepared, it has a sickly odour, which is more evident when it begins to pass into caprylic acid. When heated, it gives off vapours which attack the throat, but have an aromatic odour. In a freezing mixture, it solidifies to a white mass of imperfectly crystalline texture. It begins to boil at 280° C., the temperature gradually increasing to 290°, when the liquid begins to decompose. Boiling water does not convert it into caprylic acid, but when left for some time in contact with moist air, it gradually changes into that substance. Potash-ley gradually changes it into caprylic acid. (Chiozza, Ann. Ch. Pharm. lxxxv. 229).

E. A.

CAPRYLIC ETHERS. *Caprylate of Methyl.* $C^8H^{15}(CH^3)O^2$, is formed, when caprylic acid dissolved in its own weight of methylic alcohol is mixed with a quarter of the weight of sulphuric acid. The liquid immediately becomes turbid, and the caprylate of methyl forms a light oily layer on the surface. It is removed, washed with water, and dried. It is a colourless, highly aromatic liquid, with an odour of wood-spirit. Its specific gravity is 0·882, and vapour-density 5·48. It is scarcely soluble in water, but dissolves readily in alcohol and in ether. (Fehling, Ann. Ch. Pharm. liii. 405.)

Caprylate of Ethyl, $C^8H^{15}(C^2H^5)O^2$, is prepared like the preceding compound. It is a colourless liquid, with a pine-apple odour. Its specific gravity is 0·8738 at 15°. It boils at 214° C. Vapour-density = 6·1. It is insoluble in water, but soluble in alcohol and ether. (Fehling). E. A.

CAPRYLONE. This name has been given to a substance which Guckelberger obtained by the destructive distillation of caprylate of barium, in quantities of about half an ounce, with excess of lime. White vapours pass off, and condense in the receiver to a yellow oily liquid, which after some time solidifies to a yellow buttery mass. By appropriate purification, it is obtained as a white crystalline body, like Chinese wax, and of feeble waxy odour. It is very soluble in alcohol and ether, whether hot or cold. It melts at 40° C., and solidifies at 38° to a radiating crystalline mass. It boils at 178°, and distils without alteration.

The boiling-point of caprylone, as calculated from that of its homologue œnanthylone, would be 300° C. The discrepancy between this number and 178°, the boiling-point of caprylone, seems to prove that this is not the true acetone. Further experiments are necessary to decide the point. E. A.

CAPRYLYL. $C^8H^{15}O$. The radicle of caprylic acid, &c.

CAPSELLA BURSA PASTORIS. *Shepherd's Purse.*—The green parts of this plant contain an acrid sulphuretted volatile oil (oil of mustard?) waxy and fatty matter, saponin, tannin, tartaric, citric, and malic acids, colouring matter, and traces of sugar. 100 pts. of the air-dried herb yielded 9 per cent. of ash containing sand, the composition of which, in 100 pts., after deducting the charcoal, was found to be: 15·7 K^2O, 8·6 Na^2O, 14·7 Ca^2O, 3·1 Mg^2O, 1·9 Fe^4O^3, 0·1 Al^4O^3, 16·2 CO^2, 6·2 SO^3, 8·4 P^2O^5, 4·2 Cl, 20·6 SiO^2 and sand. (Daubrawa, Repert. Pharm. xcix. 127.)

The seed yields by distillation with water, a volatile oil, which, according to Pless, is identical with oil of mustard. According to G. J. Mulder, the seed contains in 100 pts.: 28·8 fixed oil, 26·5 albumin, 12·3 non-nitrogenous soluble matter, 16·0 woody fibre, 11·6 water, and 4·8 ash. According to Neuburger, the seed contains 20 per cent. of oil and 23 of albumin. (Handw. d. Chem. 2te Aufl. ii. [2] 780.)

CAPSICINE. An alkaloïd obtained from Spanish pepper, the fruit of *Capsicum annuum*. (Braconnot, Ann. Ch. Phys. [2] vi. 1; Witting, Buchner's Repert. xxxvi. 15; Landerer, Vierteljahrs. pr. Pharm. iii. 34.) The same name is applied in America to an oleo-resinous extract from Cayenne pepper (*Capsicum baccatum*).

CAPUT MORTUUM. An old term for the residue of a distillation or sublimation; thus the impure ferric oxide obtained as a residue in the distillation of fuming sulphuric acid from ferrous sulphate, was called *Caput mortuum vitrioli*.

CARAGHEEN MOSS. *Irish pearl moss.* (*Sphærococcus crispus.*)—An alga, found in abundance on the coasts of the Atlantic and the North Sea. It is used as food, as a remedy in chest complaints, and for the clarification of turbid liquids. It swells up considerably in cold water, and dissolves almost wholly on boiling. The decoction forms, on cooling, a jelly having a faint saline taste, and the peculiar odour of sea-weed. According to Herberger, it contains 79·1 per cent. gelatinous matter, partially soluble in cold water, perfectly in hot water, insoluble in alcohol and ether; 9·5 mucus, insoluble in water, alcohol, and ether; 0·7 resin; 1·3 chloride of sodium; 0·7 chloride of magnesium; 8·7 skeleton, consisting of cellular substance and salts.

According to Schmidt (Ann. Ch. Pharm. li. 56), the mucus obtained by precipitating the aqueous decoction with alcohol containing hydrochloric acid, pressing the precipitate, and washing it with alcohol, contains 44·8 carbon to 6·2 hydrogen, (whence it appears to be a hydrate of carbon, like sugar, starch, &c.,) and leaves, when burnt, 10·39 per cent. ash, chiefly consisting of sulphate of calcium. The skeleton of caragheen moss leaves on incineration an ash containing sulphate and phosphate of calcium, and, according to Sarphati, likewise metallic iodides. (Handw. d. Chem. 2te Aufl. ii. [2] 782.)

CARAJURU, CRAJURU, or **CARCURU.** A red dye-stuff, imported from Para in Brazil, probably identical with *chica-red*, which is obtained from the leaves of the *Bignonia Chica*. Carajuru appears, however, to be superior to ordinary chica, and is perhaps distinguished from it by greater purity. According to Virey (J. Pharm. 1844, p. 151) it is a light mealy powder, destitute of taste and smell, and acquiring a coppery lustre by trituration. It is insoluble in water, soluble in alcohol, ether, and alkalis, and precipitated from the latter by acids in its original state. Burns with flame, leaving a considerable quantity of ash.

CARAMEL. (Péligot, Ann. Ch. Phys. lxvii. 172.—Gélis, Ann. Ch. Phys. [3] lii. 352.)—A product of the action of heat upon sugar. When cane-sugar is heated in an oil or metal bath to between 210° and 220° C., care being taken not to exceed the latter temperature, it assumes a brown colour of continually increasing depth, without giving off any permanent gas; vapour of water is, however, evolved, containing traces of acetic acid and an oily substance. When the tumefaction has ceased, the vessel is found to contain a black substance, which dissolves completely in water: this is caramel. To obtain it pure, it is dissolved in a small quantity of water and precipitated by alcohol. It may also be obtained from glucose, but not so readily.

Caramel when pure is insipid; its aqueous solution has a rich sepia tint. It is insoluble in alcohol; does not ferment under the influence of yeast; it yields copious precipitates with ammoniacal acetate of lead and baryta-water. When strongly heated it yields the same products as sugar. (Péligot.)

Caramel was long regarded as a simple proximate principle of the formula $C^{12}H^{18}O^9$, the precipitate which it forms with baryta-water having the composition $C^{12}H^{17}BaO^9$. But, according to Gélis, caramel prepared as above is a mixture of several coloured substances, some soluble, others insoluble in water, amongst which he particularly distinguishes three, viz. *caramelane*, $C^{12}H^{18}O^9$, *caramelene*, $C^{36}H^{50}O^{25}$, and *caramelin*, $C^{96}H^{102}O^{51}$. All these substances are produced from sugar by elimination of the elements of water, the atomic weight being at the same time increased, thus:

$$\underset{\text{Sugar.}}{8C^{12}H^{22}O^{11}} - 37H^2O = \underset{\text{Caramelin.}}{C^{96}H^{102}O^{51}};$$

and by keeping sugar for some time at 190° C. these products may be obtained one after the other. If crystallised cane-sugar be used, the residue, after 10 per cent. has been given off as water, consists of nearly pure **caramelane**; after 14 or 15 per cent. has gone off, the residue is rich in **caramelene**; and after a loss of 20 per cent. it consists almost wholly of **caramelin**. Grape-sugar yields products nearly resembling, but not identical with these.

Caramelane may also be obtained pure by digesting ordinary caramel with 84 per cent. alcohol, which sometimes dissolves it completely, sometimes leaves a residue amounting to 40 per cent; treating the solution (which contains caramelane, undecomposed sugar, and sometimes a little caramelene) with yeast to decompose the sugar by fermentation; evaporating the filtrate to dryness; redissolving in alcohol, which then leaves the caramelene undissolved; and evaporating the solution.

Caramelane, to which ordinary caramel chiefly owes its characteristic properties, is a brown substance, hard and brittle at ordinary temperatures, very soft at 100° C., odourless, with a strong bitter taste, deliquescent, very soluble in water, moderately soluble in aqueous alcohol, sparingly in absolute alcohol, insoluble in ether. It reduces cupric oxide in alkaline solution, also gold and silver from their salts. Nitric acid converts it into oxalic acid. The aqueous solution does not precipitate metallic salts. The alcoholic solution forms, with an alcoholic solution of neutral acetate of lead, a yellow precipitate containing $C^{12}H^{16}Pb^2O^9$; with an ammoniacal solution of acetate of lead, added in sufficient quantity to produce complete precipitation, it yields the compound $C^{12}H^{16}Pb^2O^9.Pb^2O$; and with excess of a solution of baryta in wood-spirit, a precipitate containing $C^{12}H^{16}Ba^2O^9.Ba^2O$. At 190° C. caramelane gives off water and passes into caramelene (**Gélis**). **Völckel** (Ann. Ch. Pharm. lxxxv. 59) applies the term *caramelane* to the black residue, insoluble in water, left on heating sugar to 250°—300° C. This residue is insoluble in alcohol, sparingly soluble in potash, and has, according to Völckel, the composition $C^{24}H^{26}O^{13}$. It is perhaps identical with the substance here called caramelin.

Caramelene. $C^{36}H^{50}O^{25}$.—The residue left after treating caramel with alcohol of 84 per cent. contains caramelene, which may be extracted by cold water, and separated from the solution by evaporation or by precipitation with absolute alcohol, and freed from a small quantity of admixed caramelin by redissolving it in water. It is solid and brittle, of the colour of mahogany, not hygroscopic, easily soluble in water (exhibiting a colouring power six times as great as that of caramelane) and in dilute alcohol, sparingly in strong alcohol, and insoluble in ether. It reduces cupric oxide from an alkaline solution, and is converted by nitric acid into oxalic acid. Its *barium-compound*, precipitated by alcohol, is composed of $C^{36}H^{48}Ba^2O^{25}$. With lead it forms the three compounds $C^{36}H^{48}Pb^2O^{25}$, $C^{36}H^{48}Pb^2O^{25}.3Pb^2O$, and $C^{36}H^{48}Pb^2O^{25}.5Pb^2O$.

Caramelin, $C^{96}H^{102}O^{51}$, exhibits three isomeric modifications, viz. *A*, soluble in water; *B*, insoluble in water, soluble in other liquids; *C*, insoluble in all ordinary solvents. The modifications *B* and *C* are contained in the residues left after treating caramel with cold water; and from these residues *B* may be extracted by boiling water (*B* then passing into *A*) by 60 per cent. alcohol, or by alkaline liquids. Caramelin separates from a hot aqueous solution on evaporation in films, by precipitation with alcohol as a copious precipitate, but in both cases as the modification *B*: similarly when precipitated by acids from alkaline solutions. But when caramelin *B* is dried, or even left for several days in the moist state, it passes into the modification *C*, and is then insoluble in all solvents. Caramelin *B*, which is insoluble in cold water and in strong alcohol, dissolves in a mixture of those two liquids. Its colouring power is 12 times as great as that of caramelane.

Caramelin is a black, shining, infusible substance. Like caramelane, it reduces gold and silver from their solutions, and cupric oxide in its alkaline solution. Its solution is precipitated by nearly all metallic salts. It forms the compounds $C^{96}H^{100}Ba^2O^{51}$, $C^{96}H^{100}Ba^2O^{51}.Ba^2O$, and $C^{96}H^{100}Pb^2O^{51}$. (Gélis.)

Maumené (Compt. rend. xxxix. 422) designates by the name caramelin a black-brown compound, $C^{12}H^8O^4$, insoluble in water, acids and alkalis, obtained by mixing 1 pt. of sugar with 15 to 30 pts. dichloride of tin, evaporating to dryness, and heating for a few minutes to 120°—130° C.; also by similar treatment of glucose, cellulose, dextrin, and other hydrates of carbon of similar constitution. Völckel's caramelane (p. 748) is probably the same as Gélis's caramelin.

CARANNA. A resin obtained from the *Bursera gummifera*. It is sent into the market in pieces wrapped in leaves; is grey-black outside, dark brown within; has a shining fracture; is brittle and easily powdered. It melts when heated, emitting an aromatic smell. It has a bitterish taste. It resembles resin of guaiac in some respects, and was at one time in repute among the Germans for smoking in pipes, as a remedy in gout. A distilled oil of caranna was also prescribed for a like purpose. It is now disused.

CARAPA BARK. The bark of a tree indigenous in Guiana and Hispaniola, called *Carapa guianensis*, *Persoonia guareoides*, and *Xylocarpus Carapa*. It has a bitter taste, like that of cinchona bark, and is used in intermittent fevers. It is said to contain quinic acid, a red colouring matter, and an organic alkaloïd called carapine, which forms crystalline salts with hydrochloric and acetic acids. (Petroz and Robinet, J. Pharm. vii. 293, 349.)

The wood of the same tree, which is beautifully veined, is much prized for furniture.

In the bark of *Carapa tulucana*, Caventou (J. Pharm. xxxv. 189) found one yellow and two red dyes, and a bitter principle, which he calls tulucumine.

The root-bark of *Carapa molucensis* exudes a whitish powder when wounded; it is bitter and astringent, and is said to be used as a remedy against cholera and biliary diseases.

CARAPA OIL. A bitter fat oil, obtained by pressure in the heat of the sun from the kernels of *Carapa guianensis* and *C. tulucana*. It is used by the Indians for protecting the skin against the punctures of insects. It solidifies at + 4° C. and melts at 10°; dissolves sparingly in alcohol, easily in ether; is saponified by alkalis. Its bitter taste is said to be due to strychnine, and to be removed by sulphuric acid. The fruits yield by further pressure, assisted by heat, a fat which melts at 40°—50° C. (Cadet, J. Pharm. v. 49.—Bouillay, *ibid.* vii. 293.)

CARAT. An arbitrary weight by which gold and gems are weighed or estimated. The diamond carat is equal to 4 grains whereof 612 are contained in the troy ounce; in other words, the troy ounce contains 153 diamond carats or 612 diamond-grains.

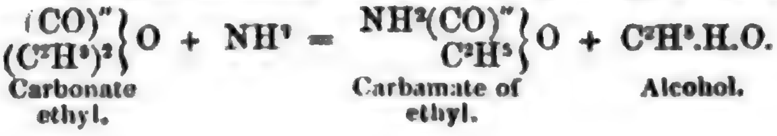
In estimating or expressing the fineness of gold, the whole mass is supposed to weigh 24 carats of 12 grs. each, either real or merely proportional, like the assayer's weights; and the pure gold is called fine. Thus, if gold is said to be 23 carats fine, it is to be understood that in a mass weighing 24 carats, the quantity of pure gold is 23 carats. U.

CARBAMIC ACID. $CH^3NO^2 = \left.\begin{matrix} NH^2(CO)'' \\ H \end{matrix}\right\} O$.—This acid is not known in the free state, neither have any of its metallic salts, properly so-called, been obtained. Its ammonium-salt, $N^2H^6CO^2 = \left.\begin{matrix} NH^2(CO)'' \\ NH^4 \end{matrix}\right\} O$, is the so-called *anhydrous carbonate of ammonium*, and its compounds with alcohol-radicles constitute the class of bodies called urethanes: *e.g.* carbamate of ethyl or ethyl-urethane, $C^3H^7NO^2 = \left.\begin{matrix} NH^2(CO)'' \\ C^2H^5 \end{matrix}\right\} O$. These bodies might also be regarded empirically as compounds of carbonic anhydride with the corresponding alcohol-bases: *e.g.* ethylurethane as $CO^2 + C^2H^7N$ (ethylamine); but their formation and properties do not accord with this latter view.

The urethanes are produced, together with sal-ammoniac, by the action of ammonia gas on the chlorocarbonates of the alcohol-radicles:

$$\underset{\text{Chlorocarbonate of ethyl.}}{C^2H^5.CO^2Cl} + 2NH^3 = NH^4Cl + \underset{\text{Ethyl-urethane.}}{C^2H^5.CH^2NO^2}$$

2. By the action of anhydrous ammonia on the corresponding carbonic ethers:



$$\underset{\text{Carbonate ethyl.}}{\left.\begin{matrix} (CO)'' \\ (C^2H^5)^2 \end{matrix}\right\} O} + NH^3 = \underset{\text{Carbamate of ethyl.}}{\left.\begin{matrix} NH^2(CO)'' \\ C^2H^5 \end{matrix}\right\} O} + \underset{\text{Alcohol.}}{C^2H^5.H.O.}$$

3. By the action of chloride of cyanogen on the alcohols:

$$C^2H^5.H.O + CN.Cl + H^2O = \left.\begin{matrix} NH^2(CO)'' \\ C^2H^5 \end{matrix}\right\} O + HCl$$

Carbamic acid in which the whole of the oxygen is replaced by sulphur, constitutes sulphocarbamic acid, CH^3NS^2 (*q. v.*)

There is also an oxysulphocarbamic acid, the ethyl- and amyl-salts of which have been obtained, viz. xanthamide, $\left.\begin{matrix} NH^2(CO)'' \\ C^2H^5 \end{matrix}\right\} S$, and xanthamylamide $\left.\begin{matrix} NH^2(CO)'' \\ C^5H^{11} \end{matrix}\right\} S$. (See those articles; also page 206.)

Carbamate of Ammonium. *Anhydrous Carbonate of Ammonia.* $N^2H^6CO^2 = \left.\begin{matrix} NH^2(CO)'' \\ NH^4 \end{matrix}\right\} O$.— This salt, which was discovered by H. Davy, and further investigated by J. Davy and H. Rose, is produced: 1. By passing a mixture of carbonic anhydride and ammonia-gas through a number of glass tubes cooled to a low temperature. In whatever proportion the gases may be mixed, they always unite in the proportion of 2 vol. NH^3 to 1 vol. CO^2.—2. By subliming a mixture of carbonate of sodium and sulphamate of ammonium, $N^2H^6SO^3$, both perfectly dry. (H. Rose.)

It is a white mass which smells of ammonia, has a strong alkaline reaction, volatilises a little above 60° C., and condenses again below 60°. The specific gravity of its vapour is 0·8992 (H. Rose), 0·90 (Bineau). Now 2 vols. ammonia + 1 vol. CO^2, weigh $1·1787 + 1·5252 = 2·7039$, which is nearly three times the observed specific gravity of the vapour. Hence the two gases appear to unite without condensation, although not in equal volumes. Probably the compound exists only in the solid state, and is resolved by heat into CO^2 and $2NH^3$.

Vapour of sulphuric anhydride converts carbamate of ammonium into sulphamate of ammonium with evolution of carbonic anhydride. Heated in sulphurous anhydride, it yields an orange-coloured sublimate. Hydrochloric acid decomposes it with aid of heat, yielding sal-ammoniac and carbonic anhydride.

Carbamate of ammonium dissolves readily in water, yielding a solution which gives the reactions of neutral carbonate of ammonium, from which, indeed, it differs only by the elements of water $[N^2H^6CO^2 = (N^2H^4)^2CO^3 - H^2O]$. It appears, however to be capable of existing in solution for a short time as carbamate; for on passing carbonic anhydride into aqueous ammonia, taking care that the liquid does not become hot, the resulting solution does not precipitate chloride of calcium or chloride of barium till after some time, unless the liquid be heated. This circumstance is of importance in chemical analysis; thus, in determining the amount of carbonic acid in a mineral water by means of chloride of calcium and ammonia, it is necessary to leave the liquid to stand for some time, or heat it to the boiling point, in order to insure that the whole of the carbonic acid is precipitated as carbonate of calcium. (Kolbe.)

According to H. Rose, ordinary carbonate of ammonium prepared by sublimation often contains carbamate. (Gm. ii. 430).

Carbamate of Amyl. *Amyl-urethane*, $C^6H^{13}NO^2 = CH^2(C^5H^{11})NO^2$.—(Medlock, Ann. Ch. Pharm. lxxi. 104.—A. Wurtz, J. Pharm. [3] xx. 22).—Obtained by adding ammonia to amylic alcohol saturated with chlorocarbonic oxide, and washing the resulting crystalline mass with water to separate sal-ammoniac; or by passing gaseous chloride of cyanogen into amylic alcohol and distilling, chloride of amyl then passing over first, and afterwards the carbamate.

This compound crystallises from boiling water in beautiful silky needles, soluble in alcohol and ether. It melts at 66° C. and distils without alteration at 220°. Distilled with caustic baryta, it yields ammonia and amylic alcohol, with a residue of carbonate of barium. It dissolves completely in cold sulphuric acid, and is precipitated therefrom by water. Heated with sulphuric acid, it forms amyl-sulphuric acid and ammonia, with evolution of carbonic and sulphurous anhydrides.

Carbamate of Ethyl. *Urethane.* $C^3H^7NO^2 = CH^2(C^2H^5)NO^2$. (Dumas. Ann. Ch. Phys. liv. 233.– Cahours, Compt. rend. xxi. 629.—Liebig and Wöhler, Ann. Ch. Pharm. liv. 370.—Gerhardt, Compt. chim. 1846, p. 120.—Wurtz, Compt. rend. xxii. 503, J. Pharm. [3] xx. 19) —This compound is prepared: 1. By leaving carbonate of ethyl in contact with an equal volume of aqueous ammonia in a corked flask till it completely disappears, and evaporating in a dry vacuum.—2. By treating chlorocarbonate of ethyl with ammonia, and distilling: the action is very violent.—Alcohol of ordinary strength is saturated with gaseous chloride of cyanogen; the solution is heated for some hours in a sealed long-necked flask placed in a water-bath; and the liquid when cold is decanted from the deposit of sal-ammoniac arising from a secondary action, and distilled. Chloride of ethyl then passes over first, then alcohol at 80° C.

(p. 749), after which, the temperature rises, and urethane passes over, condensing in laminæ.

Carbamate of ethyl forms large transparent colourless crystals: even a few drops of its solution left to evaporate are sure to yield these crystals. It melts below 100° C., and distils at about 180° without alteration if dry; but in the moist state it suffers partial decomposition, giving off torrents of ammonia. It dissolves readily in water, forming a solution which does not precipitate silver-salts; also in alcohol and ether. Its vapour-density, by experiment, is 3·14, by calculation (2 vols.) = 3·08.

Carbamate of Methyl. *Urethylane.* $C^2H^5NO^2 = CH^2(CH^3)NO^2$.—Obtained like the preceding compounds. Crystallises in long tables derived from an oblique rhomboïdal prism, with very elongated terminal faces. The crystals are not deliquescent, they melt between 52° and 55° C., and solidify at 52° when perfectly dry. Boiling-point 177° C. Vapour-density, experimental = 2·62; by calculation (2 vol.) = 2·60. It is very soluble in water, less in alcohol, and still less in ether. 100 pts. of water at 11° C. dissolve 217 pts. of it, whereas 100 pts. alcohol at 15° C. dissolve only 73 pts. Dilute sulphuric acid decomposes urethylane into methylic alcohol, acid sulphate of ammonium, and carbonic anhydride:

$$\left.\begin{matrix}NH^2(CO)''\\CH^3\end{matrix}\right\}O + \left.\begin{matrix}SO^2\\H^2\end{matrix}\right\}O^2 + H^2O = CH^3.H.O + \left.\begin{matrix}SO^2\\H.NH^4\end{matrix}\right\}O^2 + CO^2.$$

Strong sulphuric acid blackens it, eliminating sulphurous anhydride and inflammable gases. Potash decomposes it in the same manner as dilute sulphuric acid.

Carbamate of Tetryl. $C^5H^{11}NO^2 = CH^2(C^4H^9)NO^2$.—Obtained by heating tetrylic alcoholic with liquid chloride of cyanogen, best in a sealed tube, distilling and collecting that which passes over above 220° C. This distillate solidifies on cooling in a crystalline mass, which, when recrystallised from boiling alcohol, forms shining nacreous scales, unctuous to the touch, insoluble in water, soluble in alcohol and ether; they melt at a gentle heat and distil without alteration. (Humann, Ann. Ch. Phys. [3] xliv. 340.)

Substitution-derivatives of Carbamic Acid.

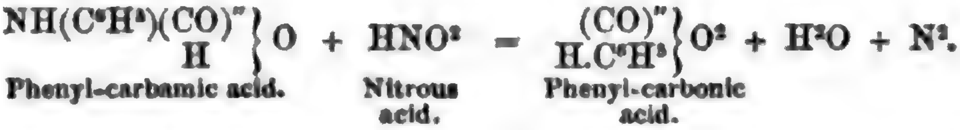
Ethyl-carbamic Acid. $C^3H^7NO^2 = \left.\begin{matrix}NH(C^2H^5)(CO)''\\H\end{matrix}\right\}O$.—This acid, isomeric with urethane, is not known in the free state; but its ethylammonium-salt, $\left.\begin{matrix}NH(C^2H^5)(CO)''\\C^2H^8N\end{matrix}\right\}O$, is identical with the so-called *anhydrous carbonate of ethylamine*, $(C^2H^7N)^2.CO^2$, obtained by passing carbonic anhydride into anhydrous ethylamine cooled by a freezing mixture. It is a snow-white powder, whose aqueous solution, like that of carbamate of ammonium, does not immediately precipitate chloride of barium, unless aided by heat. (Wurtz, Ann. Ch. Phys. [3] xxx. 483.)

Ethylcarbamate of Ethyl. Ethylurethane. $C^5H^{11}NO^2 = C^3H^6(C^2H^5)NO^2$.—Produced by heating cyanate of ethyl with alcohol in a sealed tube: $C(C^2H^5)NO + C^2H^6O = C^5H^{11}NO^2$; sometimes obtained as an accessory product in the preparation of cyanate of ethyl. It is an oily liquid, smelling like carbonate of ethyl. Specific gravity 0·9862. Boiling point 174—175° C. Vapour-density 4·071. Potash decomposes it, forming alcohol, ethylamine, and carbonate of potassium: $C^5H^{11}NO^2 + 2KHO = C^2H^6O + C^2H^7N + K^2CO^3$. Heated with strong sulphuric acid, it yields carbonic anhydride, sulphate of ethylamine, and probably also ethylsulphuric acid. (Wurtz, Compt. rend. xxxvii. 182; Gerh. ii. 929; iv. 869.)

Methyl-carbamic Acid, like the corresponding ethyl-compound, is not known in the separate state, but forms a methylammonium-salt, $\left.\begin{matrix}NH(CH^3)(CO)''\\CH^6N\end{matrix}\right\}O$, which may also be regarded as *anhydrous carbonate of methylamine*, $(CH^5N)^2.CO^2$: it is formed by passing carbonic anhydride into dry methylamine, or by distilling a mixture of fused hydrochlorate of methylamine and carbonate of calcium. In the latter case, however, it is mixed with carbonate of methylamine. (Wurtz, Ann. Ch. Phys [3] xxx. 450, 461.)

Phenyl-carbamic Acid. *Carbanilic Acid. Anthranilic Acid.* $C^7H^7NO^2 = \left.\begin{matrix}NH(C^6H^5)(CO)''\\H\end{matrix}\right\}O$. (Fritzsche, Ann. Ch. Pharm. xxxix. 83; Liebig, *ibid.* xxxix. 91; Gerland, Chem. Soc. Qu. J. v. 133.)—This acid, which contains the elements of 1 at. carbonic anhydride and 1 at. phenylamine, C^6H^7N, and is likewise isomeric with oxybenzamic acid, is obtained by boiling indigo with strong caustic potash, replacing the water as it evaporates, and adding peroxide of manganese before the indigo completely disappears, till the liquid no longer deposits blue indigo on being left at rest. The mass is then dissolved in water and supersaturated with dilute sulphuric acid; the filtered liquid is neutralised with potash and evaporated to dryness; and the residue is digested with alcohol, which dissolves chiefly phenyl-carbamate of potassium, and leaves it in an impure state when evaporated. It is then dissolved in water, acetic acid added, and the yellow or brownish crystals of phenyl-carbamic acid thereby precipitated are purified by animal charcoal and recrystallisation (Fritzsche). According to Chancel this acid is likewise produced by the action of potash on phenyl-carbamide.

Phenyl-carbamic acid crystallises in transparent, colourless, shining prisms or laminæ, often of considerable size. It dissolves very sparingly in cold water, much more in boiling water, very easily in alcohol and ether. Its solutions have an acid reaction. It melts at 132° C., and sublimes unaltered. By distillation from coarsely pounded glass, it is resolved into carbonic anhydride and phenylamine. It carbonises when heated with phosphoric anhydride. Strong sulphuric acid converts it into phenyl-sulphamic acid. When nitrous acid gas is passed into its warm dilute aqueous solution nitrogen is evolved, and the solution yields, when concentrated, crystals of salicylic (phenyl-carbonic acid):



$$\underset{\text{Phenyl-carbamic acid.}}{\left.\begin{matrix}NH(C^6H^5)(CO)''\\H\end{matrix}\right\}O} + \underset{\substack{\text{Nitrous}\\\text{acid.}}}{HNO^2} = \underset{\substack{\text{Phenyl-carbonic}\\\text{acid.}}}{\left.\begin{matrix}(CO)''\\H.C^6H^4\end{matrix}\right\}O^2} + H^2O + N^2.$$

The metallic phenyl-carbamates are but little known. The *calcium-salt*, $C^7H^6CaNO^2$, forms rhombohedral crystals, sparingly soluble in cold, moderately in boiling water. The *silver-salt*, $C^7H^6AgNO^2$, is deposited in shining laminæ on mixing a dilute boiling solution of the calcium-salt with nitrate of silver. The solution of the ammonium-salt likewise precipitates the salts of *copper*, *lead*, and *zinc*.

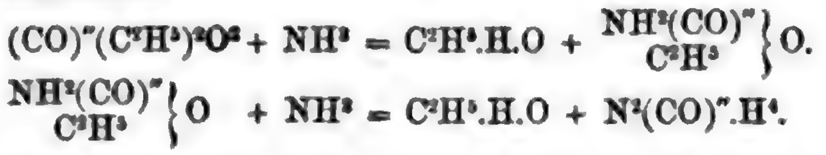
Phenyl-carbamates (?) *of Ethyl and Methyl.*—Chancel (Compt. rend. xxx. 751), by treating the nitrobenzoates of ethyl and methyl with sulphydrate of ammonium, obtained compound ethers, which he regards as phenyl-carbamates; but from their mode of formation it is more probable that they are oxybenzamates, which are isomeric therewith. (See OXYBENZAMIC ACID.)

CARBAMIDE. $CH^4N^2O = N^2.(CO)''.H^2.H^2$.—This compound is the primary diamide of carbonic acid, and has the same composition as urea, with which indeed it is in all probability identical. It is formed in various ways:

1. By the action of ammonia on oxychloride of carbon, both being perfectly dry (Regnault, Ann. Ch. Phys. [2] lxix. 180; Natanson, Ann. Ch. Pharm. xcviii. 287):

$$COCl^2 + 4NH^3 = CH^4N^2O + 2NH^4Cl.$$

The mixture of carbamide and sal-ammoniac thus produced is soluble in water and in aqueous alcohol; and on adding excess of baryta-water to the solution, evaporating in vacuo, exhausting the residue with absolute alcohol, evaporating to dryness, dissolving in a small quantity of water, treating the solution with nitric acid, and decomposing the resulting nitrate of carbamide with carbonate of barium, the carbamide is obtained in the separate state (Natanson).—2. By the action of ammonia on carbonate of ethyl. When the two substances are heated together in a sealed tube to 180° C., carbamate of ethyl is first formed (at 100°), and afterwards converted by the excess of ammonia into carbamide:



$$(CO)''(C^2H^5)^2O^2 + NH^3 = C^2H^5.H.O + \left.\begin{matrix}NH^2(CO)''\\C^2H^5\end{matrix}\right\}O.$$

$$\left.\begin{matrix}NH^2(CO)''\\C^2H^5\end{matrix}\right\}O + NH^3 = C^2H^5.H.O + N^2(CO)''.H^4.$$

3. By the action of heat on the isomeric compound, cyanate of ammonium, $NH^4.CNO$, or even when a solution of that salt is left to evaporate spontaneously, also when cyanate of potassium is mixed with sulphate of ammonium, the mixture left to evaporate, and the residue exhausted with alcohol.—4. By decomposing ammonio-cupric fulminate with sulphydric acid (see FULMINIC ACID).—5. In the decomposition of oxamide (*q. v.*) at a red heat.—6. By the oxidation of uric acid.

The product obtained by the last four processes is urea; the same substance occurs as an animal excretion in the urine, in which indeed it was first discovered, being produced by the oxidation of the nitrogenous tissues. Whether the carbamide produced by the action of ammonia on carbonic ether or on oxychloride of carbon is identical with this, or only isomeric, is a point perhaps not absolutely decided. Nevertheless it agrees with urea in its most essential characters, viz. in forming a sparingly soluble crystalline salt with nitric acid, and in being resolved by the action of the stronger acids into ammonia and carbonic anhydride, as represented by the equation:

$$CH^4N^2O + H^2O = 2NH^3 + CO^2.$$

It is true that Regnault did not obtain a crystalline salt by adding nitric acid to the mixture of carbamide and sal-ammoniac produced by the first process; perhaps in consequence of the presence of the sal-ammoniac. Natanson, however, did obtain a crystalline nitrate in the manner above described. No decided difference has, indeed, been pointed out between carbamide and urea. We shall, however, refer to the article Urea for the preparation and properties of the substance usually so called, and shall here describe a number of substitution-products, commonly called *compound ureas.*

Substitution-products of Carbamide: Compound Ureas.

The hydrogen in carbamide may be more or less replaced by organic radicles, acid or basic. The compounds containing 1 at. of an alcohol-radicle, are obtained chiefly by the action of ammonia on the cyanates of those radicles, just as carbamide or urea itself is produced by the action of ammonia on cyanic acid (cyanate of hydrogen.)

$$\underset{\text{Cyanic Acid.}}{HCNO} + NH^3 = \underset{\text{Carbamide.}}{CH^4N^2O.}$$

$$\underset{\text{Cyanate of Ethyl.}}{C^2H^5.CNO} + NH^3 = \underset{\text{Ethyl-carbamide.}}{CH^3(C^2H^5)N^2O.}$$

Those which contain 2 at. of an alcohol-radicle are produced in like manner by the action of an amine-base on the cyanate of an alcohol-radicle, *e.g.* ethyl-allylcarbamide, by the action of ethylamine on cyanate of allyl. All these carbamides containing basic radicles form crystalline-salts with nitric acid, and are resolved by the action of sulphuric or hydrochloric acid, or of alkalis, into carbonic anhydride and an amine base, just as carbamide is resolved under similar circumstances into carbonic anhydride and ammonia.

The carbamides containing acid radicles are produced by the action of the chlorides of those radicles on urea. They do not form salts with nitric acid. When heated they are resolved into cyanuric acid and the corresponding acid amide (*vide infra*).

a. Carbamides or *Ureas containing Acid radicles.* (Zinin, Ann. Ch. Pharm. xcii. 403.—Moldenhauer, *ibid.* xciv. 100.)

Acetyl-carbamide. $C^3H^6N^2O^2 = N^2\left\{\begin{matrix}(CO)''\\ C^2H^3O.\\ H^3\end{matrix}\right.$ Crystallises from boiling alcohol in long silky needles, and from boiling water, in stars or tufts of rhomboïdal prisms Dissolves in 100 pts. of cold and 10 pts. of boiling alcohol; much more soluble in water, insoluble in ether. At 160° C. it yields a slight woolly sublimate; melts at 200° (Zinin), at 112° (Moldenhauer), and at a higher temperature is resolved into cyanuric acid and acetamide:

$$3C^3H^6N^2O^2 = C^3H^3N^3O^3 + 3(N.H^2.C^7H^3O).$$

It is not precipitated by nitric acid or by mercuric nitrate.

Benzoyl-carbamide. $C^8H^8N^2O^2 = N^2.(CO)''.C^7H^5O.H^3$.—Obtained by heating powdered urea with chloride of benzoyl to 150°—155° C. As soon as all the urea is melted upon the chloride, the mixture must be removed from the bath and briskly stirred, whereupon it becomes pasty. The product washed with cold alcohol yields benzoyl-carbamide as a crystalline powder. It crystallises from boiling alcohol in thin elongated rectangular laminæ, often united in groups. It is much less soluble in water and in ether than in cold alcohol; strong boiling hydrochloric acid dissolves it better than pure water. Heated on platinum-foil it melts, emitting the odour of cyanide of phenyl (benzonitrile), afterwards that of cyanic acid, and finally volatilises altogether. Heated to 200° C. in a tube, it melts to a colourless liquid, which at a higher temperature, is resolved into cyanuric acid and benzamide. Ammonia has no action on benzoyl-carbamide. Potash dissolves it readily, and acids separate it from the solution. The alkaline solution, when boiled, gives off ammonia, and forms carbonate and benzoate of the alkali-metal.

Butyryl-carbamide, $C^5H^{10}N^2O^2 = N^2.(CO)''.C^4H^7O.H^3$.—Crystallises readily from water in small scales, from alcohol in thin elongated rhombic laminæ. It is tasteless and inodorous. Melts at 176° C. to a yellowish liquid which solidifies in a crystalline mass on cooling. A high temperature decomposes it like acetyl-urea. It aqueous solution is not precipitated by nitric acid, oxalic acid, or mercuric nitrate.

Valeryl-carbamide, $C^6H^{12}N^2O^2 = N^2(CO)''.C^5H^9O.H^3$, crystallises from boiling water in small nacreous crystals, unctuous to the touch; from alcohol in needles. It is nearly insoluble in cold water, melts at 91° C. and when carefully heated yields a sublimate of large iridescent scales.

β. Carbamides or *Ureas containing Basylous radicles:*

Allyl-carbamide, $C^4H^8N^2O = N^2.(CO)^{\prime\prime}.C^3H^5.H^3$. (Cahours and Hofmann, Phil. Trans. 1855, p. 555.)—Obtained by the action of ammonia on cyanate of allyl, ($C^3H^5.CNO + NH^3 = C^4H^8N^2O$.) Crystallises easily by evaporation both from water and from alcohol. Its composition is that of thiosinamine in which the sulphur is replaced by oxygen.

Allyl-sulphocarbamide, $N^2.(CS)^{\prime\prime}.C^3H^5.H^3$, also called thiosinamine, is produced by the action of ammonia on oil of mustard. Ethyl-, phenyl-, and naphthyl-derivatives of it are produced by treating oil of mustard with ethylamine, phenylamine and naphthylamine.

Diallyl-carbamide. *Sinapoline.* $C^7H^{12}N^2O = N^2.(CO)^{\prime\prime}.(C^3H^5)^2.H^2$. — Produced: 1. By the action of oxide of lead and water on sulphocyanate of allyl (oil of mustard):

$$2(C^3H^5.CNS) + 3Pb^2O + H^2O = C^7H^{12}N^2O + Pb^2CO^3 + 2Pb^2S.$$

2. By heating cyanate of allyl with water or with aqueous potash:

$$2(C^3H^5.CNO) + H^2O = C^7H^{12}N^2O + CO^2.$$

If potash is used, care must be taken that the action does not go too far; otherwise nothing but amine-bases will be formed (Cahours and Hofmann. *loc. cit.*) For the properties and reactions of this compound, see Sinapoline.

Amyl-carbamide. $C^6H^{14}N^2O = N^2.(CO)^{\prime\prime}.C^5H^{11}.H^3$. (A. Wurtz, Compt. rend. xxxii. 417).—Produced by the action of ammonia on cyanate of amyl. It is decomposed by potash into amylamine and carbonate of potassium. It forms a crystalline nitrate.

Benzyl-carbamide. *Toluyl-urea.* $C^8H^{10}N^2O = N^2.(CO)^{\prime\prime}.C^7H^7.H^3$.—This substance, or more probably an isomer thereof, is produced by the action of sulphydrate of ammonium on nitrotoluamide. (Noad, Phil. Mag. [4] vii. 142. (See Toluamide.)

Ethyl-carbamide, $C^3H^8N^2O = N^2.(CO)^{\prime\prime}.C^2H^5.H^3$. (Wurtz, Compt. rend. xxxii. 414.)—Produced by the action of ammonia on cyanate of ethyl. Dissolves readily in water and alcohol, and crystallises from alcohol in large prisms which decompose at 200° C., with evolution of ammonia and other products. The aqueous solution is decomposed by chlorine, forming a heavy liquid which crystallises gradually. Nitric acid does not form a precipitate in the aqueous solution, but crystals of nitrate of ethyl-carbamide are obtained on evaporation.

Diethyl-carbamide, $C^5H^{12}N^2O = N^2.(CO)^{\prime\prime}.(C^2H^5)^2.H^2$.—Produced, like the allyl-compound, by the action of water on cyanate of ethyl; also by the action of ethylamine on cyanate of ethyl: $C^2H^5.CNO + C^2H^7N = C^5H^{12}N^2O$. The nitrate forms very acid deliquescent rhombic prisms containing $C^5H^{12}N^2O.HNO^3$. (Wurtz.)

Ethyl-allyl-carbamide, $C^6H^{12}N^2O = N^2.(CO)^{\prime\prime}.C^2H^5.C^3H^5.H^2$. (Cahours and Hofmann, *loc. cit.*)—By the action of ethylamine on cyanide of allyl. Crystallises in beautiful prisms.

Similar compounds are formed by the action of methylamine, amylamine, and phenylamine on cyanate of allyl.

Ethyl-allyl-sulphocarbamide, $N^2(CS)^{\prime\prime}.C^2H^5.C^3H^5.H^2$. Syn. of Ethylthiosinamine. (See Thiosinamine.)

Ethyl-amyl-carbamide, $C^8H^{18}N^2O = N^2(CO)^{\prime\prime}.C^2H^5.C^5H^{11}.H^2$. — Action of amylamine on cyanate of ethyl. (Wurtz.)

Methyl-carbamide, $C^2H^6N^2O = N^2.(CO)^{\prime\prime}.CH^3.H^3$. (Wurtz, *loc. cit.*)—Obtained by the action of ammonia on cyanate of methyl; also by evaporating a mixture of sulphate of methylamine and cyanate of potassium and extracting the residue with alcohol. Crystallises in long transparent deliquescent prisms. The aqueous solution is neutral to test-paper, and if somewhat concentrated yields with nitric acid a precipitate of $C^2H^6N^2O.HNO^3$.

Dimethyl-carbamide, $C^3H^8N^2O = N^2.(CO)^{\prime\prime}.(CH^3)^2.H^2$. (Wurtz, *loc. cit.*)—Isomeric with ethyl-carbamide. Produced by the action of water, or of methylamine on cyanate of methyl. Crystallises easily; melts at 97° C.; is permanent in the air; volatilises without alteration; dissolves readily in water and alcohol; combines with nitric acid, forming the salt $C^3H^8N^2O.HNO^3$.

Methyl-ethyl-carbamide. $C^4H^{10}N^2O = N^2.(CO)^{\prime\prime}.CH^3.C^2H^5.H^2$.—Very deliquescent substance, obtained by the action of methylamine on cyanate of ethyl. (Wurtz.)

Naphthyl-carbamide, $C^{11}H^{10}N^2O = N^2(CO^{\prime\prime}).C^{10}H^7.H^3$. (H. Schiff, Chem. Gaz. 1857, p. 211.)—Obtained by saturating a solution of naphthylamine in anhydrous ether with cyanic acid gas, and recrystallising from hot alcohol. Flat, shining, flexible needles, nearly insoluble in water, more soluble in alcohol, easily soluble in ether: the latter solution yields a crystalline precipitate with oxalic acid. Naphthyl-carbamide yields by spontaneous decomposition, a resinous substance, whose alcoholic solution is coloured violet by acids, and red again by alkalis. The same reaction has been observed to be produced on test-paper by a tincture of madder (Sacc), and by nitrosonaphthalin (Church and Perkin, Jahresber. d. Chem. 1856, p. 609).

NAPHTHYL-ALLYL-SULPHOCARBAMIDE. $N^2(CS'').C^{10}H^7.C^3H^5.H^2$.—Syn. of NAPHTHYL-THIOSINAMINE. (See THIOSINAMINE.)

PHENYL-CARBAMIDE, $C^7H^8N^2O = N^2.(CO)''.C^6H^5.H^3$. *Phenyl-urea, Aniline-urea, Carbanilamide, Carbamide-carbanilide.* (A. W. Hofmann, Ann. Ch. Pharm. liii. 57; lvii. 265; lxx. 130; lxxiv. 14; Gm. xi. 503.)—This compound is obtained: 1. By passing cyanic acid vapour into anhydrous phenylamine, kept as cool as possible; dissolving the resulting crystalline mass in hot water; filtering to separate diphenyl-carbamide (which is produced more abundantly in proportion as the phenylamine has been more heated); and cooling the filtrate to the crystallising point.—2. By treating sulphate or hydrochlorate of phenylamine with aqueous cyanate of potassium, and separating the resulting phenyl-carbamide (cyanate of phenylamine) by digestion in alcohol.—3. By mixing phenylamine with an aqueous solution of chloride of cyanogen (obtained by passing chlorine gas through aqueous hydrocyanic acid), purifying the resulting crystals with animal charcoal, and recrystallising from hot water.—4. Cyanate of phenyl mixed with ammonia, immediately solidifies in the form of phenyl-carbamide, $C^6H^5.CNO + NH^3 = C^7H^8N^2O$.

Phenyl-carbamide forms fusible needles and laminæ, sparingly soluble in cold, easily in boiling *water*, easily also in *alcohol* and *ether*. It dissolves in *nitric acid*, but scarcely to a greater amount than in water, and crystallises therefrom unaltered, differing in this respect from carbamide. It dissolves also without alteration in *cold sulphuric acid*, but when heated therewith, it is resolved into carbonic anhydride,, phenyl-sulphamic acid, and acid sulphate of ammonium:

$$C^7H^8N^2O + 2H^2SO^4 = CO^2 + \left.\begin{matrix} N.H.C^6H^5.(SO^2)'' \\ H \end{matrix}\right\} O + NH^4.H.SO^4.$$

Heated above its melting-point, it is resolved into ammonia, diphenyl-carbamide, and cyanuric acid:

$$\underset{\text{Phenyl-carbamide.}}{6[N^2.(CO)''.C^6H^5.H^3]} = 3NH^3 + \underset{\text{Diphenyl-carbamide.}}{3[N^2.(CO)''.(C^6H^5)^2.H^2]} + \underset{\text{Cyanuric acid.}}{N^3.H^3.(\overset{'''}{CO})^3}$$

By boiling with strong *potash-ley*, or more quickly by fusion with *hydrate of potassium*, it yields ammonia, phenylamine, and carbonate of potassium:

$$C^7H^8N^2O + 2KHO = NH^3 + C^6H^7N + K^2CO^3.$$

It is not decomposed by boiling with dilute acids or alkalis.

The name *phenyl-urea* has hitherto been generally applied to the isomeric compound, which Chancel obtained by the action of sulphydrate of ammonium on nitrobenzamide (Gerh. Traité, i. 427). This compound is a powerful base; but it does not agree with the ureas, either in its mode of formation, or in its reaction with alkalis. It should rather be regarded as *oxybenzodiamide* (*q. v.*) the primary diamide of oxybenzoic acid ($C^7H^6O^3$). Its formation may be represented by the equation:

$$\underset{\text{Nitrobenzamide.}}{N\left\{\begin{matrix} C^7H^4(NO^2)O \\ H^2 \end{matrix}\right.} + 3H^2S = \underset{\text{Oxybenzo-diamide.}}{N^2\left\{\begin{matrix} (C^7H^4O)'' \\ H^4 \end{matrix}\right.} + 2H^2O + S^3.$$

When treated with potash, it yields ammonia, and an acid which is probably oxybenzoic acid. The reaction consists of two stages, ammonia and oxybenzamic acid being formed in the first, ammonia and oxybenzoic acid in the second:

$$\underset{\text{Oxybenzo-diamide.}}{N^2\left\{\begin{matrix} (C^7H^4O)'' \\ H^4 \end{matrix}\right.} + H^2O = NH^3 + \underset{\text{Oxybenzamic acid.}}{\left.\begin{matrix} N.H^2.(C^7H^4O)'' \\ H \end{matrix}\right\} O}$$

$$\underset{\text{Oxybenzamic acid.}}{\left.\begin{matrix} N.H^2.(C^7H^4O)'' \\ H \end{matrix}\right\} O} + H^2O = NH^3 + \underset{\text{Oxybenzoic acid.*}}{\left.\begin{matrix} C^7H^4O \\ H^2 \end{matrix}\right\} O^2}$$

The true phenyl-urea is the compound above described as phenyl-carbamide.

ETHYL-PHENYL-CARBAMIDE, $C^9H^{12}N^2O = N^2.(CO)''.C^2H^5.C^6H^5.H^2$, is obtained by dissolving phenylamine in cyanate of ethyl. Great heat is evolved, and the mixture on cooling solidifies to a crystalline mass. It is slowly decomposed by potash, yielding phenylamine, ethylamine, and carbonic anhydride. (Wurtz, Compt. rend. xxxii. 417.)

---

[*] See a paper by Dr. Hofmann (Proc. Roy. Soc. x. 602), where however the acid formed is said to be not oxybenzoic, but benzoic acid.

NITROPHENYL-CARBAMIDE, $C^7H^7N^3O^3 = N^2.(CO)''.C^6H^4(NO^2).H^3$. — Produced, together with dinitromelaniline, by the action of gaseous chloride of cyanogen on nitrophenylamine dissolved in ether. (Hofmann, Ann. Ch. Pharm. lxvii. 156; lxx. 137.)

DIPHENYL-CARBAMIDE. *Diphenyl-urea, Carbanilide, Carbophenylamide.* $C^{13}H^{12}N^2O = N^2.(CO)''.(C^6H^5)^2.H^2$ (Hofmann, Ann. Ch. Pharm. lvii. 266; Gm. xi. 349).—Produced: 1. By the action of cyanate of phenyl on phenylamine, or on water:

$$2[N.(CO)''.C^6H^5] + H^2O = CO^2 + N^2.(CO)''.(C^6H^5)^2.H^2.$$

2. By the action of phenylamine on oxychloride of carbon.—3. In the decomposition of diphenyl-sulphocarbamide by potash.—4. By the dry distillation of phenyl-carbamide, melanoximide, or oxalate of melaniline. (See those compounds.)

Diphenyl-carbamide forms white silky needles, which melt at 205° C. and distil without decomposition. It is odourless at ordinary temperatures, but has a suffocating odour when heated. It dissolves sparingly in *water*, abundantly in *alcohol* and *ether*.

When quickly heated in the moist state, it yields carbonate of phenylamine, together with other products. With strong *sulphuric acid*, it gives off carbonic anhydride, and forms water and phenylsulphamic acid:

$$N^2\left\{\begin{matrix}(CO)''\\(C^6H^5)^2\\H^2\end{matrix}\right. + 2\left(\begin{matrix}SO^2\\H^2\end{matrix}\right\}O^2\Big) = (CO)''.O + H^2O + 2\left(\begin{matrix}N.H.C^6H^4.(SO^2)''\\H\end{matrix}\right\}O.\Big)$$

By boiling with *potash*, it is resolved into phenylamine and carbonate of potassium.

Diphenyl-carbamide is isomeric with *flavine*, an organic base produced by the action of reducing agents on dinitrobenzophenone. This base is indeed sometimes regarded as diphenyl-urea (Gerh. i. 430); but it does not exhibit the characters of a urea. (See FLAVINE.)

PHENYLSULPHOCARBAMIDE, $C^7H^8N^2S = N^2(CS)''.C^6H^5.H^3$. (Hofmann, Proceedings of the Royal Society, ix. 276.)—Produced by the action of alcoholic ammonia on sulphocyanate of phenyl:

$$C^6H^5.CNS + NH^3 = C^7H^8N^2S.$$

The mixture, on being gently warmed, quickly solidifies into a crystalline compound, which may be obtained in beautiful needles by crystallisation from boiling water.

Phenylsulphocarbamide is a weak base, and forms a *chloroplatinate* containing $C^7H^8N^2S.HCl.PtCl^2$. It also combines with *nitrate of silver*. By boiling with nitrate of silver, it is converted into phenyl-carbamide.

PHENYL-ALLYL-SULPHOCARBAMIDE. $N^2.(CS)''.C^6H^5.C^3H^5.H^2$. — Syn. with PHENYL-THIOSINAMINE. (See THIOSINAMINE.)

DIPHENYL-SULPHOCARBAMIDE. *Sulphocarbanilide, Sulphophenyl-urea.* $C^{13}H^{12}N^2S = N^2(CS)''.(C^6H^5)^2.H^2$. (Hofmann, Ann. Ch. Pharm. lvii. 266; lxx. 144; Gm. xi. 350. Further, Proc. Roy. Soc. x. 274.—Laurent and Delbos, J. Pharm. [3] x. 309.—Laurent and Gerhardt, Ann. Ch. Phys. [3] xxii. 103; xxiv. 196.)—This compound is obtained: 1. By the action of sulphide of carbon on phenylamine, the action being accelerated by addition of alcohol (Hofmann):

$$2C^6H^7N + CS^2 = C^{13}H^{12}N^2S + H^2S.$$

—2. By heating a mixture of phenylamine, sulphocyanate of potassium, and sulphuric acid, the diphenyl-sulphocarbamide then distilling over, while sulphate of ammonium remains behind (Laurent and Gerhardt).—3. By mixing phenylamine with sulphocyanate of phenyl: $C^6H^5.CNS + C^6H^7N = C^{13}H^{12}N^2S$. (Hofmann.)

Diphenyl-sulphocarbamide separates from the mixture of phenylamine and sulphide of carbon, in crystalline scales or rhombic tables; from alcohol, in brilliant iridescent laminæ. It dissolves sparingly in water, easily in alcohol. It has a peculiar odour, especially when heated, and a bitter taste exceeding in intensity that of any other known substance. It melts at 140° C., and distils without decomposition. Heated with strong *sulphuric acid*, it forms phenyl-sulphamic acid, giving off carbonic anhydride and sulphydric acid (Hofmann):

$$C^{13}H^{12}N^2S + 2H^2SO^4 = CO^2 + H^2S + 2\left(\begin{matrix}N.H.C^6H^4.(SO^2)''\\H\end{matrix}\right\}O\Big)$$

By *phosphoric anhydride*, *chloride of zinc*, or *hydrochloric acid gas*, it is resolved into phenylamine and sulphocyanate of phenyl (Hofmann). Fused with *potash*, it yields phenylamine, together with sulphydrate and carbonate of potassium:

$$C^{13}H^{12}N^2S + 3KHO = 2C^6H^7N + K^2CO^3 + KHS.$$

When boiled with *alcoholic potash*, it is converted into diphenyl-carbamide:

$$C^{13}H^{12}N^2S + K^2O = K^2S + C^{13}H^{12}N^2O.$$

Similarly when its alcoholic solution is boiled with *mercuric oxide*. It is not decomposed by dilute acids or alkalis.

PIPERYL-CARBAMIDE. *Piperyl-urea, Piperidine-urea.* $C^6H^{12}N^2O = N^2(CO)''.C^5H^{10}.H^2$ (Cahours, Ann. Ch. Phys. [3] xxxviii. 76.)—Obtained by boiling sulphate of piperidine with cyanate of potassium, evaporating to dryness, and exhausting with strong alcohol. It appears also to be formed when vapour of cyanic acid or moist chloride of cyanogen is passed into piperidine. The alcoholic solution yields it, by spontaneous evaporation, in long white needles.

Methyl-piperyl-carbamide, $C^6H^{11}(CH^3)N^2O$, and *Ethyl-piperyl-carbamide*, $C^6H^{11}(C^2H^5)N^2O$, are produced by the action of piperidine on the cyanates of methyl and ethyl.

CARBANIL. Syn. of CYANATE OF PHENYL. (See CYANIC ETHERS.)

CARBANILIDE. Syn. of DIPHENYL-CARBAMIDE (p. 756).

CARBANILIC ACID. Syn. of PHENYL-CARBAMIC ACID (p. 751).

CARBANILETHANE and **CARBANIMETHYLANE.** PHENYLCARBAMATES OF ETHYL and METHYL (p. 752).

CARBAZOTE. The name given by Thaulow (J. pr. Chem. xxxi. 220) to the gas evolved by ignition of cyanide of silver, which he regards as isomeric but not identical with cyanogen. It has a peculiar odour, and strongly irritates the eyes and respiratory organs. Specific gravity 1·73. Liquefies at $-4°$ C. Burns with red flame. It dissolves in potash, and the solution when neutralised with nitric acid does not precipitate iron-salts. (Thaulow.)

CARBAZOTIC ACID. Syn. with PICRIC ACID.

CARBIDES, or *Carburets*. Compounds of carbon with metals. These compounds have not been much studied: none of them occur as natural minerals, and it is difficult to obtain them in definite form. The usual effect of the union of carbon with a metal, is to render it hard and brittle. (See the several metals.)

CARBOBENZIDE. Syn. with BENZONE.

CARBOBENZOIC ACID. See CINNAMEIN (p. 981).

CARBO-HYDROGENS. See HYDROCARBONS.

CARBOLIC ACID. Syn. with PHENIC ACID.

CARBON. *Symbol* C. *Atomic weight* 12.—Carbon is one of the most abundant of the elements, existing both in the free state and in an endless variety of combinations. It is found pure in the diamond; nearly pure in graphite or plumbago, less pure as anthracite. It occurs also abundantly in the form of carbonates, especially carbonate of calcium, and is an essential constituent of organic bodies, from which it may be separated in the form of charcoal, by distilling off the more volatile elements, hydrogen, oxygen, nitrogen, &c.

Carbon in the free state is a solid body, destitute of taste and odour, infusible and non-volatile, excepting at the temperature produced by a powerful electric current. The several modifications exhibit great diversities of colour, lustre, transparency, hardness, density, and power of conducting heat and electricity. It exhibits crystalline forms belonging to two different systems, the regular and the hexagonal, and several amorphous modifications.

1. *Diamond.* This valuable gem consists of pure or nearly pure carbon. It is found in alluvial soils produced by the disintegration of ancient rocks, the principal localities being in India, Borneo, Brazil, and the Urals. Diamonds occur thinly scattered through large quantities of soil, and very careful washing and examination are required to separate them.

The diamond crystallises in forms belonging to the regular system, namely, the octahedron, which is usually the predominating form, though it rarely occurs alone; also the cube, the rhomboïdal dodecahedron, which is very frequent; the triakis-octahedron, a figure of 24 faces, formed by the superposition of a low triangular pyramid on each face of the octahedron; and the hexakis-octahedron, a 48-sided figure formed in like manner, by a 6-faced acumination of the octahedron. Intermediate forms are also of frequent occurrence, the secondary faces being sometimes so numerous as to give the crystal the appearance of having convex faces. Sometimes the faces are really curved, and consequently intersect in curved edges: the dodecahedron and octahedron frequently occur with convex faces. Hemihedral forms and twin-crystals are also found. (For figures, see the article CRYSTALLOGRAPHY.)

All diamonds cleave easily in directions parallel to other faces of the regular octahedron, which is therefore the primary form. The fracture is conchoïdal. The specific gravity of the diamond is 3·5295 according to Thomson; 3·55 according to Pelouze. It is the hardest substance known, being capable of scratching all others. Diamonds with curved edges are also capable of cutting glass, and are much used for that purpose, the curved edges penetrating the glass like a wedge; those with straight edges merely scratch.

The purest diamonds are colourless and transparent; but many exhibit various shades of yellow, red, green, brown, and black; these coloured diamonds leave, when burnt, from 0·65 to 0·2 per cent. of ash: colourless diamonds leave but a trace. The diamond has a strong lustre (called *adamantine*), and high refractive and dispersive power: hence its peculiar brilliancy. The lustre of the natural diamond is greatly increased by cutting it in a peculiar manner, so as to give it numerous facets capable of reflecting and dispersing light in various directions. This is effected by pressing the diamond against a revolving metal disc covered with a mixture of diamond dust and oil, no other substance being hard enough to abrade the diamond. The dust for this purpose is obtained either by collecting that which falls away in the process of cutting and polishing, or by pounding up diamonds which have not sufficient transparency to be valuable as gems. Diamonds are sometimes found in opaque spheroïdal lumps, destitute of crystalline structure and transparency, and useless excepting in the form of powder.

The diamond conducts electricity but slowly. Like all other forms of carbon, it neither melts nor volatilises at the heat of the most powerful furnace; but when placed between the charcoal cones of a powerful voltaic battery, it becomes white-hot, swells up, splits into fragments, and after cooling, presents the aspect of coke prepared from bituminous coal. When very strongly heated in the air or in oxygen gas, it takes fire and burns completely away, forming carbonic anhydride. This fact of the combustibility of the diamond, which had been conjectured by Newton from its great refracting power, was first demonstrated in 1694, by the Florentine academicians, who succeeded in burning it in the focus of a concave mirror. Lavoisier and Guyton-Morveau, and afterwards Davy, showed that the sole product of the combustion in oxygen is carbonic anhydride, and therefore that the diamond is pure carbon.

2. *Graphite.*—This name is applied to several varieties of native carbon containing from 95 to nearly 100 per cent. of that element, some crystalline, others amorphous, but all perfectly opaque, having an iron-black or steel-grey colour, and metallic lustre, producing a black shining streak on paper; sectile; of specific gravity 1·209, hardness between 1 and 2, and conducting electricity nearly as well as the metals. Graphite was formerly regarded as a carbide of iron, but the iron is now known to be merely in a state of mixture, as also small quantities of silica and alumina.

α. *Crystallised or Foliated Graphite.*—This variety is found occasionally in small six-sided tables belonging to the hexagonal system, cleaving perfectly in the direction of the base, and having the basal planes striated parallel to the alternate sides. More commonly, however, it occurs in foliated or granular masses. It is found imbedded in quartz near Travancore in Ceylon, and near Moreton Bay in Australia; with olivine and sphene at Ticonderoga in the State of New York, and in gneiss at Stourbridge, Massachussets, where it presents a structure between scaly and fine granular, and an occasional approximation to distinct crystallisations (Dana, ii. 27). It is also obtained artificially by melting cast-iron containing a large proportion of carbon and leaving it to cool slowly. It is tough and difficult to pulverise by mechanical means, but it may be reduced to the state of very thin laminæ by prolonged trituration with water.

β. *Amorphous Graphite.*—This variety, also called *plumbago* or *black lead*, is found in Borrowdale, Cumberland, where it occurs in nests of trap in the clay-slate, and is largely imported into this country from Germany, principally from Griesbach near Passau. The Borrowdale mine was formerly very rich, but now appears to be nearly exhausted (see *Ure's Dictionary of Arts, Manufactures and Mines*, iii. 467). Amorphous graphite is softer than the crystalline variety, and makes a much blacker streak on paper: it is therefore better adapted for the making of pencils. Some kinds of amorphous graphite, occurring in the coal measures, have very much the appearance of anthracite: such is the case with the graphite of New Brunswick.

Graphite resembles the other modifications of carbon in being unalterable when heated in close vessels, excepting at the temperature of the electric current, and in yielding carbonic anhydride when burnt in contact with oxygen. But it differs essentially from all other forms of carbon when subjected to the action of certain oxidising agents, such as a mixture of chlorate or acid chromate of potassium with sulphuric or nitric acid, or a mixture of nitric and sulphuric acids. In this case Brodie has shown (Ann. Ch. Phys. [3] xlvi. 351; further, Phil. Trans. 1860, i.; Ann. Ch. Pharm. cxiv. 7) that it is converted into a peculiar acid, called *graphitic acid*, which is best obtained by heating pulverised graphite with chlorate of potassium and nitric acid, as long as yellow vapours are given off, then washing it with a large quantity of water, drying it on the water-bath, and repeating this series of operations several times. In this manner the graphite is ultimately converted into thin transparent crystals of graphitic acid, $C^{11}H^4O^5$. Brodie, however, regards this acid as analogous in composition to the acid $Si^4H^4O^5$, which Wöhler obtained by the action of oxidising agents on graphitoïdal silicon; and accordingly he supposes that the atomic weight of graphite is different from that of the other forms of carbon, and equal to 33, which he denotes by the symbol Gr (graphon); substituting this value in the preceding formula of graphitic acid, it becomes $Gr^4H^4O^5$. (See ATOMIC WEIGHT OF CARBON, p. 757; also GRAPHITIC ACID.)

Graphite cannot be converted into graphitic acid by a single treatment with oxidising agents, however long continued; but by subjecting it to this treatment for a certain time, then washing it with water and igniting, it may be purified and obtained in a state of very minute division. A good way of proceeding is to mix coarsely pounded graphite with $\frac{1}{14}$ of its weight of chlorate of potassium, add the mixture to a quantity of strong sulphuric acid equal to twice the weight of the graphite, heat the whole in the water-bath as long as yellow vapours of chloric oxide are evolved, wash the cooled mass with water, then dry and ignite it; it then swells up and leaves finely divided graphite. If the graphite to be purified contains siliceous matters, a little fluoride of sodium should be added to the mixture before heating.

Graphite is used for making pencils, for polishing stoves, and other articles, for diminishing the friction of machinery, for making crucibles, and in the electrotype process for coating the surfaces of wood and other non-conducting materials, so as to render them conductive.

3. *Anthracite* or *stone-coal* is an amorphous variety of carbon containing about 90 per cent. of that element associated with hydrogen, oxygen, nitrogen, and ash. It is intermediate in composition and properties between graphite and bituminous coal, being blacker than graphite, and having a higher lustre than ordinary coal. Specific gravity 1·3 to 1·7. Hardness = 2 to 2·1. It burns with difficulty, requiring a strong draught to keep it in a state of active combustion: hence it is fit only for burning in close stoves and furnaces; it does not cake together like bituminous coal. Anthracite occurs abundantly in South Wales, in the departments of Mayenne and Isère in France; also in Pennsylvania and Rhode Island.

4. *Carbon obtained from Organic Substances by Dry Distillation or Imperfect Combustion.*—When animal or vegetable substances are strongly heated in close vessels, the more volatile elements, viz. the oxygen, hydrogen, and nitrogen, with part of the carbon, are driven off in the form of gaseous products, some of which afterwards condense in the liquid form, while a considerable portion of the carbon remains behind in the form of a black mass, called charcoal, of greater or less compactness, according to the nature of the original substance. If the substance thus treated — wood or coal, for example — contains any inorganic materials, such as potash, soda, lime, &c., these remain behind with the charcoal. The purest kind of charcoal is that obtained by heating sugar, starch, or some other organic substance, free from inorganic elements, in a close vessel. There then remains a black, brilliant, porous charcoal, which is nearly pure carbon, but contains a small quantity of hydrogen and oxygen, which cannot be driven off even by the most intense and long-continued heat.

a. Wood-Charcoal.—Wood consists of carbon, hydrogen, and oxygen, the two latter being in the proportion to form water. When heated in the open air, it burns completely away, with the exception of a small quantity of white ash; but if the supply of air is limited, only the more volatile ingredients burn away, and the greater part of the carbon remains behind. This is the principle of the process of *charcoal-burning* as it is practised in countries where wood is abundant, on the Harz mountains in Germany, for instance. A number of billets of wood are built up vertically in two or three rows into a large conical heap, which is covered over with turf or moistened charcoal-ash, holes being left at the bottom for the air to get in. A hollow space is also left in the middle of the heap, to serve as a flue for the gaseous matters which are evolved. The heap is set on fire by throwing burning pieces of wood into the central opening, near the top of which, however, a kind of grate, made of billets of wood, is placed, to prevent the burning fuel from falling at once to the bottom. The combustion then proceeds gradually from the top to the bottom, and from the centre to the outside of the heap; and as the central portions burn away, fresh wood is continually thrown in at the top, so as to keep the heap quite full. The appearance of the smoke shows how the combustion is proceeding; when it is going on properly, the smoke is thick and white; if it becomes thin, and especially if a blue flame appears, it is a sign that the wood is burning away too fast, and the combustion must then be checked by partially stopping up the holes at the bottom, or by heaping fresh ashes on the top and sides, and pressing them down well so as to diminish the draught. As soon as the combustion is completed, the heap is completely covered with turf or ashes, and left to cool for two or three days. It is then taken to pieces, and the portions still hot are cooled by throwing water or sand upon them. The quantity of charcoal thus obtained varies with the manner in which the combustion is conducted. 100 parts of wood yield on the average from 61 to 65 parts by measure, or 24 parts by weight of charcoal. When the burning is very carefully conducted, the quantity may amount to 70 per cent. by measure.

In England a large quantity of charcoal is obtained in the dry distillation of wood for the preparation of acetic acid. For this purpose the wood is heated to redness in cast-iron cylinders, whereupon a number of volatile products are given off, including a large quantity of tarry matter, an inflammable spirit called wood-spirit or wood-naphtha, and acetic acid; and in the retorts there remains a quantity of charcoal.

For the manufacture of gunpowder, charcoal is sometimes prepared by subjecting wood in iron cylinders to the action of over-heated steam. (Violette, Ann. Ch. Phys. [3] xxiii. 475.)

Wood-charcoal is more or less compact, according to the kind of wood from which it is formed. The lighter woods, such as willow, yield a very porous charcoal, having comparatively little power of conducting heat and electricity; box-wood, on the contrary, yields a very compact charcoal, which is a good conductor of heat and electricity, and is admirably adapted for exhibiting the voltaic light. The density and conducting power of charcoal are greatly increased by exposing it in close vessels to a very high temperature. Charcoal retains the form, and to a considerable extent the external structure of the wood, so that a horizontal section exhibits distinctly the concentric rings and the traces of the medullary rays. When burned it leaves from 1 to 5 per cent. of ash. According to Berthier, 1000 parts of lime-wood leave 50 parts of ash; of oak, 25; birch 10; fir 8; hornbeam 26; beech 30.

b. Coke.—Ordinary bituminous coal, which consists of the remains of ancient forests and peat-mosses, and appears to have been formed from wood by a process of slow decay going on without access of air, differs from wood in containing a larger proportion of carbon, and less oxygen and hydrogen; it also contains nitrogen derived from the tissue of the plants. This substance, when heated in the open air, burns away like wood, leaving nothing but a white ash; but, when strongly heated in cast-iron cylinders, it undergoes a decomposition like that which takes place in wood under similar circumstances, a large quantity of volatile products being given off, viz. carburetted hydrogen gas (the gas used for illumination) and a tarry liquid containing ammonia and a variety of other products; while a black, dull-looking, porous mass, called *coke*, is left in the retorts. This substance also consists mainly of carbon, mixed, however, with a quantity of inorganic constituents, greater than that which occurs in wood-charcoal, so that it leaves a larger amount of ash when burned. The aspect of coke varies greatly according to the kind of coal from which it is obtained. Bituminous coals, such as the Newcastle coal, undergo a kind of semi-fusion before they decompose, and yield a very porous coke, having a brilliant metallic aspect; anthracite, on the contrary undergoes but little alteration by heating, and yields a coke having very much of the form and aspect of the original mass. Coke is used in the iron districts of South Wales and Staffordshire, for reducing the metal from the ore. It is there prepared from the coal which occurs in the same districts, by partially burning that substance in longitudinal heaps, more or less covered up with the ashes of former fires, the object being to produce a smothered combustion, similar to that already described as used for the preparation of wood-charcoal. This process is very wasteful unless carefully conducted.

c. Metallic Carbon, Glance-coal.—This is a very dense form of carbon, deposited when certain volatile organic compounds, especially hydrocarbons, are passed through red-hot tubes of porcelain or cast-iron; it collects in the upper part of the retorts in which carburetted hydrogen gas is distilled from coal, and is likewise produced in blast furnaces. It often exhibits the lustre and sonority of a metal, is very hard, a good conductor of heat and electricity, and burns with difficulty. It is used to form the negative element in Bunsen's voltaic battery.

A very hard and compact carbon, also used for the purpose just mentioned, is obtained by heating to redness, in an iron mould, an intimate and impalpable mixture of 2 pts. coke and 1 pt. bituminous coal, then several times steeping it in treacle, and subjecting it again to a very intense heat. The mass thus formed is very hard, may be sawn and filed without breaking, and conducts electricity like a metal.

d. Lamp-black.—Most of our ordinary combustibles, consisting of carbon and hydrogen, such as tallow, wax, and oil, undergo but imperfect combustion, unless assisted by an artificial draught of air. The consequence is, that a portion of the carbon, which is the less combustible element of the two, remains unburned, and is driven off in smoke, or deposited on cold surfaces in the form of *soot* or *lamp-black;* thus, a plate of glass or metal held in the upper part of a candle flame is quickly covered with a black deposit of carbon. Lamp-black is ordinarily prepared by the imperfect combustion of highly carbonised bodies, such as resin or pitch. The apparatus consists of a cylindrical stone chamber, in which is suspended a cone of iron plate, having a hole at top, and capable of moving up and down; this cone serves for a chimney during the operation. A cast-iron pot, containing the resin or pitch, is heated in a furnace outside the chamber; the vapours proceeding from it are set on fire; and the supply of air is properly regulated by apertures which may be opened and closed at pleasure. The imperfect combustion of the vapour produces a considerable quantity of lamp-black, which collects on the cone and on the walls. When the operation is finished, the cone is lowered, and as it is made to fit the chamber exactly, it scrapes the wall as it descends, and causes the deposit to fall down on the floor. Lamp-black thus obtained is always contaminated with oily matter; it may be purified by calcination in a covered crucible. Sometimes the chamber is hung with coarse cloths, on which the soot collects; they are withdrawn from time to time and scraped.

A better method of condensation is to cause the smoke and vapour to pass through an inclined iron tube, in which the oily products collect, and thence into a series of condensing chambers; the purest product is then found in the farthest chamber. The finest kind of lamp-black is obtained by burning oil or fat in lamps, and causing the products of combustion to pass through a series of iron cylinders, terminating in a chimney; the cylinders are opened at bottom from time to time, and the carbonaceous deposit removed. As obtained by either of these methods it is always more or less contaminated with oily matter. It may be purified by calcination in a covered crucible, but for the purposes to which it is chiefly applied, viz. for painting and for the manufacture of printing ink, the presence of the oil is not objectionable.

e. Animal Charcoal or *Bone-black*, is a mixture of very finely divided charcoal and phosphate of calcium obtained by calcining bones in close vessels. Its preparation and properties have been already described (p. 624).

Absorbent power of Charcoal.—Wood-charcoal and other porous forms of carbon have the property of absorbing large quantities of gases: the greater the porosity of the charcoal the greater is also its absorbing power. In its ordinary state, however, charcoal has its pores filled with atmospheric air, and to enable it to exert its full absorbing power on any other gas, it must first be freed from the air contained in it by heating it to redness and cooling it under mercury. Saussure has shown that recently ignited box-wood charcoal absorbs at 12° C. and under a pressure of 724 millimetres, the following quantities of different gases:

Ammonia . . .	90 vols.	Ethylene . .	35 vols.
Hydrochloric acid .	85 „	Carbonic oxide .	9·42 „
Sulphurous anhydride	65 „	Oxygen . . .	9·25 „
Sulphydric acid . .	55 „	Nitrogen . .	6·50 „
Nitrous oxide . .	40 „	Hydrogen . .	1·25 „
Carbonic anhydride .	35 „		

Charcoal also absorbs moisture with avidity from the air, as well as other condensable vapours, such as odoriferous effluvia. Hence freshly calcined charcoal, wrapped up in clothes which have acquired a disagreeable colour, destroys that odour. It has a considerable effect in retarding the putrefaction of animal matter with which it is placed in contact. Water is found to remain sweet, and wine to be improved in quality, if kept in casks the inside of which has been charred. In the state of coarse powder, wood-charcoal is particularly applicable as a filter for spirits, which it deprives of the essential oil they contain. (Graham's *Elements of Chemistry*, 2nd ed. vol. i. p. 338.) Water contaminated with offensive gas and other matters may also be rendered fit for drinking by filtering it through coarsely pounded charcoal interposed between two layers of sand.

Charcoal not only absorbs gases, but frequently also determines their combination. If a piece of charcoal, which has remained for some time in an atmosphere of sulphuretted hydrogen, and has absorbed a considerable quantity of that gas, be introduced into a vessel filled with oxygen, combination immediately takes place between the oxygen and the elements of the sulphuretted hydrogen, water and sulphurous acid being formed, and a portion of the sulphur separated. The charcoal always becomes very hot, and sometimes the heat is great enough to produce explosion. Similar phenomena are exhibited by other combustible gases.

This property of charcoal has been applied by Dr. Stenhouse to the construction of ventilators and respirators for purifying infected atmospheres. In a pamphlet, bearing the title "On Charcoal as a Disinfectant," Dr. Stenhouse observes: — "Charcoal not only absorbs effluvia and gaseous bodies, but, especially, when in contact with atmospheric air, rapidly oxidises and destroys many of the easily alterable ones, by resolving them into the simplest combinations they are capable of forming, which are chiefly water and carbonic acid. . . . Effluvia and miasmata are generally regarded as highly organised, nitrogenous, easily alterable bodies. When these are absorbed by charcoal, they come in contact with highly condensed oxygen gas, which exists within the pores of all charcoal which has been exposed to the air, even for a few minutes; in this way they are oxidised and destroyed." On this principle, Dr. Stenhouse has constructed *ventilators*, consisting of a layer of charcoal enclosed between two sheets of wire-gauze, to purify the foul air which accumulates in water-closets, the wards of hospitals, and in the back courts and lanes of large cities. By the use of these ventilators, pure air may be obtained from exceedingly impure sources, the impurities being absorbed and retained by the charcoal, while a current of pure air alone is admitted into the neighbouring apartments. A similar contrivance might also be applied to the gulley-holes of our common sewers, and to the sinks in private houses. Dr. Stenhouse has also constructed *respirators*, consisting of a layer of charcoal a quarter of an inch thick, interposed between two sheets of silvered wire-gauze covered with woollen cloth. They are made either to cover the mouth and nose, or the mouth alone; the former kind of respirator affords an effectual protection against malaria and the deleterious gases which accumulate in chemical works, common sewers, &c. The latter will answer the same purpose when the atmosphere is not very impure, provided the simple precaution be taken of inspiring the air by the mouth, and expiring by the nose. This form of respirator may also be useful to persons affected with fetid breath. Freshly heated wood-charcoal simply placed in a thin layer in trays, and disposed about infected apartments, such as the wards of hospitals, is also highly efficacious in absorbing the noxious matter.

Platinised Charcoal.—The power of charcoal in inducing chemical combination is increased by combination with minutely divided platinum. In this manner, a combination may be produced possessing the absorbent power of charcoal (which is much greater than that of spongy platinum), and nearly equal, as a promoter of chemical combination, to spongy platinum itself. In order to platinise charcoal, nothing more is necessary than to boil it, either in coarse powder or in large pieces, in a solution of dichloride of platinum, and, when thoroughly impregnated, which seldom requires more than ten minutes or a quarter of an hour, to heat it to redness in a closed vessel, a capacious platinum crucible being well adapted for the purpose. Charcoal thus platinised, and containing 3 grains of platinum to 50 grains of charcoal, causes oxygen and hydrogen gases to unite completely in a few minutes; with a larger proportion of platinum, the gases combine with explosive violence, just as if platinum-black were used. Cold platinised charcoal, held in a jet of hydrogen, speedily becomes incandescent, and inflames the gas. Platinised charcoal slightly warmed rapidly becomes incandescent in a current of coal gas, but does not inflame the gas, owing to the very high temperature required for that purpose. In the vapour of alcohol or wood-spirit, platinised charcoal becomes red-hot, and continues so till the supply of vapour is exhausted. Spirit of wine, in contact with platinised charcoal and air, is converted in a few hours into vinegar. Two per cent. of platinum is sufficient to platinise charcoal for most purposes. Charcoal containing this amount of platinum, causes oxygen and hydrogen to combine perfectly in about a quarter of an hour, and such is the strength of platinised charcoal which seems best adapted for disinfectant respirators. Charcoal containing only 1 per cent. of platinum causes oxygen and hydrogen to combine in about two hours; and charcoal containing the extremely small amount of $\frac{1}{4}$ per cent. of platinum, produces the same effect in six or eight hours. Platinised charcoal seems likely to admit of various useful applications; one of the most obvious of these is its adaptability to air-filters and respirators. From its powerful oxidising properties, it might also prove a highly useful application to malignant ulcers and similar sores, on which it will act as a mild but effective caustic. It might also be found useful in Bunsen's carbon battery. (Stenhouse, Chem. Soc. Qu. J. viii. 105.)

Charcoal as a Precipitant and Decoloriser.—Wood-charcoal and animal charcoal, especially the latter, possess the power of forming insoluble compounds with many dissolved substances, more particularly organic colouring matters. It precipitates iodine from its solution in iodide of potassium, also lime, nitrate of lead, and most metallic sub-salts, from their aqueous solutions: it likewise separates metallic acids from their solutions in alkalis. A solution of acetate or nitrate of lead, in which charcoal is immersed, is found after a while to contain free acetic or nitric acid. A large number of organic substances, besides colouring matters, are likewise precipitated by charcoal, viz. the bitter principles of the hop, gentian, and aloes, tannin, organic alkaloids; also resins from solution in alcohol. It is important to bear this in mind in analysing liquids which have been decolorised by animal charcoal, as many of the substances originally contained in the solution may have been carried down by the charcoal.

The peculiar power of bone-black in removing colouring matters, &c. from solution, is due to the more minute division of the charcoal resulting from the interposition of the earthy matter. If this be dissolved out by an acid, the decolorising power of the charcoal is greatly impaired, which however must be done for certain applications of it, as in the preparation of vegetable acids. Charcoal of much higher decolorising power than bone-black, is obtained by calcining dried blood, horns, hoofs, clippings of hides, glue, and other animal matters, in contact with pearl-ash, and washing the calcined mass with water. A charcoal of considerable decolorising power may likewise be prepared by carbonising vegetable substances mixed with chalk, calcined flints, or any other earthy matter. If 100 pts. of pipe-clay, made into a thin paste with water, be well mixed with 20 pts. of tan and 500 pts. of finely pounded coal, and the mass dried and ignited in a close vessel, a charcoal will be obtained very little inferior in decolorising power to bone-black. The following table, taken from Graham's *Elements of Chemistry*, 2nd edition, vol. i. p. 361, shows the efficiency of different kinds of charcoal in removing colouring matter. These substances are compared with bone-black, as being the most feeble species. The relative efficiency is not the same for different kinds of colouring matter.

Species of Charcoal. (same weight).	Relative decoloration of sulphate of indigo.	Relative decoloration of syrups.
Blood charred with pearlash . . .	50	20
Blood charred with chalk . . .	18	11
Blood charred with phosphate of calcium .	12	10
Glue charred with pearlash . . .	36	15·5
White of egg charred with the same .	34	15·5
Gluten charred with the same . . .	10·6	8·8
Charcoal from acetate of potassium . .	5·6	4·4
Charcoal from acetate of sodium . .	12	8·8
Lamp-black not calcined	4	3·3
Lamp-black calcined with pearlash . .	15·2	10·6
Bone-charcoal, after the extraction of the earth of bones by an acid, and calcination with potash	45	20
Bone-charcoal, treated with an acid . .	1·87	1·6
Oil charred with phosphate of calcium .	2	1·9
Bone-charcoal in its ordinary state . .	1	1

[On the preparation, properties, and uses of the various forms of carbon, see further. *Ure's Dictionary of Arts, Manufactures and Mines*, articles Bone-Black, Charcoal, Coke, and Lamp-Black.—Pelouze et Frémy, *Traité de Chimie*, 3me éd. i. 705—821.]

Compounds of Carbon.—Carbon unites with most other elements, but generally speaking not directly, most of its compounds being formed either in the bodies of living plants and animals in a way which we cannot trace, or derived by substitution from such compounds. The only elements with which it unites directly are oxygen, sulphur, nitrogen, and a few metals, and with these only at high temperatures. For *oxygen*, carbon exhibits no affinity at ordinary temperatures, but at a red heat, it not only combines readily with free oxygen, but is capable of separating that element from its combinations with all others, even from potassium. The temperature required for determining the combination depends upon the density of the carbon: porous wood charcoal begins to burn in the air at about 240° C.; the more compact kinds require a higher temperature; anthracite and graphite still higher; and the diamond the highest of all. The product of the combustion is carbonic anhydride, CO^2, mixed, however, if the supply of oxygen is deficient, with the lower oxide CO.

With *sulphur*, carbon also unites at a red heat, forming disulphide of carbon, CS^2.—With *nitrogen*, it unites at a red heat, provided an alkali be present, forming cyanogen, CN, which enters into combination with the alkali-metal; thus, when nitrogen gas is passed over ignited charcoal saturated with carbonate of potassium, cyanide of potassium is formed.—With *metals* also, carbon appears to unite directly under certain circumstances, as in the formation of steel by keeping iron imbedded in charcoal powder at a white heat.

The compounds of carbon and *hydrogen* constitute a very important group of organic bodies, many of them, as oil of turpentine, $C^{10}H^{16}$, existing ready formed in plants, while others, as ethylene, C^2H^4, and naphthalene, $C^{10}H^8$, are produced by the decomposition of more complex organic compounds. Most of them play the part of radicles, being capable of combining, like metals, with chlorine, oxygen, sulphur, &c., of replacing hydrogen in combination, and passing as entire groups from one state of combination to another: *e.g. ethyl*, C^2H^5, *amyl*, C^5H^{11}, *allyl*, C^3H^5, *ethylene*, C^2H^4, *amylene*, C^5H^{10}, &c. The hydrogen in these hydrocarbons, may be more or less replaced by chlorine, bromine, nitryl (NO^2), and other elements or groups, whereby derivative radicles are formed, also capable of entering into combination, replacing hydrogen, &c. like simple radicles, *e. g. bromethyl*, C^2H^4Br, *chlorethylene*, C^2H^3Cl, *dinitronaphthalene*, $C^{10}H^6(NO^2)^2$, &c. When the hydrogen in a hydrocarbon is thus completely replaced by another element, a chloride, bromide, &c. of carbon is produced. In this manner, tetrachloride of carbon CCl^4, is formed from marsh-gas CH^4, dichloride of carbon, C^2Cl^4, from ethylene, C^2H^4, &c.

CARBON, BROMIDES OF. Several of these compounds appear to exist, but only one of them, the *dibromide* C^2Br^4, has been analysed.* This body is obtained by treating alcohol or ether with bromine, saturating the resulting hydrobromic acid with potash, distilling, and treating the residue with water. Dibromide of carbon then remains as a white crystalline deposit which may be purified by washing with water (Löwig, Ann. Ch. Pharm. iii. 292). Its formation is represented by the equations:

$$\underset{\text{Alcohol.}}{C^2H^6O} + 4Br^2 = C^2Br^4 + 4HBr + H^2O.$$

$$\underset{\text{Ether.}}{C^4H^{10}O} + 8Br^2 = 2C^2Br^4 + 8HBr + H^2O.$$

It is also produced by the action of alcoholic potash on the dibromide of tribromethylene (Lennox, Chem. Soc. Qu. J. xiv. 209):

$$C^2HBr^3.Br^2 + KHO = C^2Br^4 + KBr + H^2O.$$

Dibromide of carbon forms white crystalline plates, unctuous to the touch, having an ethereal odour and saccharine taste; it melts at 50° C., and sublimes without alteration. It is nearly insoluble in water, very soluble in alcohol and ether; not decomposed by acids or alkalis. It burns in the flame of a spirit lamp, giving off vapours of hydrobromic acid, but ceases to burn as soon as it is removed from the flame. Chlorine attacks it in the melted state, forming chloride of bromine. Heated with oxide of mercury or passed over red-hot oxide of zinc, copper, or iron, it yields metallic bromine and carbonic anhydride. When passed over red-hot metallic zinc, copper, or iron, it also yields a bromide of the metal without disengagement of gas. (Lowig.)

Commercial bromine sometimes contains a liquid bromide of carbon, which may also be obtained by the action of bromine on ether and alcohol, especially if chlorine is likewise present. It is an oily, colourless, fragrant liquid of specific gravity 2·436, not solidifiable at − 25° C., boiling at 120° C., so that it is easily separated from bromine by distillation. It is insoluble in water, not decomposed by acids or dilute alkalis, but decomposed by fusion with hydrate of potassium, into bromide and carbonate of potassium (Poselger, Ann. Ch. Pharm. lxiv. 287). The same compound appears to be produced by the action of 2 pts. bromine on 1 pt. iodide of ethylene, $C^2H^4I^2$, and may be separated from bromide of iodine by means of dilute potash.

In the preparation of bromine, there is sometimes formed an oily ethereal liquid called *oil of bromine*, which appears to contain $C^2H^2Br^4$. When dropped on red-hot fragments of glass, it yields a deposit of carbon, together with crystals and a dark-brown oil, while hydrobromic acid and a combustible gas escape. The dark-brown oil appears to be a portion of the liquid which has remained undecomposed and has absorbed bromine, and the crystals consist of a bromide of carbon C^4Br^2. (M. Hermann, Ann. Ch. Pharm. xcv. 211.)

CARBON, CHLORIDES OF. Carbon does not unite directly with chlorine: but several compounds of these elements are obtained by the action of chlorine, aided by light or heat, on organic bodies, chiefly on hydrocarbons or their chlorinated derivatives, *e. g.* CCl^4 from marsh-gas (CH^4), or chloroform ($CHCl^3$), C^2Cl^4 from ethylene (C^2H^4), C^3Cl^6 from tritylene (C^3H^6), $C^{10}Cl^8$ from naphthalene ($C^{10}H^8$), &c. It is customary, however, to restrict the term chloride of carbon to four of these bodies, containing 1 and 2 atoms of carbon, while the rest are regarded as substitution-derivatives of organic radicles, *e. g.* $C^{10}Cl^8$, as perchloronaphthalene. The names and formulæ of these four compounds are given in the following table, in the left-hand column, according to the atomic weight of carbon [12] here adopted, in the right-hand column according to the smaller atomic weight of carbon [6], the latter being the names by which they are generally known:

[C = 12]			[*C* = 6]	
Protochloride . .	C^2Cl^2	or	Subchloride . .	C^4Cl^2
Dichloride . . .	C^2Cl^4	„	Protochloride . .	C^4Cl^4
Trichloride . . .	C^2Cl^6	„	Sesquichloride .	C^4Cl^6
Tetrachloride . .	CCl^4	„	Di- or Bi-chloride .	C^2Cl^4

---

* C^2Br^6 has been recently obtained. See ETHYLENES, BROMINATED.

There is, however, no real distinction between these four compounds and others formed of the same two elements, excepting that they are of lower atomic weight, and that they may be derived from disulphide of carbon, the vapour of that substance mixed with chlorine and passed through a hot tube yielding the tetrachloride, and the other three being produced, either by exposing this compound to a higher temperature or by the action of reducing agents.

TETRACHLORIDE OF CARBON, CCl^4. *Dichloride or Bichloride of Carbon. Carbonic chloride. Perchlorinated Chloride of Methyl. Perchloroformene.*—This compound, which is an analogue of marsh-gas CH^4, and of carbonic anhydride CO^2, was discovered by Regnault in 1839 (Ann. Ch. Phys. [2] lxxi. 337). It is produced: 1. By the action of chlorine on marsh-gas (Dumas, Ann. Ch. Phys. [3] lxxiii. 95).—2. By the action of chlorine on chloroform in sunshine: $CHCl^3 + Cl^2 = HCl + CCl^4$. Chloroform is gently heated in a retort exposed to the sun, and a stream of dry chlorine is passed slowly and continuously through it, the liquid which distils over being repeatedly poured back till hydrochloric acid ceases to be evolved, after which the distillate is agitated with mercury to remove free chlorine, and then rectified (Regnault).—3. By the action of chlorine on disulphide of carbon: $CS^2 + 4Cl^2 = CCl^4 + 2SCl^2$. Chlorine saturated with vapour of sulphide of carbon by passing through the liquid is made to pass through a red-hot tube containing fragments of porcelain and connected with a receiver surrounded with ice; and the yellowish-red mixture of tetrachloride of carbon and chloride of sulphur thereby obtained is very slowly added to an excess of potash-ley or milk of lime, the mixture being agitated from time to time and afterwards distilled. Tetrachloride of carbon then passes over, sometimes mixed with sulphide of carbon, if too much of that compound was mixed with the chlorine, or if the heat was not strong enough; the sulphide of carbon may be removed by leaving the liquid for some time in contact with potash-ley (Kolbe, Ann. Ch. Pharm. xlv. 41; liv. 146). Geuther (*ibid.* cvii. 212) removes the sulphide of carbon, by dissolving the mixture in alcohol, adding alcoholic potash as long as it thereby acquires a darker colour, and heating the liquid gently to promote the conversion of the sulphide of carbon into xanthate of potassium; then separates the unaltered chloride of carbon by water; and purifies it by washing.—4. By the action of pentachloride of antimony on disulphide of carbon:

$$CS^2 + 2SbCl^5 = CCl^4 + 2SbCl^3 + S^2.$$

The mixture becomes hot, and on cooling deposits crystals of trichloride of antimony mixed with sulphur, while tetrachloride of carbon remains in the liquid state. (Hofmann, Chem. Soc. Qu. J. xiii. 65.)

Properties.—Tetrachloride of carbon is a thin transparent colourless oil, having a pungent aromatic odour. Specific gravity 1·56. Boiling point 77° C. Vapour-density by experiment 5·24—5·33, representing a condensation to 2 vols. $\left(\frac{12 + 4 \,.\, 35{\cdot}5}{2} \times 0{\cdot}0693 = 5{\cdot}34.\right)$ It is insoluble in water, but soluble in alcohol and in ether.

Decompositions.—Tetrachloride of carbon passed through a red-hot tube, is resolved into free chlorine and a lower chloride of carbon, which, at a bright red heat is chiefly C^2Cl^4, at a still higher temperature C^2Cl^2, and at a dull red heat, a body isomeric with C^2Cl^6, but having only half the vapour-density of that compound (Regnault).—2. When mixed with *hydrogen* and passed through a red-hot tube filled with pumice, it yields marsh-gas and ethylene (Berthelot, Ann. Ch. Phys. liii. 69; Jahresber. d. Chem. 1858, p. 519).—3. With *sulphuretted hydrogen*, in like manner, at a low red heat it yields hydrochloric acid and sulphochloride of carbon, $CCl^4 + H^2S = 2HCl + CSCl^2$ (Kolbe).—4. Dissolved in weak alcohol and treated with *amalgam of potassium*, it gives off part of its chlorine to the potassium, and yields chloroform, $CHCl^3$, mono-chlorinated chloride of methyl, CH^2Cl^2, and marsh-gas (Regnault).—5. Treated in a flask provided with an upright condensing tube with *zinc and dilute acid*, it yields hydrochloric acid and chloroform, the latter being converted by the further reducing action of the mixture, into a body containing still less chlorine, probably CH^2Cl^2 (Geuther, *loc. cit.*)—6. It is not decomposed by aqueous potash or sulphydrate of potassium; but *alcoholic potash* slowly converts it into chloride and carbonate of potassium (Regnault). Heated with alcoholic potash to 100° C. in a sealed tube for a week, it is partly converted into ethylene (Berthelot, Ann. Ch. Pharm. cix. 118).—7. Heated to 170° or 180° C. with 3 vols. *phenylamine*, it yields carbotriphenyltriamine (Hofmann, Proc. Roy. Soc. ix. 284):

$$\underset{\text{Phenylamine.}}{6(N.H^2.C^6H^5)} + CCl^4 = \underset{\substack{\text{Hydrochlorate of carbotri-}\\ \text{phenyltriamine.}}}{[N^3.\overset{''''}{C}.(C^6H^5)^3.H^2].HCl} + \underset{\substack{\text{Hydrochlorate of}\\ \text{Phenylamine.}}}{3[(N.H^2.C^6H^5).HCl].}$$

8. With *triethylphosphine* it yields a white crystalline product. (Hofmann, *ibid.* x. 184.)

A compound, CCl^4SO^2, formed by the action of moist chlorine on sulphide of carbon, sometimes regarded as *sulphite of tetrachloride of carbon*, but more probably a chlorinated derivative of *methyl-sulphurous acid*, will be described under that head.

TRICHLORIDE OF CARBON. C^2Cl^6. *Sesquichloride of Carbon, Perchloride of Carbon, Perchlorinated Chloride of Ethylene, Chlorure de Chloroxéthose.*—This compound, which was discovered and investigated by **Faraday** (Phil. Trans. 1826, p. 47), and further by **Regnault** (Ann. Ch. Phys. [2] lxix. 166; lxxxi. 371), is produced by the action of chlorine in sunshine on various compounds and derivatives of ethyl and ethylene: 1. On dichloride of carbon, C^2Cl^4 (**Faraday**).—2. On chloride of ethylene: $C^2H^4Cl^2 + 4Cl^2 = 4HCl + C^2Cl^6$; the action also takes place, though more slowly in diffused daylight (**Faraday**), or with aid of heat (**Liebig**).—3. On chloride of ethyl, first in the shade, afterwards in sunshine: $C^2H^5Cl + 5Cl^2 = 5HCl + C^2Cl^6$ (**Laurent**, Ann. Ch. Phys. [2] lxxxiv. 328); similarly on mono-, di-, or tri-chlorinated chloride of ethyl (**Regnault**).—4. On sulphite of ethyl, with simultaneous formation of chloride of sulphuryl, chloraldehyde, and hydrochloric acid (**Ebelmen and Bouquet**, Ann. Ch. Phys. [3] xvii. 66):

$$(C^2H^5)^2SO^3 + 11Cl^2 = C^2Cl^6 + SO^2Cl^2 + C^2Cl^4O + 10HCl.$$

5. On oxide of ethyl, which, in bright sunshine, is sometimes converted at once into sesquichloride of carbon and chloraldehyde, sometimes into perchlorethylic oxide, $C^4Cl^{10}O$, 1 at. of which is resolved by distillation into C^2Cl^4O and C^2Cl^6 (**Regnault**, **Malaguti**). Several perchlorinated compound ethers (carbonic, succinic, &c.) also yield trichloride of carbon, when similarly treated.—6. On hydrochlorate of ethylamine:

$$C^2H^7N + 5Cl^2 = C^2Cl^6 + NH^4Cl + 3HCl.$$

The sal-ammoniac is ultimately resolved by the excess of chlorine into hydrochloric acid and nitrogen, which escapes, a certain portion, being, however, converted into chloride of nitrogen (**Geuther** and **Hofacker**, Ann. Ch. Pharm. cviii. 51). The formation of chloride of nitrogen must render the process dangerous.—7. Tetrachloride of carbon passed through a red-hot tube is resolved into the trichloride and free chlorine (p. 765).

Preparation.—1. Chloride of ethylene is exposed to the sun in a bottle filled with chlorine, water being frequently added in small portions to absorb the hydrochloric acid produced, and the chlorine frequently renewed as long as any action is perceptible. The crystalline product is washed with water, pressed between bibulous paper, heated to sublimation, then dissolved in alcohol, precipitated by water containing potash, again washed with water, pressed, and dried in vacuo over sulphuric acid (**Faraday**). By passing chlorine through chloride of ethylene, heated nearly to the boiling point, part of that compound is converted into trichloride of carbon, which crystallises out for the most part on cooling the liquid with ice (**Liebig**, Ann. Ch. Pharm. i. 219).—2. A bottle filled with chlorine, and containing a little chloride of ethyl, is set aside in the shade for twenty-four hours, the chlorine then renewed and the vessel exposed to the sun: such exposure at the beginning of the process would produce explosion (**Laurent**). Or better: vapour of chloride of ethyl produced by heating alcohol with strong hydrochloric acid, and purified by passing through water and oil of vitriol, is brought in contact with chlorine in a vessel exposed to the summer sun (**Regnault**).—3. Perchlorethylic oxide ($C^4Cl^{10}O$) is distilled, and the distillate is repeatedly treated with water, which takes up chloraldehyde and leaves trichloride of carbon. (**Malaguti**, Ann. Ch. Phys. [3] xvi. 6, 14.)

Properties.—Trichloride of carbon crystallises in right rhombic prisms ∞P, modified by the faces $\infty \breve{P} \infty$ and the horizontal prism $P \infty$. Angles of the prism $\infty P =$ 58° and 122° (**Brooke**); 59° and 121° (**Laurent**). The crystals are colourless, transparent, and nearly tasteless, but have an aromatic camphorous odour. They are as hard as sugar, and easily pulverised. Specific gravity = 2·0. Refracting power = 1·5767. They do not conduct electricity. They melt at 160° C.; boil and sublime at 182°, and volatilise even at ordinary temperatures. Vapour-density = 8·157, corresponding to 2 volumes $\left(\frac{2\,.\,12 + 6\,.\,35{\cdot}5}{2} \times 0{\cdot}0693 = 8{\cdot}212\right)$. Insoluble in water, soluble in alcohol, still more in ether; the solutions are not clouded by nitrate of silver. Soluble also in oils, both fixed and volatile.

Decompositions.—1. By repeated distillation, or by passing its vapour through a red-hot porcelain tube, the trichloride is resolved into the dichloride, C^2Cl^4, and free chlorine.—2. It burns with a red light in the flame of a spirit-lamp, but is extinguished on removal.—3. Passed, together with *hydrogen*, through a red-hot tube, it yields hydrochloric acid and dichloride of carbon (**Geuther**), and undergoes a similar decomposition when heated with *sulphur*, *phosphorus*, or *iodine*.—4. Most *metals* heated in the vapour of the trichloride are converted into chlorides, with separation of charcoal.—5. The vapour passed over red-hot *baryta*, *strontia*, or *lime*, yields a chloride and carbonate of the metal, with deposition of charcoal; with *oxide of zinc*, it sometimes forms oxychloride of carbon; with the *oxides of copper* and *mercury*, and with *peroxide of lead*, the products are metallic chloride and carbonic anhydride.—6. The trichloride is not altered by distillation with aqueous or alcoholic potash; but when gently heated with an alcoholic solution of *sulphydrate of potassium*, it yields dichloride of carbon, together with chloride of potassium, sulphydric acid, free sulphur, and a brown sulphur compound, apparently resulting from a secondary action (**Regnault**):

$$C^2Cl^6 + 2KHS = C^2Cl^4 + 2KCl + H^2S + S.$$

7. Heated in sealed tubes with 8 at. *hydrate of potassium*, it yields oxalate and chloride of potassium:

$$C^2Cl^6 + 8KHO = C^2K^2O^4 + 6KCl + 4H^2O;$$

but the decomposition is very imperfect, even when the mixture is heated to between 210° and 220° C. for several days (**Geuther**, Ann. Ch. Pharm. lx. 247).—8. Heated to 100° C. in sealed tubes with *alcoholic potash*, it yields the same products, together with hydrogen gas and ethylene (**Berthelot**, Ann. Ch. Pharm. cix. 118). The principal reaction is probably represented by the equation:

$$C^2Cl^6 + 7KHO + C^2H^5.K.O = C^2K^2O^4 + 6KCl + 4H^2O + C^2H^4,$$

and the free hydrogen results from a secondary decomposition, a number of liquid products and brown insoluble substances being formed at the same time. Trichloride of carbon is not attacked by ammonia, nitric acid, or sulphuric acid. Boiling nitric acid dissolves it, part separating on cooling, the rest on addition of water. In contact with chlorine and water, it does not yield trichloracetic acid.

DICHLORIDE OF CARBON. C^2Cl^4. *Protochloride of Carbon, Perchlorethylene, Chlorēthose.*—Discovered and examined by **Faraday** (Phil. Trans. 1821, p. 47), further by **Regnault** (Ann. Ch. Phys. [2] lxx. 104; lxxxi. 372). It is produced by the action of a red heat on the trichloride or tetrachloride of carbon, either alone or in presence of hydrogen (pp. 765, 766); by the action of nascent hydrogen on the trichloride at ordinary temperatures; also by that of alcoholic sulphydrate of potassium on the trichloride, and of alcoholic potash on the tetrachloride (p. 765).

Preparation.—1. Vapour of trichloride of carbon is passed through a red-hot tube filled with fragments of glass, whereupon a large quantity of chlorine is set free, and the dichloride passes over in the form of a liquid coloured yellow by chlorine. It is purified by passing it several times through the red-hot tube, then shaking it up with mercury, and rectifying at as low a temperature as possible (**Faraday**).—2. The trichloride is added by small portions to an alcoholic solution of sulphydrate of potassium, and, as soon as the evolution of sulphuretted hydrogen has ceased, the liquid is distilled, and the alcoholic distillate diluted with water: the dichloride then separates in the form of a heavy liquid: this process is easier than the preceding (**Regnault**).—3. Trichloride of carbon is mixed with water and granulated zinc, and sulphuric acid added from time to time with agitation, till all the trichloride is decomposed. On subsequently distilling the liquid, dichloride of carbon passes over with the aqueous vapour. (**Geuther**, Ann. Ch. Pharm. cvii. 212.)

Properties.—Very mobile liquid, of specific gravity 1·619 at 20° C. (**Regnault**), 1·612 at 10° (**Geuther**). Refracting power = 1·4875 (**Wollaston**). It does not conduct electricity. It remains liquid at −18° C.; boils at 122° (**Regnault**), 116·7° (**Geuther**). Vapour-density, by experiment = 5·82, corresponding to 2 volumes. $\left(\frac{2\,.\,12 + 4\,.\,35{\cdot}5}{2} \times 0{\cdot}0693 = 5{\cdot}75.\right)$ It is insoluble in water, acids, and aqueous alkalis, but dissolves in alcohol, ether, and oils, both fixed and volatile.

Decompositions.—1. At a red heat it is resolved into free chlorine and the protochloride, C^2Cl^2.—2. When its vapour is passed over red-hot *baryta*, vivid ignition takes place, with formation of chloride of barium and carbonic anhydride, and separation of charcoal.—3. Heated for some time to 200° C., with 6 at. *hydrate of potassium*, it is completely converted into oxalate and chloride of potassium, with evolution of hydrogen gas (**Geuther**, Ann. Ch. Pharm. cx. 247):

$$C^2Cl^4 + 6KHO = C^2K^2O^4 + 4KCl + 2H^2O + H^2.$$

4. It absorbs dry chlorine in sunshine, forming the trichloride, C^2Cl^6; but if exposed to an atmosphere of chlorine under a layer of water, it yields trichloracetic acid. (**Kolbe**, Ann. Ch. Pharm. liv. 181):

$$C^2Cl^4 + 2H^2O + Cl^2 = C^2HCl^3O^2 + 3HCl.$$

5. It absorbs bromine in sunshine, yielding chlorobromide of carbon, $C^2Cl^4Br^2$.

PROTOCHLORIDE OF CARBON, C^2Cl^2. *Subchloride of Carbon, Julin's Chloride of Carbon.*—This compound was discovered in 1821, by Julin, a manufacturer of nitric acid at Abo in Finland, who obtained it accidentally in distilling crude nitre with burnt green vitriol in cast-iron retorts, the cast-iron probably furnishing the carbon, and the crude nitre the chlorine (Ann. Ch. Phys. [2] xviii. 269). It was more exactly investigated by Phillips and Faraday (Phil. Trans. 1821), and afterwards by Regnault (Ann. Ch. Phys. [2] lxx. 104), who prepared it by passing vapour of chloroform or of dichloride of carbon, through a strongly ignited porcelain tube filled with fragments of porcelain, dissolving the crystalline product in ether, filtering, evaporating to dryness, and subliming. In performing this process, care must be taken not to heat the porcelain tube too strongly; otherwise, no chloride of carbon will be obtained, but only a deposit of charcoal.

Properties.—Protochloride of carbon forms white, delicate needles, apparently four-sided, having a silky lustre. It melts, boils, and sublimes between 175° and 200° C., but may be sublimed without fusion at 120°, the sublimate then consisting of long needles. It has a peculiar odour, something like that of spermaceti, but no taste. In the cold it is almost inodorous. It is insoluble in water, but very soluble in alcohol; dissolves also in ether, and in hot oil of turpentine, whence it crystallises in needles on cooling.

The alcoholic solution does not precipitate nitrate of silver.

The vapour passed through a red-hot porcelain tube filled with fragments of rock-crystal, is resolved into chlorine and charcoal. The compound burns with bluish colour in the flame of a candle, but ceases to burn when withdrawn. It is not decomposed or dissolved by nitric, hydrochloric, or sulphuric acid, or by boiling potash. Chlorine does not act upon it, even in sunshine. Potassium burns in its vapour with intense ignition, forming chloride of potassium and depositing charcoal.

Berthelot regards this compound, not as C^2Cl^2, but as $C^{10}Cl^{10}$. The vapour-density does not appear to have been determined.

CARBON, CHLOROBROMIDE OF. $C^2Cl^4Br^2$. *Bromide of Perchorethylene, Bromure de Chloroxéthose.* (Malaguti, Ann. Ch. Phys. [3] xvi. 14.)—Dichloride of carbon exposed to sunshine in contact with bromine solidifies in a few hours to a crystalline mass, which may be purified by repeated crystallisation from alcohol. The crystals resemble those of C^2Cl^6; they have a specific gravity of 2·3 at 21° C., taste slightly aromatic, begin to volatilise at 100°, decompose at about 200° into bromine and the dichloride, and when treated with protosulphide of potassium are resolved into bromide of potassium and dichloride of carbon:

$$C^2Cl^4Br^2 + K^2S = C^2Cl^4 + 2KBr + S.$$

CARBON, DETECTION AND ESTIMATION OF. The methods of detecting and estimating carbon and its compounds have been already described under the head of ANALYSIS.

If the carbon is not already in the form of carbonic anhydride or a carbonate, it is converted into carbonic anhydride by combustion, either in an atmosphere of oxygen or with oxide of copper or chromate of lead, the amount of carbonic anhydride thereby produced being estimated by absorption in strong potash-ley (ANALYSIS, ORGANIC, pp. 225—238). This method serves for the estimation of carbon in cast-iron and other metallic compounds, as well as in organic bodies. *Gaseous carbon-compounds*, such as carbonic oxide and hydrocarbons, are converted into carbonic anhydride by explosion with excess of oxygen, the amount of that compound produced being then determined by absorption with potash. (ANALYSIS, VOLUMETRIC, OF GASES, pp. 286—288.)

Carbonates are decomposed with dilute sulphuric or hydrochloric acid, and the carbonic anhydride thereby evolved is usually determined by loss (see ACIDIMETRY, p. 38, and ALKALIMETRY, p. 149). The presence of carbonates in any mixture, solid or liquid, is detected by the effervescence which ensues on addition of dilute sulphuric or hydrochloric acid. This effervescence may, however, arise from the escape of sulphydric acid or sulphurous anhydride, if sulphides or sulphites are also present. These gases are readily distinguished from carbonic anhydride by their peculiar odours; sulphydric acid also by its property of blackening lead-salts. To detect carbonic anhydride when evolved together with one or both of these gases, the gaseous mixture is passed into baryta-water. If a precipitate is formed, carbonic or sulphurous acid may be present or both; if the former alone, the precipitate will be completely soluble in hydrochloric acid, *after treatment with chlorine-water;* but if sulphurous acid is also present, it will be oxidised by the chlorine-water, and converted into sulphuric acid, which will then form sulphate of barium, insoluble in hydrochloric acid.

The amount of carbonic anhydride in a gaseous mixture is ascertained directly by absorption with potash, sulphurous anhydride or sulphydric acid, if present, having been previously removed by absorption with peroxide of manganese (p. 282).

Carbonic acid in solution, either free or combined, in a mineral water for example, is estimated by adding ammonia and chloride of calcium, and leaving the liquid to itself in a corked flask for several hours. The carbonic acid is thereby precipitated as carbonate of calcium, containing 43·88 per cent. CO^2.

To estimate the carbonic acid in the air, a large quantity of air, the volume being measured by an aspirator (p. 427), is passed through a series of weighed potash-bulbs. Another method is to shake up a quantity of air in a closed vessel of known capacity, with an excess of lime-water of known strength, and then determine the quantity of lime remaining uncombined by means of a standard solution of oxalic acid. This method is easy of execution, and affords the means of quickly determining the varying amount of carbonic acid in the several parts of an inhabited apartment at different times.

Atomic Weight of Carbon.—Three methods have been adopted for determining the atomic weight of carbon: 1. From the quantity of carbonic anhydride produced by the combustion of a given weight of carbon.—2. By comparing the weights of equal volumes of carbonic anhydride and oxygen, it being supposed that carbonic anhydride contains its own volume of oxygen.—3. From the weight of metallic silver obtained by the combustion of organic silver-salts.

Of these methods the first is considered the most trustworthy. The amount of carbonic anhydride produced by the combustion of carbon was determined with a very near approximation to the truth by Lavoisier in 1775, afterwards with more or less accuracy by Guyton-Morveau (1785), Clément and Desormes (1802), Allen and Pepys (1807), and Saussure (1809); but the most exact determinations are those made by Dumas and Stas (Ann. Ch. Phys. [3] i. 1), and by Erdmann and Marchand (J. pr. Chem. xxiii. 159). These chemists burned weighed quantities of diamond or graphite with oxide of copper and oxygen gas, and weighed the carbonic anhydride taken up by the potash-apparatus, after it had been freed from a very small quantity of admixed water by passing over chloride of calcium or sulphuric acid. The small quantity of residual ash was deducted from the weight of the carbon employed, and the quantity of water produced in the combustion likewise taken into account.

In this manner the quantity of carbon which combines with 200 pts. of oxygen to form carbonic anhydride was found by Dumas and Stas, in fourteen experiments, to vary only between the limits 74·87 and 75·12, the mean result being 75·005, with a probable error of ± 0·013. Erdmann and Marchand, in nine experiments similarly conducted, obtained numbers varying between 74·84 and 75·19, the mean being 75·028. Now since, of the two oxides of carbon, carbonic anhydride contains, with the same quantity of carbon, twice as much oxygen as carbonic oxide, these compounds may be represented by the formulæ CO^2 and CO, a view of their constitution, which is likewise in accordance with that of the other compounds of carbon. Hence, from the above-mentioned results respecting the composition of carbonic anhydride, it follows that if the atomic weight of oxygen = 100, that of carbon will be 75, and on the hydrogen scale:

$$\begin{array}{lll} \text{If} & O = 8, & C = 6 \\ \text{and if} & O = 16, & C = 12. \end{array}$$

The reason for adopting the numbers in the last line are fully detailed in the article **Atomic Weights** (pp. 459—462).

The second method of determining the atomic weight of carbon was first adopted by Berzelius and Dulong in 1819. From specific gravity determinations then made it was concluded that equal volumes of carbonic anhydride and oxygen weighed 1·5425 and 1·1026 respectively; and assuming that carbonic anhydride contained its own volume of oxygen, the difference of the two numbers gave the weight of the carbon in the same volume, whence it was calculated that the atomic weight of carbon on the oxygen scale (O = 100) was 76·528, which number was adopted as correct for twenty years. In 1841, Wrede, following the same method, but taking into account the more exact coefficients of expansion of the gases determined by Rudberg, Magnus, and Regnault, obtained the number 75·12. Determinations not much differing from this were made in like manner by other experimenters; but the method is not capable of yielding very exact results, because the alterations of volume sustained by oxygen and carbonic anhydride for equal variations of temperature and pressure are not equal, and consequently the assumption that oxygen, in being converted into carbonic anhydride, undergoes no change of volume, cannot be true for all temperatures.

The third method, founded on the analysis of the silver-salts of organic acids, was adopted by Liebig and Redtenbacher (Ann. Ch. Pharm. xxxviii. 116). Assuming Ag = 1351 and H = 12·48 (O = 100), these chemists obtained as the mean result of their analyses, C = 75·854. The more exact determinations since made of the atomic weight of silver would lead to a slight alteration in this result. Strecker, from the same experiments, and without assuming the atomic weights of silver as previously known, calculated the atomic weight of carbon as = 75·415; but this method, as well as the second, is not considered so trustworthy as the first, the result of which, obtained by Dumas and Stas is now universally adopted.

CARBON, IODIDE OF. No compound of carbon and iodine has yet been obtained. Iodoform, CHI^3, was formerly supposed to be an iodide of carbon, the hydrogen contained in it having been overlooked. (Gm. vii. 335.)

CARBON, NITRIDE OF. Only one compound of carbon and nitrogen is known with certainty, viz. CYANOGEN, CN (*q. v.*) Many cyanogen-compounds yield by calcination a residue called mellone, which Liebig regards as a nitride of carbon containing C^3N^4. It does not, however, appear to have been obtained quite free from hydrogen (see MELLONE and MELLONIDES). According to Thaulow, a peculiar nitride of carbon, isomeric, but not identical with cyanogen, is obtained by ignition of cyanide of silver (see CARBAZOTE, p. 757).

CARBON, OXIDES OF. Two oxides of carbon are known, the protoxide CO, and the dioxide, or carbonic anhydride, CO^2, commonly called *carbonic acid.* Both are produced by the direct combination of carbon and oxygen; the former is known only in the gaseous state: the latter is gaseous at ordinary temperatures.

DIOXIDE OF CARBON. CARBONIC ANHYDRIDE, CO^2. *Anhydrous Carbonic acid, Fixed air, Mephitic air, kohlensaures gas, Kohlensäure, Gas sylvestre, Spiritus sylvestris.*—The evolution of this gas in the burning of lime and in fermentation, was known to Paracelsus and Van Helmont, the latter of whom gave it the name of *gas sylvestre;* its properties were afterwards investigated by Hales, Black, Cavendish, Priestley, and Bergmann, but its true composition was first demonstrated by Lavoisier, who showed that it was a compound of carbon and oxygen, containing 28 per cent. carbon and 72 oxygen, numbers approaching very nearly to the proportions now received as correct, viz. 27·27 carbon to 72·73 oxygen (p. 769).

Carbonic anhydride is formed by the combustion of carbon in oxygen gas, or in the air. It is a constant product of the ordinary processes of combustion, inasmuch as all substances used for fuel, such as wood, coal, oil, wax, tallow, &c. contain carbon. It is likewise formed by the respiration of animals, in various processes of fermentation, as in the preparation of wine and beer, and by the decay of animal and vegetable substances. It issues from fissures in the ground, in various localities, chiefly in volcanic districts, and is ejected in enormous quantities from the craters of active volcanos. From all these sources it is continually being poured into the atmosphere, of which it therefore forms a constant constituent: the average amount of it contained in the air in the open country, is 4 volumes in 10,000; in the air of crowded towns, it is often much greater (p. 437). It exists also in larger proportion at the bottom of wells, mines, quarries, and caverns, especially in limestone districts, where it is evolved from fissures and does not readily escape, in consequence of its greater density. Carbonic anhydride (or acid), exists also in solution in all natural waters, some, as those of Seltz, Vichy, and Spa, containing it in such quantity as to give them an effervescing character. Lastly, it is produced by the decomposition of carbonates, either by heat or by the action of the stronger acids, and is a frequent product of the decomposition of organic bodies at high temperatures.

Preparation.—The easiest way of obtaining the gas is to decompose chalk, or marble, with hydrochloric acid, in an ordinary generating vessel, provided with a gas-delivery tube:

$$Ca^2CO^3 + 2HCl = 2CaCl + CO^2 + H^2O.$$

Dilute sulphuric acid may also be used, but it is less convenient, as the sulphate of calcium produced forms a hard mass in the vessel, which is difficult to extract, whereas chloride of calcium is easily soluble: moreover, the chloride is more useful as a residual product. The gas may be received over water, or, as it is very heavy, it may be collected by simple displacement of the air, the delivery-tube being bent vertically downwards, so as to reach to the bottom of the receiver. This is also the most convenient mode of collection when the gas is required dry, a desiccating tube containing dry chloride of calcium or pumice-stone soaked in oil of vitriol, being interposed between the generator and receiver. On the large scale, carbonic anhydride may be obtained by heating chalk or marble to redness, in an iron or earthen retort.

Properties.—Carbonic anhydride is, at ordinary temperatures and pressures, a colourless gas, but may be liquefied by cold or pressure (p. 771). Its specific gravity in the gaseous state is 1·5241 (Regnault), being rather more than $1\frac{1}{2}$ times that of air. In consequence of this great density, it may be poured from one vessel to another like a liquid, and often collects at the bottom of wells, mines, and caverns, as in the *Grotto del Cane* near Naples, the atmosphere of which, within about a foot of the ground, is highly charged with the gas, while the upper part is comparatively free.

From the experiments of Regnault, it appears that the density of carbonic anhydride does not vary in the same proportion as the pressure, excepting within narrow limits: under a pressure of several atmospheres, the deviation from this law is very perceptible. The coefficient of expansion by heat between 0° and 100° C. is 0·3719 (Regnault); 0·366087 (Magnus); refracting power = 1·526 (Dulong).

Carbonic anhydride does not affect the colour of *litmus-paper*, when both are quite dry; but if moisture is present, the blue colour of the paper changes to wine-red, like that produced by boric acid: on exposure to the air, however, the redness disappears, in consequence of the escape of the gas. *Lime-water* introduced into the gas is immediately rendered turbid, in consequence of the formation of neutral carbonate of calcium, but if an excess of the gas is present, the liquid becomes clear again after a while, especially if shaken, an acid carbonate being then formed, which is soluble in water. Solution of *potash*, or a lump of moist solid potash, introduced into the gas standing over mercury, rapidly absorbs it. It dissolves in about its own volume of *water* at ordinary temperatures, and in less than $\frac{1}{2}$ of its volume of *alcohol*.

Carbonic anhydride is irrespirable; animals immersed in it soon die, not only from want of oxygen, but in consequence of a direct poisonous action, violent spasms being sometimes produced, sometimes complete atony of the cerebral faculties. Mixed with *air*, as it escapes from effervescing liquids, it produces a pungent sensation in the respiratory organs, but it cannot be said to have any decided odour. It is incombustible, and immediately extinguishes a burning taper, also the flame of sulphur or phosphorus: but *potassium* heated to redness in the dry gas, decomposes it completely, burning with a red light, and producing a deposit of charcoal mixed with carbonate of potassium. *Sodium* decomposes it in like manner, but without becoming red-hot. *Phosphorus* and *boron*, in presence of an alkali, likewise abstract all the oxygen at a red heat. *Hydrogen*, *charcoal*, *iron*, and *zinc*, at a red heat, abstract half the oxygen, converting the carbonic anhydride into carbonic oxide. It is also resolved into carbonic oxide and oxygen by the passage of electric sparks, if hydrogen gas, mercury, or some other metal is present to take up the oxygen; otherwise, the spark immediately causes the gases to recombine. *Growing plants*, or the leaves and other green parts separated from the plant, but still in the fresh state, decompose carbonic anhydride completely under the influence of daylight, and more rapidly in direct sunshine, abstracting the whole of the carbon, and setting the oxygen free. If some fresh leaves of any plant be placed in an inverted receiver, filled with water containing carbonic acid, and standing over water, and the whole be exposed to the sun, a considerable quantity of oxygen gas will collect at the top of the receiver in a few hours. This action of growing plants is the chief cause which prevents the continual accumulation of carbonic anhydride in the atmosphere, and keeps the proportion of it nearly constant. (See ATMOSPHERE, p. 438.)

Respecting the mode of determining the composition of carbonic anhydride, see p. 769. Its density corresponds to 2 volumes of vapour:

$$\frac{12 + 2 \,.\, 16}{2} \times 0{\cdot}0693 = 22 \times 0{\cdot}0693 = 1{\cdot}5246$$

and at pressures and temperatures considerably above its liquefying point, it contains a volume of oxygen exactly equal to its own.

Liquid Carbonic Anhydride.—Carbonic anhydride passes to the liquid state at 0° C. under a pressure of 36 atmospheres. Faraday effected the liquefaction by evolving the gas from carbonate of ammonia, by the action of sulphuric acid in a sealed tube (see GASES, CONDENSATION OF), but the method is dangerous, and yields but a small quantity. The liquid acid is however obtained safely and in large quantity, by the method of Thilorier (Ann. Ch. Pharm. xxx. 122). The apparatus consists of two very strong cylinders, capable of holding 6 litres or pints, made of cast-iron, or better, of lead sheathed with copper, and strengthened with a wrought-iron armature; they rest by two pins placed at the middle of their length on cast-iron supports, so that they may be placed either vertically or horizontally, and swung backwards and forwards. Into one of these cylinders is introduced 1800 grammes of acid carbonate of sodium, and 4 litres of water (or $4\frac{3}{4}$ lbs. of the soda-salt, and 7 pints of water), and a copper tube containing 1000 grammes (or $2\frac{1}{4}$ lbs.) of strong sulphuric acid, is likewise introduced in a vertical position. The cylinder is then tightly closed by a cock of peculiar construction, and swung to and fro, to cause the acid to mix gradually with the carbonate. The gas is then evolved, and not being able to escape, becomes so much condensed that it passes to the liquid state. This part of the operation requires care, as, if the mixture be made too rapidly, great heat will be evolved, and the tension of the gas enormously increased. A fatal accident happened in Paris from this cause. When the action is supposed to be complete, the generating cylinder is made to communicate, by means of a copper tube, with the second cylinder, which is placed horizontally, and provided with a stopcock like the first. This cylinder being slightly cooled, the carbonic anhydride distils over from the first, which is still warm, and condenses in the liquid state. After about a minute the cocks are closed, the cylinders separated, the charge in the first renewed; and this series of operations is repeated several times, till the second cylinder is about two-thirds filled with liquid carbonic anhydride.

Liquid carbonic anhydride is colourless and very soluble in alcohol, ether, and volatile oils, but does not mix with water. Specific gravity 0·90 at −20° C.; 0·83 at 0° C.; 0·60 at + 30° C. (Thilorier). Its tension at different temperatures is shown in the following table.

Temp. C.	Tension in Atmospheres.		Temp. C.	Tension in Atmospheres.	
	Faraday.	Mareska and Donny.		Faraday.	Mareska and Donny.
−59·4°	4·6		−5·0°	33·1	36
48·8	7·7		0·0	38·5	42
36·6	12·5		+6·3		46

26·1	17·8		15·5		57
20·0	21·5	23·6	19·0		63
15·0	24·7	25·3	23·5		68
12·2	26·8		27·0		74
10·0		27·5	30·7		80
9·4	29·1		34·5		

Solid Carbonic Anhydride.—When the liquid anhydride is suddenly relieved from the pressure under which alone it can exist, part of it flashes instantly into vapour, and in so doing produces so great a degree of cold, that the remaining portion of the liquid solidifies. To obtain the solid anhydride, the receiver containing the liquid is provided with a tube passing through its side, and reaching nearly to the opposite side, so that when the cylinder is set horizontally, this tube dips into the liquid. On opening a stopcock provided for the purpose, a quantity of the liquid is forced out by the pressure of the gas above it, and forms a white cloud of the solid anhydride, as it issues into the air. By causing this jet of vapour to pass into a cylindrical metal box, having within it an inclined metal tongue, against which the jet of liquid and vapour impinges, and is thus made to circulate within the box for some little time before it finally escapes, a considerable quantity of the solid anhydride may be collected in the form of a white flocculent mass like snow.

Solid carbonic anhydride may be left exposed to the air for some little time without evaporating, because, like all flocculent substances, it conducts heat but slowly. Its tension is 1·14 atmospheres at − 99·4° C.; 1·36 at −77·2°; 2·28 at −70·5°; 3·6 at −63·2°; 4·6 at −59·4°; 5·33 at −57·0 (Faraday). An air or spirit thermometer immersed in it sinks to −78° C. Notwithstanding this low temperature, the solid substance may be placed on the hand without occasioning a very acute sensation of cold, because it does not come into close contact with the skin, being separated from it by a film of vapour; but if pressed between the fingers, it produces a very painful sensation, and raises a blister like a burn. By mixing it with ether, its heat-conducting power is greatly increased; it therefore evaporates more quickly, and produces much more powerful frigorific effects. Mercury poured into it solidifies instantly to a mass like lead. The cold which it produces is sufficient to liquefy sulphydric acid, chlorine, nitrous oxide, and several other gases. The intensity of the cold may be still further increased by placing the mixture under an exhausted receiver. The temperature then sinks to a degree at which the liquid anhydride is not more volatile than water at 30° C., and alcohol assumes the consistence of a thick oil, but does not solidify. By exposing to this bath, tubes of glass or copper in which gases have been compressed by a forcing pump to 40 atmospheres, Faraday has succeeded in liquefying all the known gases, excepting oxygen, hydrogen, nitric oxide, carbonic oxide, and marsh-gas, and in solidifying a considerable number of them. Carbonic anhydride itself exposed to this temperature and pressure, is reduced to a vitreous transparent mass.

Carbonic Acid.—Gaseous carbonic anhydride dissolves in about its own volume of water at ordinary temperatures, forming a solution of specific gravity 1·0018. It has a sharp and slightly acid taste, turns the blue colour of litmus to wine-red, partially neutralises alkalis, and dissolves the carbonates of barium, strontium, calcium, magnesium, &c. It, therefore, possesses *acid* properties, and from the composition of the carbonates, we may infer that it contains an acid of the composition H^2CO^3. But this acid cannot be isolated, as heat, diminished pressure, or congelation immediately resolves it into water and carbonic anhydride. In short, carbonic acid as a definite compound cannot be said to be known.

The volume of carbonic anhydride dissolved by water at a given temperature, is nearly the same under all pressures; consequently the weight of the gas absorbed increases in nearly the same proportion as the pressure. This rule must not, however, be understood as strictly true, for Regnault has shown that the volume of carbonic anhydride does not vary exactly in the inverse ratio of the pressure.

Under a given pressure, the volume of gas absorbed diminishes as the temperature rises. At the boiling heat, the whole of the gas is driven off; hence carbonic acid water holding an earthy carbonate in solution deposits it when the liquid is boiled. This is the cause of the furring of kettles, boilers, &c., in which spring or river-water containing carbonate of calcium dissolved in this manner, is boiled.

The coefficients of absorption of carbonic anhydride, that is to say the volumes (reduced to 0° C. and 0·760 met.) which 1 vol. of water absorbs under the pressure of 0·760 met. and at various temperatures, are as follows:

Temp.	Vol. of Gas absorbed.	Temp.	Vol. of Gas absorbed.
0° C.	1·7697	12° C.	1·1018
2	1·6481	14	1·0321
4	1·5126	16	0·9753
6	1·3901	18	0·9318
8	1·2809	20	0·9013
10	1·1847		

(Bunsen's Gasometry. See also the article GASES, ABSORPTION OF.)

Water which has been saturated with carbonic acid under pressure, gives it up with brisk effervescence as soon as the pressure is removed. The various kinds of aërated water, *soda-water*, *effervescing lemonade*, &c., consist of water impregnated by mechanical pressure with large quantities of carbonic acid, and flavoured with various saline and other ingredients. (For a description and figure of Tylor's soda-water machine, see *Ure's Dictionary of Arts, Manufactures and Mines*, iv. 728.) Champagne and other effervescing wines and bottled beer likewise owe their sparkling properties to the presence of this gas; but in these liquids the carbonic acid is produced by the fermentation itself, the wine or beer being bottled before the fermentation is complete, whereby a considerable quantity of the gas, which would otherwise escape into the air, is retained.

For the behaviour of aqueous carbonic acid to bases, see CARBONATES.

PROTOXIDE OF CARBON. CARBONIC OXIDE. CO.—This compound, which is known only in the gaseous state, was discovered towards the end of the last century by Lassonne and by Priestley; but its true nature was first recognised some years afterwards by Woodhouse (Gilbert's Annalen, ix. 423). It is produced: 1. By the oxidation of carbon at very high temperatures, when the supply of oxygen is not sufficient for the complete conversion of the carbon into carbonic anhydride (p. 763).—2. When carbonic anhydride is exposed to a red heat in contact with hydrogen, carbon, metals, or other bodies which can abstract part of the oxygen: hence it is always produced in charcoal or coke fires, when the draught of air has to pass upwards through a considerable mass of red-hot fuel, and is the cause of the blue flame almost always seen on the top of such fires.—3. It is also formed, together with hydrogen and carbonic anhydride, when vapour of water is passed over red-hot coke or charcoal. A sample of the gaseous mixture thus formed was found by Bunsen to contain 56·03 volumes per cent. of hydrogen, 29·15 carbonic oxide, 14·65 carbonic anhydride, and 0·17 carburetted hydrogen.—4. Carbonic oxide is produced, either alone or together with carbonic anhydride, in the reduction of metallic oxides by carbon at a strong red heat. The gas evolved from iron blast-furnaces contains from 25 to 32 per cent., that from copper-refining furnaces from 13 to 19 per cent. carbonic oxide (Bunsen, Pogg. Ann. xlvi. 193; l. 81).—5. In the dry distillation of many organic compounds.—6. In the decomposition of oxalic acid and formic acid by strong sulphuric acid:

$$\underset{\text{Oxalic acid.}}{C^2H^2O^4} = CO + CO^2 + H^2O$$

$$\underset{\text{Formic acid.}}{CH^2O^2} = CO + H^2O$$

7. In the decomposition of crystallised ferrocyanide of potassium by sulphuric acid (Fownes):

$$\underset{\text{Crystallised ferrocyanide of potassium.}}{2K^2FeC^3N^3.3H^2O} + 6H^2SO^4 + 3H^2O = 6CO + \underset{\text{Sulphate of ammonium.}}{3(NH^4)^2SO^4} + \underset{\text{Sulphate of potassium.}}{2K^2SO^4} + \underset{\text{Ferrous sulphate.}}{Fe^2SO^4}$$

Preparation.—1. By heating to redness in a gun-barrel fitted with a gas-delivery tube, a mixture of oxide of iron, zinc, lead, or copper with charcoal or graphite; or of an alkaline or earthy carbonate (chalk for example) with graphite, charcoal, or iron filings; or by passing carbonic anhydride repeatedly over red-hot iron or charcoal. By either of these methods, carbonic oxide is obtained mixed with carbonic anhydride, from which it may be freed by passing the gas through milk of lime or strong potash; it may then be collected over water. The charcoal used must be previously well ignited to free it from moisture and absorbed gases.—2. By heating in a flask a mixture of oxalic acid, or an oxalate, or a formate, with excess of strong sulphuric acid, and removing the carbonic anhydride evolved when oxalic acid or an oxalate is used, as before.—3. When crystallised ferrocyanide of potassium, in the state of powder, is heated in a flask with eight or ten times its volume of sulphuric acid, carbonic oxide is evolved quite free from carbonic anhydride, and mixed only with a small quantity of vapour of hydrocyanic acid, resulting from another reaction which takes place at the same time, if the quantity of water present is more than sufficient for the above decomposition (see FERROCYANIDES). This is the most convenient mode of preparing carbonic oxide. Care must, however, be taken not to raise the heat higher than is necessary for the complete liquefaction of the mixture; for at that point the evolution of carbonic oxide ceases, and if the heating be continued, the excess of sulphuric acid acts on the ferrous sulphate produced, converting it into ferric sulphate, and being itself reduced to sulphurous anhydride, which escapes as gas and mixes with the carbonic oxide.

Properties.—Carbonic oxide is a colourless gas of specific gravity 0·96799 (Wrede); its molecule CO therefore occupies two volumes:

$$\frac{12 + 16}{2} \times 0{\cdot}0693 = 14 \times 0{\cdot}0693 = 0{\cdot}9702.$$

It is perfectly neutral to vegetable colours, and very sparingly soluble in water, which, according to Bunsen, dissolves only 0·024 or about $\frac{1}{40}$ of its bulk at 15° C. It is a very poisonous gas, acting chiefly on the nervous system, causing giddiness when inhaled, sometimes also acute pain in various parts of the body, and after a while complete asphyxia. According to Leblanc (Ann. Ch. Phys. [3] v. 223), it is to this gas that the suffocating quality of air in which charcoal has been burnt is chiefly due.

Carbonic oxide does not support the combustion of bodies which burn in oxygen, but in contact with the air it takes fire on the approach of a burning body, and burns with a blue flame, producing carbonic anhydride. Mixed with excess of oxygen, it may be exploded by the electric spark, 2 vols. of it then uniting with 1 vol. oxygen and producing 2 vol. carbonic anhydride CO^2. Now as 2 vols. CO^2 contain 2 vols. oxygen, it follows that 1 vol. oxygen must have been derived from the carbonic oxide. Hence carbonic oxide contains half its own volume of oxygen. Now the weight of 2 vols. carbonic oxide, compared with hydrogen, is 28, which, diminished by 16, the weight of 1 vol. oxygen, leaves 12 for the weight of 1 atom of carbon. Hence in carbonic oxide the same weight of carbon is united with exactly half as much oxygen as in carbonic anhydride.

The combustion of carbonic oxide may be brought about by contact with *platinum*. A wire or foil of the metal requires to be heated to 300° C. to induce the combustion: spongy platinum acts at ordinary temperatures, without becoming sensibly heated; but platinum-black introduced into the mixture of carbonic oxide and oxygen becomes red-hot and produces explosion.

Carbonic oxide reduces certain metallic oxides at a red heat, viz. the oxides of copper, lead, tin, iron, &c. It plays indeed an important part in the smelting of many metals, especially of iron.

Carbonic oxide is rapidly absorbed by a solution of *cuprous chloride* in hydrochloric acid, also by ammonical solutions of cuprous salts. This reaction affords an excellent method of removing carbonic oxide from a gaseous mixture (p. 283). It reduces *gold* from the neutral solution of its chloride without the aid of heat.

Carbonic oxide unites directly with *chlorine*, forming oxychloride of carbon or phosgene gas; also with *potassium*. (See POTASSIUM.)

It is absorbed by *hot hydrate of potassium*, yielding formate of potassium, $CO + KHO = CHKO^2$. (Berthelot, Ann. Ch. Pharm. xcvii. 125.)

CARBON, OXYCHLORIDE OF. $COCl^2$ or *Chloride of Carbonyl* $(CO)''.Cl^2$. *Chlorocarbonic oxide. Chlorocarbonic acid. Phosgene.*—This compound was discovered by J. Davy (Phil. Trans. 1812, p. 144), who obtained it by exposing to the sun's rays, a mixture of equal volumes of chlorine and carbonic oxide. The mixture gradually becomes colourless and contracts to half its original volume. The same action takes place slowly in diffused daylight; none whatever in the dark. The name phosgene originally given to the gas signifies a compound formed by light.

Oxychloride of carbon may be more conveniently prepared by passing carbonic oxide into boiling pentachloride of antimony, that compound being at the same time reduced to trichloride. The gas must be received over mercury, as water decomposes it (Hofmann, Ann. Ch. Pharm. lxx. 139). It is likewise produced when carbonic oxide is passed over red-hot chloride of lead or chloride of silver, and in the following decompositions of organic bodies:

a. By the dry distillation of trichloracetates:

$$C^2Cl^3MO^2 = COCl^2 + CO + MCl.$$

b. By the dry distillation of certain perchlorinated methylic ethers, *e. g.* of the *formate*, $C^2Cl^4O^2 = 2COCl^2$; and of the *oxalate*, $C^4Cl^6O^4 = COCl^2 + 3CO$.

c. By the action of a large excess of strong sulphuric acid on the so-called sulphite of tetrachloride of carbon (p. 766):

$$CCl^4SO^2 + H^2O = COCl^2 + 2HCl + SO^2.$$

Oxychloride of carbon is a colourless gas having a suffocating and tear-exciting odour. Its specific gravity is 3·6808 (Davy), 3·4249 (Thomson); calculated for a condensation to two volumes, it is

$$\frac{12 + 16 + 2 \,.\, 35{\cdot}5}{2} \times 0{\cdot}0693 = 3{\cdot}430.$$

Its refracting power is 3·936. It reddens moistened litmus-paper; does not fume in the air.

Oxychloride of carbon is decomposed by *water*, yielding carbonic anhydride and hydrochloric acid:

$$COCl^2 + H^2O = CO^2 + 2HCl.$$

When mixed with an equal volume of hydrogen and half its volume of oxygen, it explodes violently on the passage of an electric spark, yielding the same products. Mixed with oxygen or hydrogen alone, it is not exploded by the electric spark.

Arsenic and *antimony* heated in the gas take up the chlorine, and leave carbonic oxide equal in volume to the original gas. Many metallic oxides, *oxide of zinc*, for example, decompose it with the aid of heat, forming a chloride of the metal and carbonic anhydride equal in volume to the original gas. *Trioxide* of antimony produces trichloride and pentoxide or tetroxide of antimony, leaving carbonic oxide.

By *alcohols* it is converted into chlorocarbonic ethers, *e. g.*:

$$\overset{''}{C}O\left\{\begin{matrix}Cl\\Cl\end{matrix}\right. + \left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O = \left.\begin{matrix}(CO)''\\C^2H^5\end{matrix}\right\}O + HCl.\\ Cl.$$

With *ammonia gas*, oxychloride of carbon produces carbamide (p. 752) and chloride of ammonium. With *phenylamine* and many other organic bases, it reacts in like manner, forming substitution-derivatives of carbamide.

CARBON, SULPHIDES OF. Only one of these compounds is known with certainty. viz. the disulphide corresponding to carbonic anhydride. The formation of a protosulphide, analogous to carbonic oxide, was announced, in 1857, by Baudrimont, but his statements have not been confirmed. (See page 777.)

DISULPHIDE OF CARBON. CS^2. *Bisulphide of Carbon, Sulphocarbonic Acid.* (Lampadius, Gehlen's N. allg. Journ. d. Chem. ii. 192; Clément and Desormes, Ann. Chim. xlii. 121; Vauquelin and Robiquet, *ibid.* lxi. 145; Berthollet, Thénard, and Vauquelin, *ibid.* lxxii. 252; Berzelius and Marcet, Schw. J. ix. 284; Berzelius, Gilb. Ann. xlviii. 177; Pogg. Ann. vi. 144; Zeise, Schw. J. xxvi. 1; xli. 98, 170; xliii. 160; Couerbe, Ann. Ch. Phys. [2] lxi. 225; Kolbe, Ann. Ch. Pharm. xlv. 53; xlix. 143; Pelouze and Frémy, *Traité de Chimie*, 4ᵐᵉ éd. i. 923).—This compound, which was discovered by Lampadius in 1796, is produced by the direct combination of sulphur and carbon at high temperatures, and in the decomposition of many organic compounds. Sulphur and carbon do not combine when simply heated together in the solid state, because the sulphur volatilises before the requisite temperature is attained; but if charcoal be heated to redness and sulphur-vapour passed over it, the carbon burns in that vapour, forming CS^2.

For preparing small quantities of the disulphide, a porcelain tube is filled with fragments of charcoal, and inserted in an inclined position through a furnace having holes in its sides. The upper extremity of the tube is closed with a cork, and the lower is connected by a bent glass tube, with a bottle containing water, the lower end of the bent tube passing through the cork and dipping just below the surface of the water. When the charcoal is red-hot, the upper end of the tube is opened and a piece of sulphur put in; the sulphur melts and runs down to the lower part of the tube, where it volatilises and combines with the carbon, forming disulphide of carbon, which passes off in vapour and condenses in the liquid form at the bottom of the water. For larger quantities, a tubulated earthen retort is used, having a porcelain tube passing through the tubulus, and reaching nearly to the bottom. The retort is filled with charcoal, heated to redness in a furnace, and bits of sulphur dropt in through the tube. The neck of the retort is connected with a condensing tube kept cold by a stream of water, and passing into a receiver containing cold water as above described. The sulphide of carbon which collects at the bottom of the water is not pure, but contains excess of sulphur. It is purified by distillation at the heat of the water-bath, the sulphide of carbon then volatilising and the sulphur remaining behind.

Properties.—Disulphide of carbon is a colourless, very mobile, strongly refracting liquid, having a faint and peculiarly unpleasant odour. Its refracting power is 1·645. Specific gravity 1·293 at 0° C., and 1·271 at 15°. Boils at 46·6° under ordinary pressure, and evaporates quickly at ordinary temperatures, producing great cold. Vapour-density = 2·67, corresponding to 2 vols. $\left(\frac{12 + 2\,.\,32}{2} \times 0{\cdot}0623 = 2{\cdot}63\right)$. It is insoluble in *water*, to which, however, it imparts its odour. *Alcohol* and *ether* mix with it in all proportions. It dissolves *sulphur*, *phosphorus*, and *iodine;* sulphur and phosphorus separate from it by spontaneous evaporation in well defined crystals. It dissolves *camphor* and mixes easily with *oils*, both fixed and volatile.

Decompositions.—1. Disulphide of carbon is very inflammable, and burns with a blue flame, producing sulphurous and carbonic anhydrides.—2. The vapour passed over various *metallic oxides* at a red heat, yields the same gaseous products, together with a metallic sulphide; the sulphides thus formed are generally crystallised, and resemble those found in nature. Sulphide of carbon is indeed one of the most powerful sulphurising agents known, affording the means of producing several metallic sulphides not otherwise obtainable (Frémy). It likewise converts oxides into sulphides when heated with them in sealed tubes; with *water* at 150° C. it yields carbonic anhydride and sulphydric acid (Schlagdenhauffen, J. Pharm. [3] xxix. 401).—3. The vapour is strongly attacked by *nitric acid*, yielding sulphuric acid and nitrous vapours. —4. Sulphide of carbon heated with *chlorates* or *hypochlorites* reduces them to chlorides, with evolution of carbonic anhydride and deposition of sulphur.—5. Heated with aqueous *iodic acid* in a sealed tube, it yields hydriodic acid, together with free iodine and a deposit of sulphur, also sulphuric acid, sulphydric acid, and carbonic anhydride. Two reactions appear to go on at once, viz.:

$$2HIO^3 + CS^2 = I^2 + CO^2 + H^2SO^4 + S.$$
$$2HIO^3 + 2CS^2 + 2H^2O = 2CO^2 + 2HI + H^2SO^4 + H^2S + S^2.$$

The liquid is at first coloured violet by the free iodine, but on increasing the heat, the colour disappears, in consequence of the action of the sulphydric acid on the iodine, which produces hydriodic acid and free sulphur, the latter imparting a straw-yellow colour to the liquid (Pelouze and Frémy).—6. *Bromic acid* acts in like manner.—7. Many *metals* decompose disulphide of carbon at a red-heat, taking up the sulphur and setting the carbon free.—8. A mixture of sulphide of carbon vapour and *sulphydric acid gas* passed over *red-hot copper* yields sulphide of copper and marsh-gas (Berthelot):

$$CS^2 + 2H^2S + Cu^8 = 4Cu^2S + CH^4.$$

9. With *nascent hydrogen*, sulphide of carbon yields sulphydric acid, a crystallised body, CH^2S, and an oily substance not yet examined (Girard, Compt. rend. xliii. 39). —10. Dry *chlorine* converts it at a red heat into tetrachloride of carbon; at ordinary temperatures, into sulphochloride of carbon, $CSCl^2$; but with moist chlorine it yields trichloromethylsulphurous acid (the so-called sulphite of tetrachloride of carbon, $CCl^4SO^2 = SO^2.CCl^4$ (Kolbe).—11. *Bromine* and sulphide of carbon do not act upon each other when passed through a red-hot tube.—12. The *fixed caustic alkalis* gradually dissolve disulphide of carbon, forming a brown solution, which is a mixture of carbonate and sulphocarbonate of the alkali-metal (Zeise):

$$3CS^2 + 3K^2O = K^2CO^3 + 2K^2CS^3.$$

13. With *alcoholic potash* it yields carbonate and ethyl-oxysulphocarbonate (xanthate) of potassium, which forms a yellow precipitate with copper-salts (Zeise):

$$CS^2 + C^2H^5.K.O = \left.\begin{matrix}(CO)'' \\ C^2H^5.K\end{matrix}\right\}S^2.$$

An aqueous or alcoholic solution of caustic potash, boiled with disulphide of carbon, forms with lead-salts a black precipitate of sulphide of lead, which affords a very delicate test for sulphide of carbon. It is instantly produced on dropping a dilute solution of that compound into a boiling solution of nitrate of lead containing potash, a distinct coloration being obtained, even with a liquid containing only a drop of sulphide of carbon in a quart of water.—14. With *aqueous ammonia*, it forms sulphocarbonate and sulphocyanate of ammonium, without any carbonate (Zeise):

$$2CS^2 + 4NH^3 = (NH^4)^2CS^3 + NH^4.CNS.$$

15. With a saturated solution of *ammonia-gas in anhydrous alcohol*, it yields the same products, together with sulphocarbamate of ammonium, produced by the simple union of ammonia with the disulphide (Zeise):

$$CS^2 + 2NH^3 = (NH^2\overset{''}{C}S).NH^4.S.$$

16. With *triethylphosphine* it unites directly, forming a compound $P(C^2H^5)^3.CS^2$, which crystallises in splendid ruby-coloured prisms. The reaction affords an extremely delicate test for the presence of either of the constituent substances, and is especially applicable to the detection of sulphide of carbon in coal-gas. When a stream of the gas, purified from sulphuretted hydrogen in the usual manner, is passed through a solution of triethylphosphine in ether, contained in a bulb apparatus, a red colour soon appears in the liquid, and when sufficient gas has been passed through the liquid to evaporate the ether, the bulb-apparatus is seen to be lined with a network of the red crystals. (A. W. Hofmann, Ann. Ch. Pharm. cxv. 296.)

The sulphocarbonates M^2CS^3, or $M^2S.CS^2$, bear to disulphide of carbon the same relation that the carbonates M^2CO^3 bear to carbonic anhydride. Moreover by treating sulphocarbonate of ammonium with dilute sulphuric or hydrochloric acid, an oily, very acid liquid is precipitated, consisting of sulphocarbonic acid, H^2CS^3.

PROTOSULPHIDE OF CARBON. CS.—As already observed, it is doubtful whether this compound, the analogue of carbonic oxide, has yet been obtained, though there can be no doubt as to the possibility of its existence. Baudrimont (Compt. rend. xliv. 1000), states that it is obtained tolerably pure by passing the vapour of the disulphide over red-hot spongy platinum or pumice, and washing the resulting gas with solutions of acetate of lead and cuprous chloride, to free it from sulphydric acid and carbonic oxide, resulting from the action of air and moisture remaining in the materials. The gas thus obtained is described as colourless, smelling somewhat like the disulphide, not liquefiable at the temperature of a mixture of ice and salt; soluble in its own bulk of water; decomposed by lime-water into sulphide of calcium, and a volume of carbonic oxide equal to its own: $Ca^2O + CS = Ca^2S + CO$; and yielding when exploded with oxygen, equal volumes of CO^2 and SO^2.

Baudrimont likewise obtained the protosulphide, but mixed with sulphydric acid and carbonic oxide, by passing the vapour of the disulphide over red-hot charcoal; by the action of sulphydric acid on carbonic oxide at a red heat ($CO + H^2S = H^2O + CS$), and by several other processes.

Playfair (Chem. Soc. Qu. J. xiii. 248) endeavoured to prepare the protosulphide by passing the vapour of the disulphide over red-hot pumice, but obtained nothing but a mixture of carbonic anhydride, carbonic oxide, sulphydric acid, and nitrogen, saturated with vapour of disulphide of carbon; he observed no deposition of sulphur in the red-hot tube, though Baudrimont states that it choked up the exit-tube of his apparatus. Playfair attributes the formation of these gases to air and moisture retained by the pumice, though it had been previously ignited, or introduced into the tube together with the disulphide. He is of opinion that Baudrimont's gas, which yielded by explosion with oxygen, equal volumes of SO^2 and CO^2, was a mixture of equal volumes of CO and vapour of CS^2, which at common temperatures, and under the diminished pressure existing in the eudiometer, would have sufficient tension to diffuse itself in vapour through the carbonic oxide.

In face of these contradictory results, the question as to the actual formation of protosulphide of carbon must for the present be considered as undecided.

CARBON, SULPHOCHLORIDE OF. $CSCl^2$.—This compound, the analogue of phosgene, was discovered by Kolbe (Ann. Ch. Pharm. xlv. 53), and is produced: 1. By the action of dry chlorine on disulphide of carbon at ordinary temperatures, chloride of sulphur being formed at the same time: $CS^2 + Cl^4 = SCl^2 + CSCl^2$. A few grammes of the disulphide are left exposed for a few days to the action of perfectly dry chlorine in a closed flask, either in the dark or in sunshine; the resulting liquid is digested with water to decompose the chloride of sulphur, and the remaining oily liquid is freed from the acid products thereby formed, by repeated distillation with water and a small quantity of magnesia. It is essential to the production of this compound, that the materials be perfectly dry, as if moisture is present, another compound, trichloro-methyl-sulphurous acid is obtained (p. 776). At a red heat, a different action takes place, and tetrachloride of carbon is produced.—2. By passing a mixture of sulphydric acid and vapour of tetrachloride of carbon through a tube kept at a moderate red heat: $CCl^4 + H^2S = 2HCl + CSCl^2$.

Sulphochloride of carbon is a yellow liquid, not miscible with water, having a peculiar and powerful odour, very irritating to the eyes. Specific gravity 1·46. Boiling point 70° C. These numbers probably require correction, as it is very difficult to obtain the compound free from sulphide of carbon. It is not decomposed by water or acids, not even by fuming nitric acid. Caustic potash decomposes it slowly, forming carbonate and sulphide of potassium, and tetrachloride of carbon:

$$2CSCl^2 + 3K^2O = K^2CO^3 + 2K^2S + CCl^4.$$

CARBONATES. The carbonates form a numerous and important class of salts, many of which occur as natural minerals. They are usually divided into *normal*, *basic*, and *acid* carbonates, the normal or neutral salts having the composition

$$M^2CO^3 = M^2O.CO^2 = \left.\begin{matrix}(CO)''\\ M^2\end{matrix}\right\}O^3 \text{ [or } \mathit{MO.CO^2}\text{]}.$$

The basic carbonates, however, all contain water, and by regarding the whole or part of this water (or hydrogen) as basic, the carbonates, like the borates, phosphates, and silicates, may be divided into ortho-carbonates, $M^4CO^4 = \left.\begin{matrix}\overset{''''}{C}\\ M^4\end{matrix}\right\}O^4$, and metacarbonates, M^2CO^3,—or more generally orthocarbonates $= M^xH^{4n-x}C^nO^{4n}$, and metacarbonates $= M^xH^{2n-x}C^nO^{3n}$, the latter including the salts usually regarded as neutral carbonates. Nearly all the precipitates obtained by adding a solution of an alkaline carbonate to a salt of a heavy metal, contain water, and may be represented by one or other of these formulæ. It is difficult to say whether the ortho- or the meta-carbonates are the more numerous; but the carbonates of the stronger bases, viz. the alkali-metals and alkaline-earth metals, are certainly meta-carbonates. Only a few acid carbonates are known as definite salts, viz. those of potassium, sodium, and ammonium, and these are metacarbonates containing hydrogen, *e.g.* monopotassic metacarbonate, or diacid carbonate of potassium, $(KH)CO^3$.

Carbonates are formed by the action of carbonic acid, or the joint action of water and carbonic anhydride, on metallic oxides or hydrates, not in any case by the union of carbonic anhydride with an oxide without the intervention of water. Lime-water, or milk of lime, absorbs carbonic anhydride rapidly, forming carbonate of calcium; but perfectly dry carbonic anhydride may be passed over anhydrous lime without absorption. Even dry hydrate of potassium, KHO, absorbs carbonic anhydride but slowly, and soon becomes covered with a crust of acid carbonate of potassium ($KHO + CO^2 = KHCO^3$), which protects the rest from alteration; but the moist hydrate, or the aqueous solution, absorbs it with the greatest avidity; similarly with other bases. The carbonates of the earth-metals proper and heavy metals are most easily obtained by precipitating a soluble salt of the metal with an alkaline carbonate; but the precipitate, as already observed, almost always contains water, and very rarely has the composition of an anhydrous metacarbonate M^2CO^3. The sesquioxides, alumina, ferric oxide, chromic oxide, uranic oxide, &c., do not absorb carbonic anhydride even when moist, and their solutions, when mixed with alkaline carbonates, yield precipitates, not of carbonates, but of hydrates. Metals like zinc and iron, which readily replace hydrogen in acid solutions, may be converted into carbonates by simply immersing them in water containing carbonic acid.

Carbonates are also formed in the decomposition by heat of organic salts of the stronger bases, viz. of the alkali-metals and of the alkaline-earth metals. Oxalates are resolved into carbonates and carbonic oxide, without separation of carbon:

$$C^2M^2O^4 = CM^2O^3 + CO$$

formates into carbonates, with evolution of carbonic oxide and hydrogen, and slight separation of carbon:

$$2CHMO^4 = CM^2O^3 + CO + H^2.$$

The salts of most other organic acids yield a considerable quantity of free carbon besides combustible gases; acetates and the salts of other fatty acids, and a few others, are resolved by dry distillation into carbonates and acetones (pp. 31, 32).

The carbonates of ammonium, potassium, and sodium are easily soluble in water; carbonate of lithium dissolves in about 100 pts. of water; the carbonates of all other metals are insoluble, or nearly so, in water; but all are slightly soluble in water containing free carbonic acid. Acid carbonates are doubtless formed in this case; but none of these, excepting the acid carbonates of the alkali-metals, can be obtained in the solid state, as the solutions, when boiled or evaporated, give off carbonic anhydride and deposit neutral carbonate. All metallic carbonates, excepting carbonate of ammonium, are insoluble in alcohol. Carbonates of organic alkalis are for the most part soluble in water and in alcohol; carbonates of alcohol-radicles, insoluble in water, soluble in alcohol.

Most carbonates are easily decomposed by heat. The carbonates of the heavy metals are all decomposed at a low red heat, giving off carbonic anhydride, and leaving a residue of metal or of oxide. The carbonates of the earth-metals proper, and of calcium and strontium, require a stronger red heat to decompose them; carbonate of barium is decomposed only at a white heat; and the carbonates of the alkali-metals, when dry, resist the action of the strongest heat, excepting when a current of dry air or other gas is passed over them; in that case carbonate of sodium gives up a small quantity of carbonic anhydride, and carbonate of lithium a considerable quantity. (H. Rose.)

Nearly all carbonates are more or less decomposed by water, with the aid of heat, those of the weaker bases even at ordinary temperatures, so that precipitated carbonates are very apt to undergo partial decomposition during washing. Even the carbonates of barium, potassium, sodium, and magnesium are converted into hydrates when heated to redness in a stream of aqueous vapour; partially also in a stream of moist air or hydrogen gas: the carbonates of barium and potassium do not suffer any decomposition in a current of dry air or hydrogen. (H. Rose, Pogg. Ann. lxxxv. 99, 279; Jahresber. f. Chem. 1852, p. 309.)

Carbonates are decomposed, with evolution of carbonic anhydride, by nearly all acids, even at ordinary temperatures, and at a red heat by many acids whose salts are themselves decomposed at ordinary temperatures by carbonic acid, *e.g.* by boric, silicic, and several metallic acids. The effervescence which accompanies the decomposition affords a ready indication of the presence of a carbonate. Any of the stronger acids may be used to effect the decomposition, but, generally speaking, hydrochloric or nitric acid is preferable to sulphuric acid, because the latter often forms insoluble or sparingly soluble salts, the presence of which interferes with the reaction. If the carbonate is in solution, the liquid should be concentrated before adding the acid, as in a very dilute liquid the carbonic acid may remain dissolved instead of escaping as gas. The decomposing acid must also be added in excess, otherwise an acid carbonate of the alkali-metal will be formed, and no effervescence will be observed. If the substance to be examined is a mineral, it must be finely pulverised, and the powder should be soaked in water before adding the acid; otherwise the escape of air-bubbles might be mistaken for an evolution of carbonic anhydride. Many other volatile acids produce effervescence when eliminated from these compounds, *e.g.* hydrochloric, hydriodic, sulphurous, sulphydric acid, &c.; but they may all be distinguished from carbonic acid by their colour or their odour, also by passing the evolved gas into lime-water or baryta-water, and proceeding as described at page 768.

CARBONATE OF ALUMINIUM (?) It is doubtful whether such a compound exists. Saussure stated long ago that alkaline carbonates throw down from solutions of aluminium, a compound of hydrate of aluminium with a small quantity of the alkaline carbonate, and that the hydrate is partially soluble in aqueous carbonic acid, but is completely separated on warming the solution or exposing it to the air (Gm. iii. 309). Other chemists have, however, obtained different results. According to **Muspratt** (Chem. Soc. Qu. J. ii. 206), the precipitate formed by alkaline carbonates consists of $3Al^4O^6.2CO^2 + 16H^2O$. **Langlois** (Ann. Ch. Phys. [3] xlviii. 502) found $8Al^4O^3.3CO^2 + 40H^2O$; and **Wallace** (Chem. Gaz. 1858, 410) gives, as the composition of the precipitate, $3Al^4O^3.2CO^2 + 9H^2O$. **H. Rose**, on the contrary (Pogg. Ann. xli. 462), states that the precipitate formed by carbonate of ammonium is a compound of trihydrate of aluminium with carbonate of ammonium, $Al^2H^3O^3 + NH^4.H.CO^3$, the ammonia-salt not being removable by washing. From experiments recently made in Dr. Muspratt's laboratory by Mr. **James Barratt** (Chem. News, i. 110), it appears that the precipitate formed by carbonate of sodium in a solution of chloride of aluminium, after being washed and dried, then triturated with water, again washed, and dried over sulphuric acid, consists of pure hydrate of aluminium.

CARBONATE OF ALLYL. See CARBONIC ETHERS.

CARBONATES OF AMMONIUM. These salts have already been described (p. 190). They are all metacarbonates, and may be formulated as follows:

Neutral carbonate, $(NH^4)^2O.CO^2 \quad = \quad \left.\begin{matrix}\overset{\prime\prime}{C}O\\(NH^4)^2\end{matrix}\right\}O^2$

Acid carbonate, $\left.\begin{matrix}NH^4\\H\end{matrix}\right\}O.CO^2 \quad = \quad \left.\begin{matrix}\overset{\prime\prime}{C}O\\NH^4.H\end{matrix}\right\}O^2$

Sesquicarbonate, $2(NH^4)^2O.3CO^2 + 3aq. = \left.\begin{matrix}(\overset{\prime\prime}{C}O)^3\\(NH^4)^4.H^2\end{matrix}\right\}O^6 + aq.$

CARBONATE OF AMYL. See CARBONIC ETHERS.

CARBONATE OF BARIUM. $Ba^2CO^3 = Ba^2O.CO^2$.—This salt occurs abundantly in nature as *Witherite*, a mineral which frequently accompanies lead-ores. It crystallises in the trimetric system, isomorphously with arragonite, the crystals being frequently prismatic, from predominance of the faces ∞P, $\infty \breve{P} \infty$, and $\breve{P} \infty$. The combination $P \,.\, 2\breve{P} \infty \,.\, \infty \breve{P} \infty \,.\, \infty P$, is also common, forming a six-sided prism with pyramidal summits. Ratio of axes, $a : b : c = 0.5950 : 1 : 0.7413$. Inclination of faces: $\infty P : \infty P = 61° 30'$; $\breve{P} \infty : \breve{P} \infty = 71° 47'$; $2\breve{P} \infty : 2P \infty = 110° 42'$. Cleavage imperfect parallel to $\infty \breve{P} \infty$, ∞P, and $\breve{P} \infty$ (Kopp). It occurs also in globular, tuberose, and botryoïdal forms; structure either columnar or granular; also amorphous. Specific gravity = 4·29 to 4·35. Hardness = 3 to 3·75. Lustre vitreous, inclining to resinous on fractured surfaces. Colour white, or often yellowish or greyish. Streak white. Subtransparent to translucent. Fracture uneven. Brittle. Witherite is found on Alston Moor in Cumberland, and in splendid crystals at Fallowfield in Northumberland. It occurs also in many places on the continent of Europe, in the Altai, near Coquimbo, Chili, &c. It is sometimes found altered to heavy spar by the action of soluble sulphates.

Carbonate of barium is rapidly formed when baryta, either in the anhydrous state, or in crystals, or in solution, is exposed to the air, and is easily prepared by precipitating an aqueous solution of the chloride or nitrate with carbonate of ammonium, or a solution of the sulphide with carbonate of sodium; the salt obtained by this last method is liable to be contaminated with a sulphur-compound. It may also be prepared in an impure state by igniting in a crucible a mixture of 10 pts. of native sulphate of barium, 2 pts. of charcoal, and 5 pts. of carbonate of potassium (pearl-ash). A mixture of sulphide of potassium and carbonate of barium is then obtained, from which the sulphide of potassium may be extracted by water. The impure carbonate thus produced may be used for the preparation of other barium-salts, but the salts thus obtained will contain iron.

Carbonate of barium artificially prepared is a soft white powder. It is poisonous, and is used as rat-bane. It is very slightly soluble in water, about 1 pt. in 4000, rather more (in 588 pts. according to Lassaigne) in water saturated with carbonic acid. It dissolves easily, even in the cold, in chloride, nitrate, and succinate of ammonium, and when boiled with chloride of ammonium, it is completely decomposed, yielding carbonate of ammonium and chloride of barium. When shaken up with aqueous sulphate of potassium or sodium, it yields sulphate of barium and carbonate of the alkali-metal. It bears a strong red heat without decomposition; but at the heat of a forge-fire it gives off carbonic anhydride and leaves baryta. The decomposition is greatly facilitated by the addition of charcoal. Carbonate of barium is decomposed by vapour of water at a red heat, and very easily if mixed with an equal weight of chalk or slaked lime.

An *acid carbonate*, $2Ba^2O.3CO^2$, or $2Ba^2CO^3.CO^2$, was said by Boussingault (Ann. Ch. Phys. [2] xxix. 280) to be obtained by precipitating chloride of barium with sesquicarbonate of sodium. H. Rose, on the other hand, by mixing chloride of barium with diacid carbonate of sodium or potassium, obtained nothing but neutral carbonate of barium, and is of opinion that acid carbonates of barium cannot exist excepting in solution.

CARBONATE OF BISMUTH.—When nitrate of bismuth is dropt into a solution of alkaline carbonate, a white precipitate is formed, consisting of $Bi^2O^3.CO^2$ (Berzelius). The precipitate formed with alkaline carbonates contains $Bi^2O^3.CO^2 + \frac{1}{2}aq.$, the water escaping at 100° C. (Lefort.)

CARBONATE OF CADMIUM, Cd^2CO^3, occurs in small quantity, associated with native carbonate of zinc. Cadmium-salts yield with carbonate of ammonium, a white precipitate, containing $Cd^2CO^3 + aq.$, which gives off its water between 80° and 120° C.; at a higher temperature, carbonic anhydride goes off, and brown oxide of cadmium is left, which when exposed to the air is gradually reconverted into carbonate (Lefort, J. Pharm. [3] xii. 406). According to H. Rose (Pogg. Ann. lxxxv. 304), the precipitates formed by alkaline carbonates in solutions of cadmium, contain very little water, and approach very nearly to the formula Cd^2CO^3. Moist hydrate of cadmium absorbs carbonic acid from the air, and at 300° gives off all its water, and is converted into $2Cd^2O.Cd^2CO^3$, or $Cd^2O.Cd^4CO^4$.

CARBONATES OF CALCIUM.—The *metacarbonate*, $Ca^2CO^3 = Ca^2O.CO^2$, occurs most abundantly in all parts of the world, in the forms of calcspar, marble, limestone of various kinds, and chalk; also in egg-shells and the shells of molluscs, and, together with phosphate of calcium, in bones. It is formed when lime, either anhydrous or hydrated, is exposed to the air in its ordinary state of moisture, but not by the action of carbonic anhydride on anhydrous lime. It may be obtained pure by dissolving calcined oyster shells, chalk, or marble, in hydrochloric acid, adding ammonia or milk of lime to precipitate alumina, oxide of iron, and earthy phosphates, then filtering, precipitating the hot filtrate with carbonate of ammonium, washing thoroughly, and drying at a heat short of redness.

Carbonate of calcium is dimorphous, crystallising in the hexagonal system as calcspar (p. 721), and in the trimetric system as arragonite (p. 358). The specific gravity of the former varies from 2·6987 to 2·75; of the latter, generally from 2·92 to 3·28. The artificially prepared salt is a white powder, consisting of small crystals, which usually take the form of arragonite when precipitated from hot solutions, and of calcspar when precipitated from cold solutions, especially if dilute. The microscopic crystals of arragonite gradually change into rhombohedrons of calcspar if left for some time under the cold liquid (p. 359). The precipitate formed in hot solutions, assumes the crystalline character at once; that from cold solutions is amorphous at first, and gradually becomes crystalline.

Carbonate of calcium is tasteless, and has a slight alkaline reaction to test-paper. It is very sparingly soluble in water, requiring, according to Fresenius (Ann. Ch. Pharm. lix. 117), 88·34 pts. of boiling, and 10,601 pts. of cold water to dissolve it; the solution is slightly alkaline. Water containing free carbonic acid dissolves it much more freely. When recently precipitated, it dissolves easily in aqueous carbonate, sulphate, hydrochlorate, nitrate, or succinate of ammonium: but when it has assumed the crystalline form by long standing, it dissolves but sparingly, forming a turbid liquid. The clear solutions sometimes become turbid on standing, but do not deposit the whole of the calcium which they contain. Hence calcium can never be completely precipitated as carbonate from solutions containing ammoniacal salts. Carbonate of calcium boiled with solution of sal-ammoniac, the water being renewed as it evaporates, dissolves almost completely as chloride of calcium, with evolution of carbonate of ammonium.

Carbonate of calcium heated to full redness in open vessels, is resolved into lime and carbonic anhydride. The decomposition commences even at a low red heat, so that in estimating calcium as carbonate in analysis, the ignited precipitate should, before weighing, be moistened with carbonate of ammonium, and again heated, just sufficiently to drive off the excess of that salt; by this means, any carbonic acid that may have been driven off will be restored. In a current of air or any other gas, and especially of steam, the decomposition takes place at a lower temperature. If, on the other hand, the carbonate of calcium be ignited a closed iron tube, so that the carbonic anhydride cannot escape, it fuses to a fine-grained mass, consisting of crystals of calcspar, and having the appearance of marble.

Hydrated Neutral Carbonate of Calcium, Hydrocalcite, $Ca^2CO^3.5aq$.—This salt is obtained in small, very acute, rhombohedral crystals, of specific gravity 1·783, by boiling lime in a concentrated solution of sugar, milk-sugar, starch, or gum, and leaving the solution for some months in a cold place (Pelouze, Ann. Ch. Phys. [2] xlviii. 301). Becquerel, by exposing a solution of lime in sugar-water, to the action of a 12-pair voltaic battery, obtained crystals having the same composition, but the form of a rhombic prism with dihedral summits, like arragonite. Crystals of the same form and composition were found by Scheerer (Pogg. Ann. lviii. 382), in a running stream. Salm-Horstmar found six-sided prisms of the same composition, deposited from spring-water in the copper tube of a pump.

The crystals remain unaltered below 19° or 20° C., either in the air or under water, but crumble to a white powder at a somewhat higher temperature, and if quickly heated to 30°, they are converted into a pasty mass, which dries up to a powder. In ether at 30°, they crumble to a white powder; also in hydrated alcohol: but boiling absolute alcohol extracts from them only 2 at. water, rendering them opaque, but without change of form. The remaining crystals with 3 at. water, effloresce very quickly in the air, but may be kept unaltered at a temperature below 10°. (Gm. iii. 188.)

Orthocarbonate, Ca^4CO^4, or $2Ca^2O.CO^2$.—This, with 1 at. water (sometimes regarded as a hydrocarbonate, $Ca^2CO^3.2CaHO$), is, according to Fuchs (Pogg. Ann. xxvii. 601), the composition of the slaked lime produced by exposing quick lime to the air in its ordinary state. At a strong red heat, it gives off water and carbonic anhydride, and yields a quick lime which slakes in water, not with violence, but slowly and with only moderate rise of temperature. At a low red heat, the hydrated orthocarbonate gives off only water, leaving the anhydrous salt, Ca^4CO^4, which, according to Fuchs, is likewise produced when ordinary carbonate of calcium is exposed to a moderate red heat, only half of the carbonic anhydride being then expelled, and leaving a residue, which in contact with water does not slake but hardens, being in fact converted into the hydrated orthocarbonate.

Acid Carbonate.—This salt, which perhaps has the composition $CaHCO^3$, is known only in solution, and may be obtained in that state by passing carbonic anhydride into cold water in which the neutral carbonate is suspended. Water saturated with carbonic acid dissolves $\frac{1}{1428}$ part of the neutral carbonate, at 0° C., and $\frac{1}{1136}$ at 10° (Lassaigne, J. Chim. méd. 1848, p. 312). In consequence of this sparing solubility, solutions of calcium-salts are precipitated by alkaline bicarbonates even in the cold. The solution of the acid salt has a slight alkaline reaction if quite saturated, but if the carbonic acid is in excess, it exhibits an acid reaction. It is decomposed, with separation of the neutral carbonate, on exposure to the air, or more quickly when heated. It plays an important part in the economy of nature, being formed wherever carbonate of calcium or other calcareous formations, especially silicates, come in contact with water containing carbonic acid, and thus entering in greater or smaller quantity into the composition of almost all natural waters. Waters which contain it in considerable quantity, form deposits of carbonate of calcium on their banks or on objects immersed in them; hence the formation of calcareous petrifactions, of calcareous tufa and sinter, of stalactites, stalagmites, &c. To the same cause also is due the turbidity which appears in river or spring water when heated, and the incrustation or furring of kettles and boilers. The formation of this incrustation may to a certain extent be prevented, by the addition of sal-ammoniac to the water, whereby, as already observed, the carbonate of calcium is converted into soluble chloride.

Carbonate of Cerium, $Ca^2CO^3 + 3aq.$, or $Ce^2H^2CO^4 + 2aq.$, formed, on exposing hydrated cerous oxide to the air, or by precipitation, is a white powder, which when ignited the air, is partly converted into lemon-yellow coroso-ceric oxide. It occurs native, with fluoride of calcium, as *Parisite* (*q. v.*)

Chromous Carbonate, is obtained by adding a solution of protochloride of chromium to carbonate of potassium. The precipitate is red or reddish-brown, if the solution is hot, but has the form of dense yellow or bluish-green flakes, if the solution is cold: it appears, however, to have the same composition in all cases. (Moberg.)

Carbonates of Cobalt. The anhydrous carbonate Co^2CO^3, is obtained by heating chloride of cobalt with carbonate of calcium to 150° C. in a sealed tube for eighteen hours, or by decomposing the chloride with a solution of acid carbonate of sodium supersaturated with carbonic acid, and heated to 140° in a strong vessel closed with a cork, through which the carbonic acid escapes slowly. It is a light rose-coloured, sandy powder, composed of microscopic rhombohedrons, and is not attacked in the cold by acids, not even by nitric or hydrochloric acid. (Sénarmont, Ann. Ch. Phys. [3] xxx. 129.)

The precipitates formed by adding cobalt-solutions to alkaline carbonates, are all hydrated carbonates, or double carbonates of cobalt and the alkali-metal. The former may be represented as ortho- or meta-carbonates, combined in various proportions with hydrate of cobalt, the composition varying according to the temperature and concentration of the solutions.

The precipitate formed on adding sulphate of cobalt to neutral carbonate of sodium, the solutions being concentrated or moderately dilute, and either hot or cold, is rose-coloured, and when dried at 100° C., consists of $Co^2CO^3.3CoHO + \frac{1}{2}aq.$, or $Co^4CO^4.CoHO + \frac{3}{2}aq.$ (Setterberg, Pogg. Ann. xix. 55; Winkelblech, Ann. Ch. Pharm. xiii. 148; H. Rose, *ibid.* lxxx. 237). But very weak solutions mixed at the boiling heat, yield a blue precipitate, consisting of $Co^2CO^4.4CoHO + aq.$, or $Co^4CO^4.2CoHO + 2aq.$ The precipitates are very difficult to wash. Heated above 150° C. in contact with the air, they gradually give off water and carbonic anhydride, and are converted into sesquioxide of cobalt (H. Rose). The first-mentioned precipitate is partly converted into sesquioxide by boiling with water (Field, Chem. Soc. Qu. J. xiv. 50). The same precipitate digested with solution of diacid carbonate of sodium or of ammonium, is gradually converted into $3Co^2CO^3 + aq.$ (H. Deville, Ann. Ch. Phys. [3] xxxiii. 75.)

A hydrated carbonate of cobalt called *Remingtonite*, whose precise composition is not known, occurs as a soft, earthy, rose-coloured incrustation, on thin veins of serpentine, at a copper-mine near Finksburg, Carroll County, Maryland. (J. C. Booth, Sill. Am. J. [2] xv. 48.)

Carbonate of Cobalt and Potassium.—Nitrate or sulphate of cobalt forms with excess of diacid carbonate of potassium a rose-coloured precipitate, which gradually changes to a network of rose-coloured crystals, easily decomposed by water, and consisting of a meta-carbonate, $(Co^2KH)C^2O^6 + 4aq.$, [or $2(CoO.CO^2) + KO.2CO^2 + 9HO$](H. Rose, H. Deville). Nitrate of cobalt and sesquicarbonate of potassium, yield distinct crystals, containing $CoKCO^3 + 2aq.$ (Deville.)

Carbonate of Cobalt and Sodium.—Nitrate of cobalt and sesquicarbonate of sodium, yield a mixture of small prismatic crystals, $CoNaCO^3 + 2aq.$, and dark-red crystals, apparently cube-like rhombohedrons, containing $CoNaCO^3 + 5aq.$ (Deville).

Carbonates of Copper.—Two of these compounds occur as natural minerals, viz. *Malachite* and *Azurite*. They may be most simply represented as orthocarbonates, viz.:

Malachite as *tetracupric orthocarbonate*, $Cu^4CO^4 + aq.$

Azurite as *tricupric orthocarbonate*, $\left.\begin{matrix}Cu^3\\H\end{matrix}\right\}CO^4$.

They may also be regarded as metacarbonates combined with cupric hydrate, viz. malachite as $Cu^2CO^3.2CuHO$; azurite as $Cu^2CO^3.CuHO$. The hydrated tetracupric salt is formed artificially by precipitation. The anhydrous metacarbonate Cu^2CO^3, is not known.

Tetracupric Orthocarbonate, $Cu^4CO^4 + aq.$ *Malachite, Green Carbonate of Copper, Mountain green, Atlas ore.*—This mineral forms prismatic crystals belonging to the monoclinic system, in which the lengths of the orthodiagonal, clinodiagonal, and principal axis are to one another as 1·273 : 1 : 0·5358. The inclination of the clinodiagonal to the principal axis does not differ much from 90°. The crystals are generally reduced to thin prisms by predominance of the faces ∞P and $\infty P\infty$, and terminated by oP, $+P$, $-P\infty$. Cleavage perfect parallel to $-P\infty$ and ∞P (Kopp). More frequently, however, it occurs in laminar, fibrous, compact, or earthy masses. Specific gravity = 3·7 to 4·0. Hardness = 3·5 to 4. It varies in colour from emerald to grass-green, and exhibits all degrees of transparency down to perfect opacity. It takes a high polish, and when in large masses is cut into tables, snuff-boxes, vases, &c. Malachite usually accompanies other ores of copper. Perfect crystals are very rare. The fibrous variety occurs abundantly in Siberia, at Chessy in France, at Sandlodge in Shetland; the compact variety at Schwartz in the Tyrol, in Cornwall, and in Cumberland. At the copper mines of Nischne Tagilsk, a bed of malachite was opened which yielded many tons of the mineral. Malachite is also found on the west coast of Africa, and in several localities in North America. (Dana, ii. 458.)

Cupric salts treated with alkaline carbonates, yield at first a greenish-blue precipitate, consisting, according to Brunner, of $Cu^4CO^4 + 2aq.$; which, however, when left in contact with the liquid, and washed, becomes compact and green, and acquires the composition of malachite. When heated to 200° C. it is slowly converted into black cupric oxide, which obstinately retains a small quantity of water. Malachite slowly decomposes in the same manner at 220°. The tetracupric salt, either native or precipitated, is decomposed by boiling with water, giving up carbonic acid, and being entirely converted into black oxide of copper. (H. Rose; F. Field, Chem. Soc. Qu. J. xiv. 71.) By digestion with neutral carbonate of sodium at 120° F. (48·8° C.) it is converted into $6Cu^2O.CO^2$, or $Cu^4CO^4.4Cu^2O$. Boiled with sesquicarbonate of sodium, it dissolves, forming a blue liquid, which is not decomposed even by long boiling; but when sulphate of copper is boiled for a very long time with sesquicarbonate of sodium, a green precipitate of tetracupric carbonate is obtained, and on filtering from this and adding more sulphate of copper to the filtrate, the basic salt just mentioned is precipitated, as a dense black powder (Field). According to Deville, tetracupric carbonate digested with neutral carbonate of sodium, is partly converted into $8Cu^2O.CO^2 + 5H^2O$.

Anhydrous tetracupric carbonate, Cu^4CO^4, or $2Cu^2O.CO^2$, occurs, according to Thomson (*Mineralogy*, i. 601), as *mysorin*, a mineral from Mysore in Hindostan, containing also ferric oxide and silica. Dana suggests that it may be only an impure malachite.

Tricupric Orthocarbonate, Cu^3HCO^4 (or $3CuO.2CO^2 + aq.$) *Azurite, Lasurite, Blue Carbonate of Copper, Blue Malachite, Chessy Copper, Chessylite, Kupferlasur.*—This mineral occurs in fine crystals, belonging to the monoclinic system, in which the orthodiagonal, clinodiagonal, and principal axis are to one another as 1·181 : 1 : 2·076. Inclination of axes 87° 39′. Observed faces $\infty P . oP . [P\infty] . [\frac{1}{3}P\infty] . \infty P\infty$, together with others of less frequent occurrence. The crystals are often prismatically elongated in the direction of the orthodiagonal. Cleavage parallel to $[P\infty]$ (Kopp's *Krystallographie*, p. 303). The mineral occurs also massive and in imitative shapes, having a columnar composition, also dull and earthy. Specific gravity = 3·5 to 3·831. Hardness = 3·5 to 4·25. Lustre vitreous, almost adamantine. Colour, various shades of azure, passing into Prussian-blue. Streak-blue, lighter than the colour. Transparent to sub-translucent. Fracture conchoïdal. Brittle. It is found in splendid crystallisations at Chessy near Lyons, in fine crystals also in Siberia, at Moldavia in the Bannat, at Wheal Buller, near Redruth in Cornwall; at Porto Bello, South America; and in small quantities at Alston Moor, Wanlockhead, &c. It is found also in the States of Pennsylvania, New York, and New Jersey. (Dana, ii. 459.)

Azurite when ground to fine powder forms a bright blue pigment; but it is not of much use, as it is apt to turn green by exposure. When boiled with water, it decomposes like malachite, yielding black oxide of copper. Heated with a concentrated solution of diacid carbonate of sodium, it yields a blue solution, which, after protracted boiling, deposits a green precipitate of malachite (Field). According to Phillips (Ann. Ch. Phys. [2] vii. 44) a cupric carbonate, called *blue verditer*, having the same composition as azurite, is obtained by a secret process.

Potassio-cupric Carbonate.—Nitrate of copper forms with diacid carbonate of potassium, a deep blue liquid, which after a few hours deposits a silky mass, consisting of $5Cu^2O.K^2O.5CO^2 + 10$ aq. or $(Cu^{10}K^2H^8)C^5O^{20} + 6$ aq. (Deville, Ann. Ch. Phys. [3] xxxiii. 75).

Sodio-cupric Carbonate, $CuNaC^2O^3 + 3$ aq., is obtained by adding an acid solution of nitrate of copper to carbonate of potassium containing soda, and leaving the precipitate in the liquid for a considerable time; also by the action of diacid carbonate of sodium on tetracupric carbonate at 40°—50° C. It forms rhombic prisms, having the angles of the obtuse edges = 123° 14′, and acuminated with four faces resting on the prismatic edges. (Deville.)

Cuprous Carbonate?—The yellow precipitate obtained by adding carbonate of sodium to a solution of cuprous chloride in hydrochloric acid was said by Colin to be a cuprous carbonate, but according to L. Gmelin (*Handbook*, v. 414), it is merely cuprous hydrate.

Carbonate of Cuprammonium, $(NH^3Cu)^2CO^3$, is obtained in large deep blue crystals by dissolving tricupric or tetracupric carbonate in carbonate of ammonia, and pouring the solution into alcohol. It is rapidly decomposed by water into carbonate of ammonia and a basic carbonate of copper, $Cu^4CO^4.2CuHO + 2$ aq. (Favre, *Traité de Chimie par Pelouze et Frémy*, iii. 201). The same ammoniacal compound appears to be formed when cupric oxide or finely divided metallic copper is digested in ammonia with access of air.

CARBONATE OF DIDYMIUM is obtained as a white, slightly rose-coloured precipitate containing $Di^2CO^3 + 2$ aq., on adding an alkaline carbonate to the solution of a didymium-salt. At 100° C. it gives off two-thirds of its water and a small quantity of carbonic acid. (Marignac.)

CARBONATE OF ETHYL. See CARBONIC ETHERS.

CARBONATE OF GLUCINUM is produced when the hydrate is exposed to the air, also by precipitating glucinum-salts with alkaline carbonates, not in excess, and by boiling a solution of carbonate of glucinum and ammonium. It appears to vary in composition; the precipitate obtained by the last-mentioned process has, according to Schaffgotsch, the composition $5Gl^2O.CO^2 + 5$aq. or $Gl^4CO^4.6GlHO + 2$aq. It appears to be decomposed by boiling with water. It dissolves in alkaline carbonates, forming double salts.

Carbonate of Glucinum and Ammonium.—When a solution of glucina in aqueous carbonate of ammonia is heated to the boiling point, till the liquid begins to show turbidity, then filtered, and the filtrate mixed with alcohol till it becomes milky, white transparent crystals are gradually deposited, containing $4Gl^2O.3CO^2.H^2O + 3[(NH^4)^2O.CO^2]$ or perhaps $GlHO.3Gl(NH^4)CO^3$. They become dull on exposure to the air, are insoluble in absolute alcohol, but dissolve readily in cold water, and are decomposed by hot water, with evolution of carbonate of ammonia. (Debray, Ann. Ch. Phys. [3] xliv. 5.)

Carbonate of Glucinum and Potassium, $GlHO.3GlKCO^3$, is obtained in the same manner as the ammonium-salt, which it resembles in its properties. (Debray.)

Carbonate of glucinum likewise forms a double salt with carbonate of sodium.

CARBONATES OF IRON.—*Ferric carbonate* does not appear to exist. The precipitate formed by alkaline carbonates in solution of ferric nitrate, consists, according to L. Gmelin (*Handbook*, v. 222), of ferric hydrate without a trace of carbonic acid. According to Soubeiran (Ann. Ch. Phys. [2] xliv. 326), the precipitate thrown down by alkaline carbonates from ferrous salts, contains, after thorough washing and exposure in thin layers to the moist air of a cellar for six months, 71·4 per cent. ferric oxide (quite free from ferrous oxide), 8·3 carbonic anhydride, and 20·0 water; but it is doubtful whether a definite carbonate is formed.

Double carbonates of ferricum and the alkali-metals appear to be capable of existing in solution, though not in the solid state. When a ferric salt is precipitated by concentrated carbonate of ammonia, the precipitated ferric hydrate gradually redissolves, but is slowly deposited again on diluting with water. Well washed ferric hydrate, however, does not dissolve in carbonate of ammonia, so that the presence of the ammoniacal salt formed in the decomposition appears to be necessary to the solution of the ferric hydrate. Similar reactions are obtained with strong solutions of carbonate of potassium or sodium.

Ferrous Carbonate.—The anhydrous metacarbonate Fe^2CO^3 or $Fe^2O.CO^2$, exists abundantly as a natural mineral, viz. *Spathic* or *Sparry iron ore*, also called *Chaly-*

lite, Siderite, Siderose, Brown spar, Sphærosiderite, Junkerite, Strahlstein, Eisenspath, Spatheisenstein, Oligonspath. This mineral forms rhombohedral crystals, having for their primary form a rhombohedron, in which the principal axis is to the secondary axes as 0·8117 : 1, and the inclination of the faces meeting in the terminal edges = 107° 0′, this form being either solitary or predominant, and often with curved faces; sometimes in twin-crystals. It also occurs in botryoïdal and globular forms (as *sphærosiderite*), occasionally in silky fibrous masses; often cleavable massive, with cleavage planes undulate; also coarse or fine granular. Specific gravity = 3·7 to 3·9. Hardness = 3·5 to 4·5. Lustre vitreous to pearly. Streak white. Colour ash-grey, yellowish-grey, greenish-grey; also brown and brownish-red, rarely green; sometimes white. Translucent to subtranslucent. Fracture uneven. Brittle. (Dana, ii. 445.)

Pure ferrous carbonate would contain 37·93 per cent. carbonic anhydride and 62·07 ferrous oxide. The mineral always contains more or less of the carbonates of manganese, magnesium, and calcium. A black variety from Babbowsky gave 36·61 CO^2, 57·91 Fe^2O, 1·51 Mn^2O, trace of Mg^2O, 0·59 Ca^2O, and 0·60 gangue. A specimen from the neighbourhood of Durham yielded 35·90 CO^2, 54·57 Fe^2O, 1·15 Mn^2O, 3·18 Ca^2O, and 2·63 water (= 97·43). The variety called oligonspar contains 25·31 per cent. manganous oxide; other varieties contain 12 to 15 per cent. magnesia.

Ferrous carbonate is a very abundant mineral, occurring in gneiss, mica slate, clay slate, and in connection with the coal formation. At Freiberg it occurs in silver mines. In Cornwall it accompanies tin. It is also found accompanying copper and iron pyrites, galena, vitreous copper, &c. In New York, according to Beck, it is almost always associated with specular iron. Occasionally it is found in trap rocks as sphærosiderite (Dana). A siliceous or argillaceous variety called *clay iron stone*, which occurs in the coal measures, is one of the most abundant and valuable ores of iron. Very large quantities of it are found and worked in South Staffordshire, at Merthyr Tydvil in South Wales, and near Glasgow.

Anhydrous ferrous carbonate may be prepared artificially by processes similar to those already described for carbonate of cobalt (p. 782). It then forms a greyish-white crystalline sand, composed of minute rhombohedrons, scarcely attacked by dilute acids, nearly unalterable in dry air, gradually assuming a light red tint in moist air. It is of a darker grey colour and less alterable in the air in proportion as the heat employed in its preparation has been greater and longer continued. (Sénarmont, Ann. Ch. Phys. [3] xxx. 129.)

Hydrated ferrous carbonate is precipitated on mixing a ferrous salt with an alkaline carbonate, in thick white flakes, which, on exposure to the air, absorb oxygen and give off carbonic acid, first assuming a dirty green colour, and ultimately changing to yellowish-brown ferric hydrate. Hence it is difficult to obtain the precipitated ferrous carbonate in a pure and definite state. The best mode of proceeding is to precipitate ferrous sulphate quite free from ferric sulphate, with alkaline monocarbonate or bicarbonate, both salts being dissolved in water which has been thoroughly freed from air by boiling, wash the precipitate out of contact with the air, *e.g.* by decantation with thoroughly de-aërated water, keeping the vessel quite full and closed, and dry it in an atmosphere of carbonic anhydride. The salt thus prepared is a greenish tasteless powder, which is used in medicine; it is tolerably permanent if thoroughly dried; but if moist it oxidises quickly in the air, becoming hot, and giving off water and carbonic acid. It may be rendered more permanent by mixing it with sugar while moist.

Acid Salt.—Aqueous carbonic acid dissolves ferrous carbonate; also metallic iron with evolution of hydrogen. The solution, which exists in many natural waters, called *chalybeate waters*, is colourless, has a slightly ferruginous taste, is decomposed, with separation of ferric hydrate, by contact with the air, and gives a black precipitate with sulphuretted hydrogen. To preserve chalybeate water in vessels, they must first be filled with carbonic anhydride, then opened and filled below the surface of the water, and lastly corked under water. A less efficient mode of preservation is the introduction of iron wire and a few grains of sugar.

CARBONATE OF LANTHANUM, $La^2CO^3 + 3$ aq., is found native as *Lanthanite*, a mineral (formerly mistaken for carbonate of cerium) occurring in four-sided plates or minute tables of the trimetric system, with bevelled edges; also fine-granular, and earthy. Specific gravity 2·67 (?) Hardness 2·5 to 3. It has a dull or pearly lustre, and greyish-white, faint pink, or yellowish colour. It is found coating cerite at Bastnas in Sweden, and in silurian limestone, with the zinc ores of the Saucon valley, Lehigh county, Pennsylvania. The American mineral was found by J. L. Smith to contain 54·90 per cent. La^2O, with oxide of didymium, 22·58 CO^2, and 24·09 water (= 101·57), the formula requiring 52·94 La^2O, 21·11 CO^2, and 25·95 water. With borax or phosphorus-salt it yields a glass having an amethystine colour, arising from didymium. (Dana, ii. 456.)

Carbonate of lanthanum obtained by precipitation forms a white gelatinous mass, which gradually changes into shining crystalline scales.

Carbonates of Lead.—The anhydrous metacarbonate, Pb^2CO^3 or $Pb^2O.CO^2$, is found native as *white lead ore* or *cerusite*, in crystals of the trimetric system, isomorphous with arragonite, witherite, and strontianite, and in which the brachydiagonal, macrodiagonal, and principal axis are in the ratio of 0·6100 : 1 : 0·7236. Ordinary combination $P . \infty P . \breve{P}\infty . 2\breve{P}\infty . \infty P\infty$, with $2\breve{P}\infty$ predominant. Inclination of faces, $\infty P : \infty P = 62° 46'$; $\breve{P}\infty : \breve{P}\infty = 71° 47'$; $2\breve{P}\infty : 2\breve{P}\infty = 110° 42'$. Cleavage moderately easy parallel to ∞P, less so parallel to $2\breve{P}\infty$. It is sometimes found in twin-crystals, the face of combination being ∞P (Kopp's *Krystallographie*, p. 261); rarely fibrous; often granularly massive and compact. Specific gravity 6·465 to 6·480. Hardness 3 to 3·5, in some earthy varieties as low as 5·4. Colourless when pure, transparent or translucent in various degree and with adamantine lustre. Fracture conchoïdal. Very brittle. White lead ore is found in Cornwall and Cumberland, at Leadhills and Wanlockhead in Scotland, in Siberia, in the Harz, in Bohemia, and many other localities. It sometimes occurs altered to phosphate of lead by the action of water containing phosphate of calcium; to galena by the action of sulphuretted hydrogen, and to minium by oxidation; also more or less to magnesite, malachite, and chrysocolla. (Dana.)

Horn-lead or *cerasine* is a compound of carbonate and chloride of lead.

Hydrocarbonates.—The precipitate formed in solutions of lead-salts by alkaline carbonates varies in composition according to the temperature and concentration of the liquids. According to Berzelius, the anhydrous metacarbonate is obtained by treating nitrate of lead with excess of carbonate of ammonia; according to Lefort (J. Pharm. [3] xv. 26), by precipitating with alkaline carbonates in the cold, whereas from hot solutions a hydrated salt, $3Pb^2O.CO^2.H^2O$, is obtained. According to H. Rose (Ann. Ch. Pharm. lxxx. 235), the precipitate always contains hydrate of lead. Equivalent quantities of nitrate of lead and neutral carbonate of sodium in cold strong solutions yield the compound $6Pb^2CO^3.2PbHO + aq.$, which gives off some of its water at 100° C., and takes up more carbonic acid; with cold dilute, or hot concentrated solutions, the compound $5Pb^2CO^3.2PbHO$ is obtained, and with hot dilute solutions $3Pb^2CO^3.2PbHO$. When the carbonate of sodium is added in excess, the precipitate consists chiefly of $Pb^2CO^3.PbHO$ or $(Pb^3H)CO^4$, but contains a small quantity of soda.

Hydrated carbonates of lead are also formed by the direct action of carbonic acid on hydrate of lead, and the compounds thus obtained differ from the precipitated carbonate, in being amorphous and perfectly opaque, whereas the precipitated carbonate is an aggregate of minute transparent crystalline grains. Hence the carbonate formed by absorption of carbonic acid is much better adapted for a pigment, and is extensively used as such under the name of *white lead* or *ceruse*; its great opacity gives it that quality which painters call *body*, enabling a small quantity of it to form a brilliant white coating over a considerable surface.

There are two methods of prepared white lead. In the older, called the Dutch method, because it was originally practised in Holland, thin sheets of lead are placed over gallipots containing weak acetic acid (water with about 2½ per cent of the strong acid), the pots being embedded in fermenting tan, the temperature of which varies from 140° to 150° F. The action is often very rapid, the metal disappearing in a few weeks to the centre of the sheet. In this process from 2 to 2½ tons of lead (4480 to 5600 lbs. are converted into carbonate by a quantity of vinegar containing not more than 50 lbs. of strong acetic acid. It is evident, therefore, that the metal is neither oxidised nor carbonated at the expense of the acetic acid. The oxygen is derived from the air, and the carbonic acid from the fermenting tan; the acetic acid merely serves to dissolve the oxide of lead and convert it into a basic acetate, which is easily decomposed by carbonic acid, the acetic acid being thereby set free to act upon another portion of oxide of lead. That this is really the mode of action, is shown by what takes place in the more modern process, in which oxide of lead (litharge) is mixed with water and about 1 per cent. of neutral acetate of lead, and carbonic acid gas is passed over it: in this manner the oxide is quickly converted into excellent white lead. Nitrate of lead has also been used in this latter process in place of the acetate.

White lead is a mixture or compound of carbonate and hydrate of lead, in various proportions. Mulder (Ann. Ch. Pharm. xxxiii. 242), from the analysis of numerous samples, concluded that there are three varieties of it, viz.: $Pb^2CO^3.PbHO$; $5Pb^2CO^3.6PbHO$, and $3Pb^2CO^3.2PbHO$. J. A. Phillips (Chem. Soc. Qu. J. iv. 165) found the composition of four samples to agree with the first of these formulæ, one with the third, and another to contain $5Pb^2CO^3.2PbHO$.

White lead is often mixed with heavy spar and gypsum, the addition of which renders it less liable to be blackened by the action of sulphuretted hydrogen. Oxide of zinc is likewise added for the same purpose. (Gm. iv. 127. *Ure's Dictionary of Arts, Manufactures and Mines*, iii. 1015; *Graham's Chemistry*, 2nd edition, ii. 120.)

Acid Carbonate.—Carbonate of lead dissolves slightly in water containing carbonic acid; the solution contains from $\frac{1}{8000}$ to $\frac{1}{5000}$ of lead-oxide, is rendered turbid by alkaline carbonates, and coloured brown by sulphuretted hydrogen. (See LEAD.)

Carbonate of Lead and Sodium. $4Pb^2CO^3.Na^2CO^3$.—Produced, according to Berzelius (Pogg. Ann. xlvii. 199), when nitrate of lead is precipitated by carbonate of sodium, the precipitate boiled in the alkaline liquid, then washed and dried at 160° C.

CARBONATE OF LITHIUM, Li^2CO^3.—This salt, which is slightly soluble in water, exists in the waters of Carlsbad, Franzensbad, and others. It is prepared by dissolving an excess of carbonate of ammonia in a concentrated solution of chloride of lithium, and washing the resulting precipitate with alcohol; or by precipitating sulphate of lithium with acetate of barium, evaporating the filtrate, and decomposing the residual acetate of lithium by ignition. The salt melts at a low red heat, and solidifies to a vitreous mass on cooling. It is not decomposed by heat. It dissolves in 100 pts. of cold water (Vauquelin); in 130 pts. at 13° C., and in 128·5 pts. at 100° (Kremers Jahresber. d. Chem. 1856, p. 275). The saturated solution boils at 100° (Kremers *ibid.* p. 294). The solution is alkaline, and deposits the salt by slow evaporation, in small prisms. It decomposes the salts of ammonia, and gives up its carbonic acid to caustic baryta and lime.

Water saturated with carbonic acid dissolves carbonate of lithium more freely than pure water.

CARBONATES OF MAGNESIUM.—The anhydrous metacarbonate, Mg^2CO^3, or $Mg^2O.CO^2$, occurs native as *magnesite*, associated with serpentine and other magnesian rocks. It is found in rhombohedral crystals, isomorphous with calcspar. Ratio of the principal axis to the secondary axes = 0·8117 : 1. Angle of the terminal edges = 107° 25. Cleavage perfect parallel to the rhombohedral faces. It also occurs massive, granular, or fibrous, sometimes in radiating groups; also very compact. Specific gravity = 2·8 to 3. Hardness = 3·5 to 4·5. It is white, or with various shades of yellow, grey, and brown, has a vitreous or silky lustre, and exhibits all degrees of transparency, down to complete opacity. Fracture flat, conchoïdal. It is infusible before the blowpipe, and dissolves slowly and with little effervescence in acids. It occurs nearly pure, with only small quantities of water and the carbonates of iron, manganese, and calcium, in Moravia, Styria, Silesia, Piedmont, Spain, and at several localities in the United States. Carbonate of magnesium occurs also associated in various proportions with the carbonates of iron, manganese, and calcium, forming the minerals sphærosiderite, diallogite, dolomite, bitter spar, &c.

Anhydrous metacarbonate of magnesium cannot be prepared by precipitating a soluble magnesium-salt with an alkaline carbonate, as the precipitate thus formed always contains hydrate of magnesium; but by suspending the washed precipitate in water, passing carbonic acid gas through the liquid till the precipitate is dissolved, and evaporating the solution by heat, the anhydrous salt is obtained as a crystalline powder, which when examined by the microscope, exhibits the form of arragonite (H. Rose, Pogg. Ann. xlii. 366). It is likewise obtained by heating sulphate of magnesium with carbonate of sodium, to 160° C. in a sealed tube, or by enclosing a soluble magnesium-salt, together with an alkaline dicarbonate supersaturated with carbonic acid, in a strong vessel closed by a cork, through which the carbonic acid can escape slowly. By this last method, it is obtained in microscopic rhombohedrons, like native magnesite (Sénarmont, Compt. rend. xxviii. 693; Ann. Ch. Phys. [3] xxx. 129). Anhydrous carbonate of magnesium is therefore isodimorphous with carbonate of calcium. When moistened with water, it gives an alkaline reaction with litmus and violets. If the solution of carbonate of magnesium in excess of carbonic acid be left to evaporate spontaneously, or kept for some time at 50° C., it deposits small hexagonal prisms, containing $Mg^2CO^3 + 3aq.$: they give up their water in warm air, becoming opaque, but retaining their form. The same hydrated crystals are obtained by mixing the solutions of sulphate of magnesium and sesquicarbonate of potassium and sodium, and leaving the mixture to stand. A saturated solution of carbonate of magnesium in aqueous carbonic acid, exposed for some time to a winter temperature, deposits transparent oblique prismatic crystals, containing 5 at. water: $Mg^2CO^3 + 5aq.$ They are converted into the preceding, with loss of transparency, by exposure to the air, more quickly in sunshine, and by immersion in water at 50° C. If boiled with water, they give up part of their carbonic acid, and are ultimately converted into $2Mg^2CO^3.MgHO + 2aq.$ (Fritzsche.)

Hydrocarbonates. a. $5Mg^2O.4CO^2 + 5aq. = 2Mg^2CO^3.MgHO + 2aq. = (Mg^5H^3)C^2O^6 + aq.$—Produced, as just mentioned, by the action of water on $Mg^2CO^3 + 5aq.$, better by boiling with water containing ammonia (Fritzsche); also by precipitating sulphate of magnesium with carbonate of sodium, and drying the precipitate at 100° C. (H. Rose, Ann. Ch. Pharm. lxxx. 234); also, according to Berzelius, by boiling a solution of acid carbonate of magnesium for a long time. It is a white granular powder.

b. $4Mg^2O.3CO^2 + 4aq. = 3Mg^2CO^3.2MgHO + 3aq. = (Mg^8H^4)C^3O^{12} + 2aq.$—Found native as *Hydromagnesite*, in small white, brittle, or acicular crystals, of the monoclinic system, or in chalky crusts. Specific gravity = 2·145 to 2·18. Hardness of the crystals = 3·5. It is found at Hrubschitz in Moravia in serpentine; in Negroponte near Kumi; and crystallised with serpentine and brucite (hydrate of magnesium), in Lancaster county, Pennsylvania. *Lancasterite* is a mixture of brucite and hydromagnesite. (Dana, ii. 456.)

A substance of the same composition is obtained by mixing sulphate of magnesium with excess of a hot solution of carbonate of potassium, and boiling the precipitate with fresh quantities of water, as long as any acid carbonate dissolves out (Berzelius); also, according to Fritzsche, by boiling a saturated solution of the acid carbonate, and twice boiling the resulting precipitate with fresh quantities of water. It is a white powder, slightly soluble in water, and forming an alkaline solution. When dried at 100° C. in the air, it absorbs carbonic acid, and is converted into $5Mg^2O.4CO^2 + 5aq.$ (H. Rose.)

c. $3Mg^2O.2CO^2 + 3aq.$ (?) Obtained, according to Fritzsche (Pogg. Ann. xxxvii. 310), by precipitating sulphate of magnesium with a very large excess of carbonate of sodium, boiling the whole till the precipitate passes from the flocculent to the granular condition; then washing and boiling rapidly with water, pouring off the liquid, and twice boiling the residue with fresh water. It consists of small grains mixed with a small quantity of the original flocculent precipitate. According to Berzelius, the precipitate obtained as above may contain carbonate of sodium. According to H. Rose, the precipitate formed by carbonate of sodium with sulphate of magnesium always contains $5Mg^2O$ to $4CO^2$, whatever may be the temperature and strength of the solutions.

The pharmaceutical preparation known as *Magnesia alba*, is a mixture of the several hydrocarbonates of magnesium, the proportions depending on the relative quantity of the precipitant, the degree of dilution, and the temperature at which precipitation takes place. It is prepared on the large scale by precipitating sulphate, nitrate, or chloride of magnesium with carbonate of potassium or sodium. Various mineral waters containing sulphate of magnesium, such as the Epsom water, are used for the purpose, also the mother-liquor of sea-water, of many salt-springs, and of many kinds of saltpetre; most of these liquids, however, contain lime, which must be previously separated by sulphate of potassium or sodium. After being well washed with hot water, it forms a very light, and bulky powder. The utmost degree of lightness is obtained by allowing the precipitate to freeze while still moist. (Gm. iii. 228.)

Acid Carbonate.—Magnesia alba shaken up with aqueous carbonic acid, forms a solution having a bitter taste and alkaline reaction, and containing, according to Soubeiran, just twice as much carbonic acid with the same quantity of magnesia as the normal salt (probably $MgHCO^3$). It becomes turbid at 75° C., but recovers its clearness on cooling. When heated to 50° C., or evaporated in vacuo, it deposits the trihydrated metacarbonate, $Mg^2CO^3 + 3aq.$ (Berzelius, Fritzsche.)

Carbonate of Magnesium and Ammonium, $Mg(NH^4)CO^3 + 2H^2O$, crystallises in translucent rhombohedrons from a mixture of the cold aqueous solutions of sulphate or chloride of magnesium and sesquicarbonate of ammonia, the latter in excess, or from a solution of hydrate of magnesium in sesquicarbonate of ammonia.

Carbonate of Magnesium and Potassium, $(Mg^4K^2H^2)C^4O^{12} + 8aq.$, is deposited after a few days in large crystals from a cold aqueous mixture of chloride or nitrate of magnesium with excess of diacid carbonate of potassium. The crystals become opaque and lose water at 100° C., and are decomposed by water, which dissolves the acid carbonates of potassium and magnesium, and leaves a residue consisting of the hydrocarbonate $3Mg^2CO^3.MgHO + 8aq.$ (Berzelius.)

H. Deville (Ann. Ch. Phys. xxxiii. 75), obtained the salt by the same process in microscopic crystals, apparently having the form of oblique rhombic prisms. By using sesquicarbonate of potassium instead of the diacid carbonate, he obtained, together with the preceding, another double salt, containing $MgHCO^3 + 2aq.$ The latter is obtained separately in small rhombic prisms by digesting *magnesia alba* for twelve or fifteen hours at 60° or 70° C., with diacid carbonate of potassium.

Carbonate of Magnesium and Sodium, $MgNaCO^3$, is obtained in anhydrous microscopic crystals by digesting *magnesia alba* in like manner with diacid carbonate of sodium. A mixture of a magnesium-salt with diacid carbonate of sodium yields no double salt, but only $Mg^2CO^3 + 3aq.$

CARBONATE OF MANGANESE.—The anhydrous carbonate occurs native as *Di-*

allogite, also called *Red Manganese, Rhodochrosite, Brown Spar, Manganspath.* It forms rhombohedral crystals, isomorphous with calcite, in which the principal is to the secondary axes as 0·8117 : 1, and the inclination of the faces meeting in the terminal edges = 106° 51′. The crystals are tabular, exhibiting the faces $R\,.\,-\frac{1}{2}R\ \infty R\,.\,0R$. It occurs also in globular and botryoïdal forms; likewise granular massive; occasionally as an impalpable powder. Specific gravity 3·4 to 3·6; of a variety from Kapnik, 3·592. Hardness 3·5 to 4·5. It is translucent, of rose-red or brownish colour, and vitreous lustre inclining to pearly. Streak white. Fracture uneven. Brittle. It is found in the Saxon mines, at Nagjày and Kapnik, in Transylvania, near Elbingerode in the Harz, &c. At Glendree in the county of Clare, Ireland, it forms a layer of yellowish-grey colour, two inches thick, below a bog. It also occurs in the pulverulent form, coating triplite, at Washington, Connecticut. It is generally mixed with the carbonates of calcium and magnesium, the proportion of carbonate of manganese varying from 97 to 75 per cent. A sample from Ireland, analysed by Gruner (Ann. Min. [3] xviii. 61), gave 97·1 per cent. Mn^2CO^3, 0·7 Fe^2CO^3, 1·0 Ca^2CO^3, 0·8 Mg^2CO^3, and 0·1 Mn^4O^3.

Anhydrous carbonate of manganese may be obtained artificially as a very fine amorphous, faintly rose-coloured powder, by heating chloride of manganese in a sealed tube with carbonate of sodium to 160° C., or with carbonate of calcium to 140°—170° from 12 to 48 hours. (Sénarmont, Compt. rend. xxviii. 693.)

By precipitating manganous salts with carbonate of potassium or sodium, a white precipitate is formed, which, after washing with boiling water, and drying in vacuo over oil of vitriol, is a snow-white tasteless powder, containing, according to the analyses of Ure, Turner, John, and Forchhammer, $2Mn^2CO^3 + aq.$ (Gm. iv. 214). According to H. Rose (Ann. Ch. Pharm. lxxx. 235) equivalent quantities of chloride of manganese and carbonate of sodium yield a precipitate containing $5Mn^2CO^3.2MnHO$.

Carbonate of manganese, whether anhydrous or hydrated, is permanent at ordinary temperatures, but when heated to redness in the air, assumes a dark brown colour, and is converted into manganoso-manganic oxide. Ignited in an atmosphere of hydrogen, it yields greenish-grey manganous oxide. Ignited in chlorine gas, it yields, according to Wöhler, a crystalline mixture of chloride of manganese and manganoso-manganic oxide:

$$4Mn^2CO^3 + Cl^2 = 2MnCl + 2Mn^2O^2 + 4CO^2.$$

Chlorine-water or aqueous hypochlorite of calcium converts it, first into manganoso-manganic oxide, afterwards into peroxide. When recently precipitated, it dissolves in ammoniacal salts. It is soluble in 7680 pts. of pure water, and in 3480 pts. of aqueous carbonic acid. (John.)

Carbonates of Mercury.—*Mercuric* nitrate gives with neutral or acid carbonate of potassium or sodium, a brown-red precipitate, containing $4Hg^2O.CO^2$, or $3Hg^2O.Hg^2CO^3$ (Setterberg, Pogg. Ann. xix. 60.) From mercuric chloride, alkaline bicarbonates precipitate, not a carbonate but an oxychloride.

Mercurous nitrate yields with carbonate of potassium, a black or yellow powder, consisting of *mercurous carbonate*, Hhg^2CO^3. It is very apt to give off carbonic acid; and the best way of obtaining it of definite composition is to mix mercurous nitrate with a slight excess of alkaline bicarbonate, set the mixture aside for a few days, and stir it frequently, then wash as quickly as possible, and dry in vacuo over oil of vitriol (Setterberg, *loc. cit.*) It is converted into mercuric oxide by exposure to the air. Alkalis blacken it, separating metallic mercury. (Gm. vi. 15.)

Carbonate of Methyl. See Carbonic Ethers.

Carbonate of Nickel.—The anhydrous salt, Ni^2CO^3, is obtained by heating chloride of nickel with alkaline carbonates in sealed tubes, in the same manner as carbonate of cobalt (p. 782), is a greenish-white crystalline powder, composed of minute rhombohedrons, scarcely attacked by strong acids at ordinary temperatures. (Sénarmont.)

A *hydrocarbonate of nickel*, $Ni^2CO^3.4NiH^3O^2$, called *Emerald-nickel*, occurs in the form of a stalactitic crust on chrome-iron ore, at Texas, Lancaster County, Pennsylvania, also at Swinaness in Unst, Shetland. It is amorphous, with an uneven somewhat scaly fracture. Specific gravity = 2·67 to 2·623. Hardness 3 to 3·25. Colour, emerald-green with strong vitreous lustre. Streak green. It gives off water when heated, and turns blackish. (B. Silliman, Jun. Sill. Am. J. [2] vi. 248.)

Hydro-nickelmagnesite, a mineral allied to the preceding, but containing magnesium as well as nickel, is found in the same localities in serpentine. (Shepard *ibid.* 250.)

Nickel-salts treated with alkaline carbonates, yield a pale apple-green, flocculent precipitate, which, after washing and drying, sometimes forms a loose, earthy, pale-green mass having a faint metallic lustre, sometimes, especially after continued washing with boiling water, a thick blackish-green mass, having a conchoïdal wavy fracture. The precipitates thus formed always contain water, their composition varying according to the temperature, strength, and proportions of the solutions employed. According to H. Rose (Ann. Ch. Pharm. lxxx. 237), the precipitate formed in the cold with sulphate of nickel and neutral carbonate of sodium consists, when dried at 100° C., chiefly of $Ni^2CO^3.3NiHO + 2aq.$; if boiled with a large quantity of water, it appears to take up water and lose carbonic acid. If heated in the air above 100°, it gradually gives off carbonic acid and water, and is partly converted into peroxide of nickel. Precipitated carbonate of nickel does not appear to be altered by digestion with bicarbonate of soda, even at 60° to 70°. (H. Deville.)

Carbonates of Nickel and Potassium.—By methods similar to those adopted with the corresponding cobalt-salts (p. 782), Deville obtained the salt $(NiK)CO^3 + 2aq.$ in shining apple-green microscopic needles, and $(Ni^2KH)C^2O^6 + 4aq.$, in light green crystals, apparently having the form of oblique rhombic prisms. The last was also obtained by Rose.

Carbonate of Nickel and Sodium, $(NiNa)CO^3 + 5aq.$, is obtained like the cobalt-salt, in small crystals, which appear to be cube-like rhombohedrons. (Deville.)

Carbonates of Palladium.—On adding an alkaline carbonate to a solution of palladium, a light yellow precipitate is formed, at first without evolution of carbonic anhydride; but on continuing the precipitation, effervescence ensues, and the precipitate turns brown. It retains a small quantity of carbonic acid when dry. (Berzelius.)

Carbonates of Potassium.—Three of these salts are known, all having the constitution of metacarbonates, viz. the *dipotassic* or *neutral carbonate*, K^2CO^3 or $K^2O.CO^2$, the *monopotassic* or *di-acid carbonate*, commonly called *bicarbonate*, $KHCO^3$ or $K^2O.H^2O.2CO^2$, and the *tetrapotassic* or *sesqui-acid carbonate*, $K^4H^2C^3O^9$, or $2K^2O.3CO^2 + H^2O$. The last has not been obtained in very definite form, and is perhaps only a mixture of the other two.

Dipotassic Carbonate, or *Neutral Carbonate of Potassium.* K^2CO^3. *Subcarbonate of Potash. Mild* or *Aërated Vegetable Alkali. Salt of Tartar. Purified Potash. Pearlash. Alkali vegetabile fixum. Cineres clavellati depurati.*—This salt is obtained chiefly from the ashes of plants. Living plants contain the potassium-salts of several vegetable acids, acetic, malic, tartaric, oxalic, &c.; and these salts, when calcined, are transformed into carbonate, which remains in the calcined residue mixed with charcoal and the various mineral salts contained in the plant, viz. sulphate, chloride, and silicate of potassium and sodium, besides carbonate of calcium and other insoluble matters. On treating the ash with water, the carbonate of potassium is dissolved, together with the alkaline sulphates and chlorides, and a residue is left, consisting of carbonate and phosphate of calcium, silica, clay, &c. The solution is evaporated to dryness, and the residue is sold as crude potash. Sometimes lime is stirred in with the solution during the evaporation, and then the carbonate of potassium is partly converted into hydrate or caustic potash. The quantity of potash obtained from different plants varies according to their nature, the most succulent yielding the largest amount, inasmuch as the alkaline salts are chiefly contained in the sap: hence herbaceous plants yield more than shrubs or trees. The different parts of the same plant also yield different quantities—the leaves more than the branches, the bark more than the wood.

The ashes of plants are used in all countries for the alkali which they contain, both as manure for the soil, and to yield a lye for the bleaching of linen; but it is only in countries where wood is very abundant, that potash can be advantageously prepared as a commercial product. Nearly all the potash used in the arts comes from America or from Russia.

Crude potash contains from 60 to 80 per cent. of carbonate of potassium, the remainder consisting of sulphate, chloride, and small quantities of silicate of potasssium together with organic matter which has not been completely burnt. This carbonate being much more soluble than the other potassium-salts, may, for the most part, be separated from them by digesting the crude potash for several days with its own weight of cold water, then decanting the liquid, quickly evaporating it, removing it from the fire as soon as it begins to show turbidity from the formation of small crystals, and leaving it to cool, stirring all the while to prevent the formation of large crystals, which would enclose mother-liquor in their cavities. The mother-liquor is then filtered off, the crystals washed with a small quantity of solution of pure carbonate of potassium, then dried and heated to incipient redness in vessels of cast-iron, silver, or platinum. The product thus obtained, called pearlash, contains only 2 or 3 per cent. of foreign matter, which, however, is difficult to remove.

Pure carbonate of potassium may be obtained by igniting acid tartrate of potassium (cream of tartar) in a crucible. A black residue is thereby obtained, consisting of carbonate of potassium and charcoal, which is often used as a reducing agent, under the name of *black flux*. The carbonate of potassium is separated from the charcoal by solution in water, filtration, and evaporation. If the solution has a brown colour from undecomposed organic matter, the salt must be again ignited.

Carbonate of potassium is sometimes prepared by throwing into a red-hot iron vessel, by small portions at a time, a mixture of 1 pt. cream of tartar and 2 pts. nitre. The carbon of the cream of tartar is then all burnt away by the oxygen of the nitre, and there remains a white mass called *white flux*, consisting almost wholly of carbonate of potassium. It frequently, however, contains small quantities of nitrite,—which may be avoided by diminishing the proportion of nitre used,—and always a little cyanide of potassium.

Pure carbonate of potassium is, however, more easily obtained from the acid carbonate or oxalate (binoxalate). The acid carbonate, $KHCO^3$, is found in commerce in large crystals very nearly pure. It may be further purified by recrystallisation, and, when ignited in a platinum or silver crucible, yields the pure neutral carbonate. The acid oxalate of potassium may be prepared by mixing hydrate of potassium with excess of oxalic acid, and purified by several crystallisations. When ignited, it leaves pure carbonate of potassium unmixed with charcoal. (Regnault.)

The impurities which may occur in commercial carbonate of potassium are the following: *Sulphate of potassium:* detected by the turbidity produced on adding chloride of barium to the solution acidulated with hydrochloric acid and diluted. *Chloride of potassium:* cloud produced by nitrate of silver in the solution acidulated by nitric acid. *Phosphate of potassium:* crystalline precipitate by sulphate of magnesium in solution treated first with hydrochloric acid, then with excess of ammonia. *Nitrate or nitrite of potassium:* reddish brown colour by ferrous sulphate in solution of the salt in excess of sulphuric acid. *Cyanide of potassium:* Prussian blue, formed by ferrosoferric sulphate and excess of hydrochloric acid. *Soda:* crystalline precipitate with acid metantimonate of potassium (p. 327). *Carbonate of calcium:* retained in solution, partly through the medium of the carbonate of potassium: cloud with oxalic acid after neutralisation with acetic acid. *Silica:* remains undissolved on acidulating with hydrochloric acid, evaporating to complete dryness, and digesting the residue in dilute hydrochloric acid. *Oxide of copper:* red-brown precipitate with ferrocyanide of potassium in acidulated solution.

Carbonate of potassium is very soluble in water, 1 pt. of the anhydrous salt dissolving, according to Osann, in 1·05 pt. of water at 3° C. (37·4° F.), in 0·9 pt. at 12·1° C. (54° F.), and in 0·49 pt. at 70° C. (158° F.) The most concentrated solution, containing 48·8 per cent. of the anhydrous salt, has a specific gravity of 1·54 at 15° C., and boils at 113° C. (235·4 F.) (Dalton). It has a strong alkaline taste and reaction, but is only slightly corrosive. A highly concentrated hot solution deposits on cooling rhombic octahedrons containing 20 per cent. of water, corresponding to the formula $K^2CO^3 + 2aq$.

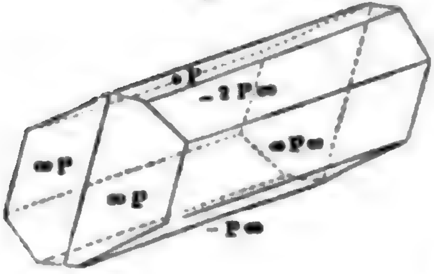
Both the crystals and the anhydrous salt deliquesce rapidly in the air, forming an oily liquid. The anhydrous salt melts at a red heat, volatilises at a white heat. It is not decomposed by any temperature in close vessels; but at a red heat, not sufficient to melt it, it is partly decomposed and converted into hydrate by a stream of aqueous vapour or moist air; it is not decomposed by dry air or dry hydrogen gas. Charcoal, at a bright red heat, decomposes it, with separation of potassium and formation of carbonic oxide and other products (see POTASSIUM). The aqueous solution, containing not less than 10 pts. of water to 1 pt. of the dry salt, is decomposed by lime at ordinary temperatures, and more quickly at the boiling heat, the carbonic acid being removed and caustic potassa produced. With more concentrated solutions, the reverse action takes place, caustic potassa abstracting carbonic acid from carbonate of calcium.

Carbonate of potassium is much used in chemical manufactures, especially for the preparation of soft soap, in glass making, and in the preparation of cyanide of potassium, ferrocyanide of potassium, Prussian blue, &c.; also for the preparation of nitrate of potassium from the nitrates of sodium, magnesium, and calcium.

Monopotassic Carbonate, or *Di-acid Carbonate of Potassium.* $KHCO^3 = K^2O.H^2O.2CO^2$. *Bicarbonate of Potassa. Berthollet's neutral Carbonate of Potassa.*—This salt is obtained by passing carbonic acid gas to saturation into a solution of 1 pt. of the commercial neutral carbonate in 4 or 5 pts. of water. Crystals of the acid carbonate soon form, and may be purified by washing with a small quantity of cold water. If a flocculent precipitate should form at first, consisting of alumina or silica, it must be removed by filtration. The carbonic acid evolved in alcoholic fermentation, or that which in some localities escapes from the soil, may be utilised for this purpose. A very good way of preparing the acid carbonate is to expose the mixture of neutral carbonate and charcoal, obtained by calcining cream of tartar and slightly moistened with water, to the action of carbonic acid gas; the presence of the charcoal greatly facilitates the absorption of the carbonic acid. The acid carbonate is dissolved out from the charcoal by boiling water and left to crystallise (Wöhler, Ann. Ch. Pharm. xxiv. 49). It must not be boiled in iron vessels, as it would dissolve a small quantity of the iron.

Acid carbonate of potassium crystallises in large rhomboïdal prisms belonging to the monoclinic system. Ratio of orthodiagonal to clinodiagonal to principal axis = 0·3734 : 1 : 0·491. Inclination of clinodiagonal to principal axis = 76° 35′. The crystals often exhibit the faces $\infty P . 0P . \infty P \infty . -P \infty . +2P \infty$ (*fig.* 125), the face $-P\infty$ frequently predominating so far as to obliterate the adjacent faces. $\infty P : \infty P = 138°$. Cleavage parallel to $\infty P \infty$, $-P\infty$, and $0P$. The crystals contain no water of crystallisation. When heated to 100° C., they give off water and carbonic anhydride, and are reduced to neutral carbonate: $2KHCO^3 - H^2O - CO^2 = K^2CO^3$.

Fig. 125.



Acid carbonate of potassium is much less soluble in water than the neutral carbonate. 100 pts. of water dissolve of it, according to Poggiale:

At 0° C. . . .	19·61 pts.	At 50° C. . . .	37·92 pts.
„ 10 . . .	23·33 „	60 . . .	41·35 „
„ 20 . . .	26·91 „	70 . . .	45·24 „

The aqueous solution when boiled gives off carbonic acid, and is gradually changed into neutral carbonate. The decomposition is sufficiently slow to admit of the purification of the acid carbonate from a boiling solution without much loss.

It dissolves but sparingly in boiling alcohol, only indeed to the amount of 1 pt. in 1200.

The aqueous solution of acid carbonate of potassium, mixed with the salts of other metals, generally forms double carbonates (pp. 782—788). It does not precipitate magnesium-salts in the cold, a character by which it is readily distinguished from the neutral carbonate.

Acid carbonate of potassium is much used in chemical operations where a pure potassium-salt is required, as it is very easily obtained in a pure and definite state. It is also used in medicine, in cases of gout and uric acid gravel.

Sesquicarbonate of Potassium?—A salt intermediate in composition between the two preceding, was said by Berthollet to be obtained in crystals, by mixing 100 pts. of the neutral with 131 pts. of the acid carbonate (1 at. K^2CO^3 with 2 at. $KHCO^3$), or by heating a solution of the di-acid carbonate as long as carbonic acid goes off; but according to H. Rose (Pogg. Ann. xxxiv. 149), the latter process yields almost pure neutral carbonate of potassium. The salt prepared by the first process should contain $K^4H^2C^3O^9$, or $2K^2O.3CO^2 + H^2O$; but its existence does not appear to have been satisfactorily proved.

Carbonate of Silver, Ag^2CO^3, is produced by precipitating nitrate of silver with an alkaline carbonate. It is white at first, but becomes yellow when the soluble salts are washed out, and blackens when exposed to light or gently heated. It dissolves readily in strong ammonia, and the solution treated with absolute alcohol yields a precipitate containing ammonia and carbonate of silver. (Berzelius.)

At 200° C. it gives off carbonic anhydride, and leaves pure oxide of silver, which begins to give off oxygen at 250°. By precipitating nitrate of silver with a large excess of alkaline carbonate and boiling, a basic carbonate is obtained, having, when dried at 100°, the composition $3Ag^2O.CO^2$, or $Ag^2CO^3.2Ag^2O$, perhaps only a mixture. (H. Rose, Ann. Ch. Pharm. lxxxiv. 202.)

Carbonates of Sodium.—Three of these salts are known, corresponding in composition to the potassium salts.

Disodic Carbonate, or *Neutral Carbonate of Sodium*, Na^2CO^3. *Subcarbonate of Soda. Soda. Mild mineral alkali. Alkali minerale fixum.*—This salt exists in the soda-lakes of Egypt and Hungary, and in the volcanic springs of Iceland, &c.; it also frequently occurs, mixed with sulphate of sodium, in the form of an efflorescence on walls, being formed from sodium-salts contained in the mortar. It is largely used in the arts, and was formerly obtained from *barilla*, the ash of *Salsola soda* and other plants growing on the sea-shore, and from the ash of sea-weed called *kelp*: but at the present day, nearly all the soda of commerce is obtained from common salt, by a process invented by Leblanc, towards the end of the last century, and perfected by D'Anfret and D'Arcye. This process consists of three stages:

1. The conversion of chloride of sodium into sulphate by heating it with sulphuric acid.
2. The conversion of the sulphate into carbonate by heating it in a reverberatory

furnace with chalk or limestone and coal. The materials are mixed in the proportion of about 3 pts. of dry sulphate of sodium, 3½ pts. chalk, and 2 pts. coal. The sulphate of sodium is reduced to sulphide, with evolution of carbonic oxide; and the sulphide of sodium is converted by the carbonate of calcium into carbonate of sodium and sulphide of calcium, which, by taking up lime, is for the most part converted into an insoluble oxysulphide of calcium:

$$2Na^2SO^4 + 3Ca^2CO^3 + C^9 = 2Na^2CO^3 + Ca^6S^2O + 10CO.$$

Part of the carbonic acid is, however, driven off from the lime by the heat, before it can act on the sulphide of sodium, and consequently, the fused mass contains, besides carbonate of sodium, a variable but always large amount of caustic soda.

The crude soda obtained by this process, has the appearance of dark-grey, half-vitrified balls,—hence called "black balls,"—being brought into this form by stirring while in the semi-fused state. It varies considerably in composition, as the following analyses will show, one of a sample from Cassel analysed by Unger, another from Newcastle, by Richardson.

Composition of Black Balls, or Crude Soda.

	Cassel.	Newcastle.
Carbonate of sodium	23·57	9·89
Caustic soda	11·12	25·64
Sulphate of sodium	1·99	3·64
Chloride of sodium	2·54	0·60
Carbonate of calcium	12·90	15·67
Oxysulphide of calcium	34·76	35·57
Sulphide of iron	2·45	1·22
Silicate of magnesium	4·74	0·88
Charcoal	1·59	4·28
Sand	2·02	0·44
Water	2·10	2·17
	99·78	100·00

3. *Purification.*—The crude or ball soda, after being crushed under millstones and sifted, or loosened and disintegrated by hot vapour, is lixiviated with warm water, which dissolves up the carbonate of sodium and the other soluble salts, leaving the oxysulphide of calcium undissolved. To effect the extraction with the smallest possible quantity of water, the crude soda is placed in perforated sheet-iron boxes, suspended just below the surface of the liquid, and is subjected to a continuous process of exhaustion in a series of lixiviating tanks, arranged somewhat like the pans for the evaporation of boric acid (p. 637). Each box containing the crude soda is first suspended in the lowest cistern, which contains a nearly saturated lye, then transferred to the next, which contains a somewhat weaker lye, and so on till it arrives at the highest, into which pure water is admitted from a cistern. When the lye in the lowest tank is saturated, it is transferred to the evaporating pan, its place being supplied by that in the next, which in its turn is replaced by the third, &c. In this manner, each portion of liquid gets thoroughly saturated, and the ball soda completely exhausted of soluble salts. The concentrated solution is boiled down to dryness, and yields a salt consisting chiefly of carbonate of sodium mixed with caustic soda and sulphide. This is called *soda-salt.*

4. To purify this product further, it is mixed with one-fourth of its bulk of sawdust, and exposed to a low red heat in a reverberatory furnace, for about four hours: the carbonic acid produced by the combustion of the sawdust, then converts the caustic soda into carbonate; also the sulphide, with evolution of sulphuretted hydrogen. This product contains about 50 per cent. of alkali, and forms soda-salt of the best quality.

5. To obtain *crystallised carbonate*, the purified soda-salt is dissolved in water, and the liquid when clarified is boiled down till a pellicle forms on the surface. The solution is then run into shallow crystallising vessels, and after standing for a week, the mother-liquor is drawn off, and the crystals are drained and broken up for the market. The crystals thus obtained contain 10 at. of water. The mother-liquor, which contains the foreign salts is evaporated to dryness for soda-salt.

The crystallisation of carbonate of sodium generally affords a safe guarantee of its purity; the crystals also dissolve in water much more quickly than the anhydrous salt, and are therefore more convenient for many purposes. But when the salt is required in the anhydrous state, as for glass-making, or as a flux in metallurgic operations, or where large quantities are wanted, as in the soap-manufacture, the soda-salt is preferred, as the large quantity of water in the crystals (nearly 63 per cent.) greatly increases the cost of transport. For some purposes, the crude soda as it leaves the furnace is sufficiently pure. In preparing it to be sold for such purposes, sulphate of sodium is used containing 10 to 12 per cent. of common salt; this remains unchanged in the soda, and communicates to it the property of easily falling to pieces in damp air, thus obviating the necessity of grinding.

For further details respecting the soda-manufacture, see *Miller's Chemistry*, vol. ii.; *Ure's Dictionary of Arts, Manufactures, and Mines*, iii. 720; *Chemical Technology, by Richardson* and *Watts;* Payen, *Précis de Chimie industrielle*, 4^{me} éd. i. 296.

Other methods of obtaining carbonate of sodium from the chloride have been proposed, but none of them appear to be able to compete with that above described.—1. Sulphate of iron produced by the oxidation of iron pyrites, is a cheap article, and has been proposed as a substitute for sulphuric acid in the first stage of the process: sulphate of sodium and chloride of iron are formed, the latter volatilising; or the two salts are dissolved together in water, and the solution is exposed to a low temperature, whereupon sulphate of sodium crystallises out, while chloride of iron remains in solution; or the sulphate of sodium may be made to crystallise out by raising the liquor to the boiling point.—2. Sulphate of sodium may be formed by roasting iron pyrites in a reverberatory furnace with common salt.—3. Sulphate of sodium is decomposed by a solution of caustic baryta or strontia, these earths being procured by decomposing the native sulphates with steam at a red heat; the sulphuric acid thereby set free might be used for converting the chloride of sodium into sulphate (Tilghmann).—4. Chloride of sodium is decomposed by hot steam in presence of alumina, whereby aluminate of sodium is formed; and the solution of this salt is decomposed by a current of carbonic acid gas (Tilghmann).—5. Ammonia gas is passed into a solution of chloride of sodium; then carbonic acid, whereby chloride of ammonium and acid carbonate of sodium are produced:

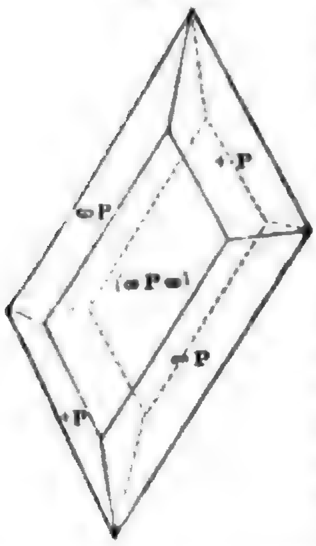
$$NaCl + NH^3 + CO^2 + H^2O = NaHCO^3 + NH^4Cl.$$

The acid carbonate of sodium being the less soluble salt of the two, crystallises out; it is converted into neutral carbonate by heat, and the carbonic acid evolved is used again. The mother-liquor containing the sal-ammoniac is boiled, to drive off any carbonate of ammonium that it may contain, and this salt is collected; the solution is then boiled with lime, to liberate the rest of the ammonia. In this manner the operation may be conducted with but little loss. (Schloessing and Roland.)

The impurities found in commercial carbonate of sodium are, *sulphide*, *hyposulphite*, *sulphate*, *chloride* and *ferrocyanide of sodium;* also *potassium-salts*, *carbonate of calcium*, and *carbonate of magnesium*. It may be purified by repeated crystallisation, or by washing the commercial crystals with cold water, dissolving them in hot water, stirring and cooling rapidly, to prevent formation of large crystals, then draining off the mother-liquor, and washing the crystalline powder with cold water. (Gay-Lussac.)

Neutral carbonate of sodium in the anhydrous state, is a white powder composed of translucent particles. It has a specific gravity of 2·4659 (Karstin). It melts at a moderate red heat, more easily than carbonate of potassium. It is quite undecomposible by heat in close vessels, but is easily decomposed when heated to redness in a current of steam or moist air, less easily in a current of dry air or hydrogen (H. Rose). It is decomposed by charcoal at a bright red heat, yielding carbonic oxide and sodium. In contact with water, it becomes heated, and forms a hydrate which dissolves. It has an alkaline taste and reaction, but is even less caustic than carbonate of potassium.

Fig. 126.



Hydrates.—There are several *hydrates* of neutral carbonate of sodium. — *a.* The ordinary crystals which separate from a moderately strong solution at ordinary temperatures, contain 10 at. (62·69 per cent.) water, $Na^2CO^3 + 10H^2O$. They belong to the monoclinic system. Orthodiagonal: clinodiagonal: principal axis = 0·7049 : 1 : 1·0452. Inclination of clinodiagonal = 57·40°. Ordinary combination + P . ∞ P . [∞ P ∞] (*fig.* 126); ∞P : ∞ P = 100° 20′. Cleavage tolerably distinct parallel to ∞ P ∞, less distinct parallel to [∞ P ∞]. Specific gravity = 1·423 (Haidinger). They effloresce in moderately dry air, crumbling to a white powder, and giving off 5 at. water at 12·5° C. and 9 at. at 38° (Schindler); 9 at. also in vacuo over oil of vitriol (Blücher). The 10-hydrated salt occurs as a natural product called *natron*, together with the mono-hydrate, at the soda-lakes of Egypt and Hungary, at Vesuvius, Etna, and in various parts of Asia, Africa, and America. (Dana, ii. 455.)

a. $Na^2CO^3 + 15aq.$ is obtained in crystals, when a solution of the neutral salt is exposed to a temperature of − 20° C., and the frozen water is afterwards allowed to liquefy; and $Na^2CO^3 + 9aq.$ by repeatedly crystallising a solution which at first contains a portion of acid carbonate. (Jacquelain, Compt. rend. xxx. 106.)

b. $Na^2CO^3 + 8\ aq.$ crystallises in right rhombic prisms with four-sided summits, when the 10-hydrated salt is melted and left to cool, or from a hot-saturated aqueous solution, apparently at a temperature lower than the crystallising point of the mono-hydrated, and higher than that of the deca-hydrated salt. (Thomson, *Annals of Philosophy*, 26, 44.)

c. $Na^2CO^3 + 7aq.$—This hydrate crystallises in two forms, (*a*) rhombohedral; (*b*) in trimetric crystals of the same form as Thomson's salt (which, according to Loewel, contains, not 8 at. but 7 at. water). When a solution saturated at the boiling heat is enclosed in a flask, which is corked immediately after the boiling has ceased, no crystals are deposited from it for a long time on cooling down to between 25° and 18° C.; but on cooling below 8° it deposits chiefly the trimetric 7-hydrated salt. Between 16° and 10°, it yields the rhombohedral salt (*a*), which redissolves between 21° and 22°, forms again at 19°, and on cooling from 10° to 4° becomes opaque, and passes into *b.* After cooling to a lower temperature and for a longer time, when the state of supersaturation ceases, the whole is converted into a mass of crystals of the deca-hydrated salt. (H. Loewel, Ann. Ch. Phys. [3] xxxiii. 334.)

d. $Na^2CO^3 + 6aq.$ crystallises from a solution of protosulphide of sodium exposed to the air, and frequently also from a mixed solution of carbonate of potassium and chloride of sodium. (Mitscherlich, Pogg. Ann. viii. 441.)

e. $Na^2CO^3 + 5aq.$ is formed when the 10-hydrated salt effloresces at 12·5° C. (Schindler), also when the same salt is melted in its water of crystallisation, and after the mono-hydrated salt has crystallised out between 70° and 80° C., the remaining liquid is kept for some time at 34°; it is also formed from the mono-hydrated salt by exposure to the air (Berzelius). It was once accidentally obtained at the Buxweiler soda works, in transparent rhombic octahedrons, which effloresced slightly in the air, and when dissolved in water and evaporated at 30° C. yielded the same salt. (Persoz, Pogg. Ann. xxiii. 303.)

f. $Na^2CO^3 + aq.$ is formed from the deca-hydrate by efflorescence, and is found native as *thermonatrite*, in the same localities as natron, and is indeed the more common salt of the two. It forms rectangular tables of the trimetric system with bevelled edges.

The same hydrate separates from a solution of the neutral carbonate concentrated by evaporation at the boiling heat, a circumstance which is made available in the soda manufacture for the purification of the salt, the crystalline powder which separates from the boiling solution being taken out and drained; if left to cool in the solution, it would redissolve. It does not undergo the aqueous fusion when heated, but gives off its water and becomes opaque at 87° C. It absorbs water from moist air, and is converted into the pentahydrate. In a warm atmosphere, it absorbs carbonic acid and forms sesquicarbonate.

Solution of Carbonate of Sodium.—According to Poggiale, 100 pts. of water dissolve of the anhydrous salt, 7·08 pts. at 0° C., 16·66 at 10°, 25·93 at 20°, 30·83 at 25°, 35·90 at 30°, and 48·5 at 104·6°, which is the boiling point of the saturated solution. According to Anthon, the 10-hydrated salt dissolves in 2 pts. of cold, and much less than 1 pt. of hot water. According to Loewel (*loc. cit.*) 100 pts. of a saturated solution contain of the 10-hydrated salt, 7 pts. at 0° C., 12·1 pts. at 10°, 16·2 pts. at 15°, 21·7 pts. at 20°, 28·5 pts. at 25°, 37·2 pts. at 30°, 51·7 pts. at 38°, and 45·5 pts. at 104°. Hence it appears that there is a maximum solubility at 38° C.

Solutions of carbonate of sodium are capable of assuming the state of supersaturation, like those of the sulphate. A solution saturated at the boiling heat and immediately enclosed in a sealed tube or a well corked flask, remains supersaturated at common temperatures, and frequently even when cooled several degrees below 0° C. Keeping the air in contact with the liquid from agitation, as by covering the hot solution with a glass shade, is often sufficient to prevent crystallisation at ordinary temperatures; but access of air then causes immediate solidification, attended with rise of temperature. The supersaturated solutions, as already observed, deposit the 7-hydrated salt in two different modifications, according to temperature (*vid. sup.*)

Monosodic Carbonate. Di-acid Carbonate of Sodium. Bicarbonate of Soda. $NaHCO^3$ or $Na^2O.H^2O.2CO^2$.—This salt exists in solution in alkaline mineral waters. It is prepared: 1. By passing carbonic acid gas into a solution of the neutral carbonate as long as it is absorbed.—2. By exposing the effloresced neutral carbonate placed on trays in a wooden case to an atmosphere of carbonic acid.—3. By adding commercial carbonate of ammonia (which is chiefly bicarbonate) to an equal weight of chloride of sodium, dissolved in three times its weight of water, stirring the whole well together, and leaving it to stand for several hours. Monosodic carbonate then separates in crystalline grains, while chloride of ammonium remains in solution (p. 794)

$$NaCl + NH^4.H.CO^3 = NaHCO^3 + NH^4Cl.$$

The precipitate is separated from the liquid by pressure in a screw press, but it always retains a portion of chloride of sodium.

Monosodic carbonate crystallises in oblique four-sided tables, and is sometimes obtained by the first method in crystals of considerable size; the second and third methods yield it in the form of a crystalline powder. It has a slight alkaline taste and reaction, and is permanent in dry air at ordinary temperatures. At a red heat, it gives off water and carbonic acid, and is reduced to anhydrous neutral carbonate.

100 pts. of water dissolve of monosodic carbonate, 8·95 pts. at 0° C., 10·04 pts. at 10°, 11·15 pts. at 20°, 12·24 pts. at 30°, 14·45 pts. at 40°, and 16·69 pts. at 70° (Poggiale). The solution gives off carbonic acid slowly at ordinary temperatures, more quickly at 70° C., rapidly at the boiling heat, and is ultimately reduced to neutral carbonate. It does not precipitate magnesium-salts in the cold, but at the boiling heat carbonic acid escapes and a precipitate of carbonate of magnesium is formed; this character distinguishes it from the neutral carbonate. Acid carbonate of sodium is used for the preparation of effervescing powders, and as a remedy in certain calculous disorders.

Tetrasodic Carbonate or *Sesquicarbonate of Sodium.* $Na^4H^2C^3O^8 + 2aq. = 2Na^2O.H^2O.3CO^2 + 2aq.$ — This salt, which may be regarded as a compound of the mono- and di-sodic carbonates ($2NaHCO^3 + Na^2CO^3$), is found in Africa, in the province of Sakenna, two days' journey from Fezzan, where it is called *trona;* it occurs at the foot of a mountain, forming a crust, varying in thickness from an inch to that of the back of a knife; also as *urao* at the bottom of a lake in Maracaibo, South America; efflorescences of it occur also near the Sweetwater River, Rocky mountains, mixed with sulphate and chloride of sodium (Dana, ii. 454). It is produced artificially: 1. By mixing the mono- and di-sodic carbonates in the proportions above indicated, melting them together, drying, and exposing the dried mass to the air of a cellar for some weeks; it then absorbs water, becomes crystalline, and contains spaces filled with shining crystals of tetrasodic carbonate. From a hot solution of mono- and di-sodic carbonates, the two salts crystallise out separately on cooling (Hermann, J. pr. Chem. xxvi. 312).—2. A solution of the monosodic salt, concentrated by boiling, but not boiled long enough to reduce it to the disodic salt, deposits the tetrasodic salt on cooling.—3. If 4 oz. of alcohol be poured on the top of a solution containing 100 grains of the disodic and 152 grains of the crystallised monosodic carbonate in 4 oz. of water, fine clear needle-shaped crystals of the tetrasodic salt form, after some days, at the surface of separation of the two liquids, while at the bottom of the solution, large crystals of the disodic carbonate are found covered by a crust of the monosodic salt. (Winckler, *Gmelin's Handbook*, iii. 83.)

The crystals of the native salt belong to the monoclinic system. Orthodiagonal: clinodiagonal: principal axis = 0·3552 : 1 : 1·282. Inclination of clinodiagonal to principal axis = 53° 50′. Observed combination $\infty P . 0P . + P\infty$, prismatically elongated in the direction of the orthodiagonal. $\infty P : \infty P = 132° 30′$. Cleavage very perfect, parallel to $+ P\infty$. They are colourless, transparent, or translucent, with vitreous lustre. Specific gravity 2·112. Hardness 2·5 to 3. Structure foliated, radiating; fracture conchoïdal. The artificial crystals are small, and of the same form as the native crystals. The salt has an alkaline taste and reaction, and is not efflorescent. At a red heat, or when its aqueous solution is boiled for many hours, it is reduced to the neutral carbonate. It is intermediate in solubility between the two preceding salts. According to Poggiale, 100 pts. of water dissolve of it, 12·63 pts. at 0° C., 18·30 pts. at 20°; 38·95 pts. at 40°; 29·68 pts. at 60°; 35·80 pts. at 80°; and 41·59 pts. at 100°. The solution is not rendered turbid by 1 pt. of sulphate of magnesium dissolved in 10 pts. of water. Evaporated in vacuo over oil of vitriol, it yields a mass of crystals composed of the mono- and di-sodic carbonates together. (H. Rose, Pogg. Ann. xxxii. 160.)

Carbonate of Sodium and Potassium. $KNaCO^3 + 6aq.$—Separates from a solution containing equivalent quantities of the component salts, in monoclinic crystals exhibiting the faces $\infty P . \infty P\infty . [\infty P\infty] . \infty P2 . [\infty P2] . 0P . + P . + P2 . + P\infty . + 2P\infty [P\infty] . + 2P\infty$. Inclination of faces; $\infty P : \infty P$ in the clinodiagonal principal section = 108° 34′; $0P : \infty P\infty = 131° 48′$; $0P : \infty P = 122° 46′$; $0P : + P\infty = 124° 48′$; $0P : + 2P\infty = 84° 19′$ (Marignac, Compt. rend. xlv. 650). Nearly the same angular values were observed by Sénarmont. The crystals are permanent in the air. A salt containing $K^2Na^4C^3O^9 + 18aq.$ is mentioned by Margueritte (Ann. Ch. Pharm. lvi. 220) as crystallising from the mother-liquor of ferrocyanide of potassium, and from a concentrated solution of the simple salts; but Marignac was not able to obtain this compound, and is of opinion that the formula is deduced from an incorrect analysis.

A mixture of the neutral carbonates of sodium and potassium in equivalent proportions, fuses at a much lower temperature than either of the salts separately, doubtless in consequence of the formation of the double salt. Such a mixture is very useful in the fusion of silicates, &c.

Carbonate of Sodium and Calcium, $CaNaCO^3 + 5aq$.– Occurs abundantly, as Gay-Lussite, at Lagunilla near Merida, in Maracaibo, covering *urao;* found also at Sangerhausen in Thuringia. The crystals are monoclinic. Inclination of axes = 78° 27′; $\infty P : \infty P = 68° 50'$. Cleavage perfect parallel to ∞P: less perfect parallel to $0P$. They are yellowish-white, translucent, double refracting, extremely brittle, with conchoïdal fracture, and exhibit a vitreous lustre on the broken surface. Specific gravity = 1·92—1·99. Hardness = 2–3. The mineral decrepitates when heated, and becomes opaque from loss of water. In the hydrated state it dissolves sparingly in water, without decomposition; but the anhydrous salt is resolved by water into carbonate of sodium and carbonate of calcium. Crystals of Gay-Lussite, altered to calcite, are sometimes called *natrocalcite*. (Dana, ii. 453).

The salt may be prepared by fusing the anhydrous carbonates of sodium and calcium together in atomic proportions.

The double salts of carbonate of sodium with other metals, magnesium, cobalt, zinc, &c., are described with the carbonates of those metals.

CARBONATE OF STRONTIUM. Sr^2CO^3. — Occurs native as *Strontianite*, at Strontian in Argyleshire, where it was first observed; also in Yorkshire, at the Giant's Causeway, at Clausthal in the Harz, at Bräunsdorf in Saxony, Leogang in Saltzburg, and other localities. It forms crystals of the trimetric system, isomorphous with arragonite and witherite. Ratio of brachydiagonal to macrodiagonal to principal axis = 0·6026 : 1 : 0·7237. The crystals are often prismatic from predominance of the faces $\infty P \,.\, \infty\breve{P}\infty$ and $\breve{P}\infty$. Cleavage tolerably perfect parallel to ∞P, less perfect parallel to $2\breve{P}\infty$. Specific gravity 3·605—3·713. Hardness 3·5 to 4. Colour white with various shades of grey, green, yellow, and brown. Streak white. Lustre vitreous. Transparent or translucent. Fracture uneven. Brittle. Before the blowpipe it melts on the edges and swells up, emitting a brilliant light, and when strongly heated in the reducing flame, imparts to it a reddish tinge. Strontianite occurs altered to cœlestine by the action of soluble sulphates. *Baryto-strontianite*, from Stromness in Orkney, appears to be a mechanical mixture of the carbonates of strontium and barium.

Carbonate of strontium obtained by precipitation is a white substance, smooth to the touch and has but little cohesion. It dissolves in 18045 pts. of cold water, and in 56545 pts. of water containing ammonia or carbonate of ammonium (Fresenius); in 300,000 pts. of water, whether cold or hot (Bineau, Compt. rend. xli. 509); in 833 pts. of water saturated with carbonic acid at 10° C. (Lassaigne), and in this state it occurs in some mineral waters, whence it crystallises by evaporation in needle-shaped crystals. When heated in close vessels, it does not give off carbonic anhydride at any temperature short of that of a forge fire; but in a stream of aqueous vapour or moist air, the decomposition takes place at a lower temperature, with formation of hydrate of strontium. It is not decomposed by solutions of alkaline sulphates at any temperature. (H. Rose, Pogg. Ann. xcv. 284).

CARBONATE OF THORINUM.—Alkaline carbonates, added to solutions of thorinum-salts, throw down a basic salt, with evolution of carbonic acid. Moist hydrate of thorinum absorbs carbonic acid from the air. The anhydrous earth is not soluble in water containing carbonic acid. (Berzelius.)

CARBONATES OF URANIUM.—These salts do not appear to exist in the separate state. Alkaline carbonates throw down from uranous chloride a precipitate of uranous hydrate; from uranous sulphate, a basic sulphate; from uranic salts, precipitates consisting of double carbonates.

Ammonio-uranic Carbonate, $2[(NH^4)^2O.CO^2] + U^4O^3.CO^2$ or *Carbonate of Uranyl* * *and Ammonium*, $\left.\begin{matrix}(NH^4)^4\\(U^2O)^2\end{matrix}\right\}C^3O^9$.—On digesting the precipitate thrown down by ammonia or carbonate of ammonia from a uranic salt in a solution of carbonate of ammonia at 60°—80° C., till the liquid is saturated, then filtering hot, and leaving the filtrate to cool, this salt separates in small transparent yellow crystals. It decomposes slowly in the air at common temperatures, more quickly when heated, ultimately leaving a residue of brick-red uranic oxide. It dissolves in 20 pts. water at 15° C., more easily in water containing carbonate of ammonia. The solution, when boiled, gives off carbonate of ammonia, and deposits the whole of the uranium as a yellow precipitate, consisting, according to Arfvedson, of uranic oxide with small quantities of ammonia and carbonic acid; according to Péligot, of uranate of ammonium; according to Ebelmen, of uranic hydrate containing 2 per cent. ammonia, but no carbonic acid. (Ebelmen, Ann. Ch. Phys. [3] v. 189; Delffs, Pogg. Ann. lv. 229.)

Potassio-uranic Carbonate, $K^4(U^2O)^2C^3O^9$.—Obtained by dissolving in acid carbonate of potassium the precipitate thrown down from uranic salts by the neutral carbonate,

---

* Uranyl, U^2O, is a monatomic radicle which may be supposed to exist in the uranic salts, *e.g.* uranic nitrate, $U^4O^3.N^2O^5 = (U^2O)NO^3$. (See URANIUM.)

evaporating at a gentle heat, and recrystallising. It forms a bright-yellow crystalline crust, which gives off carbonic anhydride at 300° C., and when heated to redness leaves a red-brick mixture of uranate and carbonate of potassium. It dissolves in 13·5 pts. of water at 15° C. without decomposition, but is partially decomposed by boiling water. which throws down uranate of potassium. The same compound is deposited after a while from a cold solution of the double carbonate, if very dilute and not containing excess of carbonate of potassium. Caustic potash precipitates the whole of the uranium as uranate of potassium, even in the presence of a large excess of carbonate of potassium. Acids, if not added in large excess, produce the same light yellow precipitate as is produced by carbonate of potassium in uranic salts. The double salt is insoluble in alcohol. (Ebelmen, *loc. cit.*)

Sodio-uranic Carbonate, $Na^4(U^2O)^2C^3O^9$.—Prepared like the preceding, which it resembles.

Calcio-uranic Carbonate, $Ca(U^2O)CO^3 + 10aq.$ — Found native as *Liebigite*, in amorphous rounded masses, having a distinct cleavage in one direction, transparent, of a beautiful apple-green colour, and vitreous lustre on the fractured surface. Hardness 2 to 2·5. Gives off water when gently heated and turns blackish-grey; does not fuse at a red heat, but turns black, and acquires an orange-red colour on cooling. Occurs, with Medjidite, near Adrianople, also at Johanngeorgenstadt, and in the Joachimsthal. (J. L. Smith, Ann. Ch. Pharm. lxvi. 253.)

A *calcio-uranous carbonate*, $CaUCO^3 + \frac{2}{3}$ aq., occurring in siskin-green scaly aggregations on pitch-blende at the Elias mine near Joachimsthal, has been examined by Vogl and Lindacker (Jahrb. k. k. geol. Reichsantalt, iv. 1853, 221). A carbonate of uranium, copper, and calcium, called *Voglite*, which may be regarded as an orthocarbonate $(U^4Cu^6Ca^2H^8)C^5O^{20} + 10aq.$, occurring in the same locality in aggregations of green dichroic, crystalline, pearly scales, has also been examined by Lindacker (*loc. cit.*)

CARBONATE OF YTTRIUM, Y^2CO^3 (containing also erbium and terbium).—Precipitated from yttrium-salts by carbonate of sodium, with 13 at. water in the cold, with 2 at. at the boiling heat. It is not easily decomposed by heat; dissolves sparingly in water containing carbonic acid; decomposes ammoniacal salts and dissolves in the liquid. Its solution in carbonate of ammonia deposits, after a time, if concentrated, a white crystalline double salt, which does not redissolve in carbonate of ammonia. Carbonate of yttrium dissolves also, though less easily, in the carbonates of potassium and sodium. (Berzelius.)

CARBONATES OF ZINC.—The *neutral carbonate*, or *metacarbonate*, Zn^2CO^3, occurs native as calamine (p. 713). It is doubtful whether this anhydrous salt can be obtained by precipitation. According to Schindler (Gmelin's Handbook, v. 16) it is produced by precipitating a solution of 1 at. sulphate of zinc in 10 pts. water with 1 at. diacid carbonate of potassium or sodium; but, according to Berzelius, the precipitate thus formed is $Zn^2CO^3.3ZnHO$.

Hydrocarbonates. *Zinc-bloom*, which occurs in nature as an earthy incrustation and in reniform masses, has, according to Berzelius, the composition $5Zn^2O.CO^2 + 3aq.$, or $Zn^2CO^3.Zn^2O.6ZnHO$; according to the analyses of Smithson and Bonsdorff, it is $3Zn^2O.CO^2 + 3aq.$, or $Zn^2CO^3.4ZnHO + aq.$ It is dull and opaque, with white, greyish, or yellowish colour, and makes a shining streak. Specific gravity = 3·58 to 3·6. Hardness = 2 to 2·5 (Gm. vi. 15). *Aurichalcite*, or *green calamine* (p. 476), found in the Altai, and at Matlock in Derbyshire, may be regarded as $Zn^2CO^3.3ZnHO$, in which the zinc is partly replaced by copper. *Buratite* (p. 686) is a hydrocarbonate of zinc containing copper and calcium, perhaps a mixture.

The precipitates formed by alkaline carbonates in solutions of zinc-salts, all appear to contain water, their constitution varying with the strength and temperature of the solutions, and with the nature and proportion of the precipitant. The results obtained in individual cases are variously stated by different authors; those obtained by H. Rose (Pogg. Ann. lxxxv. 107; Ann. Ch. Pharm. lxxxiv. 210) are as follows:

a. With 1 *at. Sulphate of Zinc and* 1 *at. Neutral Carbonate of Sodium.*—When the solutions are cold and concentrated, the precipitate consists mainly of $Zn^2CO^3.3ZnHO$ $\frac{2}{3}$aq., it remains unaltered at 60° C., but, after drying at 100°, is composed of $2Zn^2CO^3.7ZnHO + \frac{1}{2}aq.$ Very dilute cold solutions and concentrated boiling solutions yield a precipitate consisting mainly of $Zn^2CO^3.ZnHO$, or Zn^3HCO^4, combined with variable quantities of water.

b. With excess of Neutral Carbonate of Sodium.—The precipitate from cold solutions contained, when dried at 100° C., $5Zn^2CO^3.18ZnHO$; from moderately warm solutions $3Zn^2CO^3.10ZnHO$ (at 100°), but if very large quantities of liquid were used, it consisted of $Zn^2CO^3.2ZnHO$.

c. With 1 *at. Sulphate of Zinc and* 1 *at. Acid Carbonate of Sodium.* ($NaHCO^3$).—The precipitates contain more carbonic acid than the preceding. When they are dried in vacuo, a large quantity of carbonic acid escapes, and there remains the compound $Zn^2CO^3.3ZnHO + aq.$

d. With excess of Acid Carbonate of Sodium.—From cold solutions a precipitate was several times formed containing $2Zn^2CO^3.5ZnHO + \frac{1}{2}aq.$ (at 100°). A precipitation on the large scale, with rather warm solutions, yielded $Zn^2CO^3.ZnHO$. The precipitate obtained with cold solutions, after standing for some time, had, when air-dried, but not washed, the composition $3(2Zn^2CO^3.ZnHO. + \frac{5}{2}aq.$; after drying at 100°, it became $2Zn^2CO^3.ZnHO$.

e. With excess of Acid Carbonate of Potassium.—The precipitate not washed, but dried between filtering paper, had the composition $2Zn^2CO^3 + 2H^2O$. After washing with cold water and drying in the air, it became $4Zn^2CO^3 + 5aq.$; at 100° it was reduced to $4Zn^2CO^3 + aq.$; and at 200° to $5Zn^2CO^3 + aq.$

According to Schindler, basic salts having the composition $8Zn^2O.CO^2 + 2aq.$, or $Zn^2CO^3.7Zn^2O.2H^2O$ and $4Zn^2O.CO^2.2H^2O$, or $Zn^2CO^3.3Zn^2O.2H^2O$, are obtained by precipitating the corresponding sulphates of zinc with carbonate of sodium. According to Boussingault, ordinary sulphate of zinc precipitated with sesquicarbonate of sodium at ordinary temperatures, yields the salt $2Zn^2O.CO^2 + 2aq.$, or $Zn^4CO^4 + 2aq.$ According to Schindler, hot solutions of these salts yield a precipitate of the same composition as zinc-bloom. (Gm. v. 15.)

All the hydrocarbonates of zinc give off their water and carbonic anhydride at 200° C., and are reduced to zinc-oxide, Zn^2O. The native carbonate remains unaltered at 200°, but slowly gives off carbonic anhydride at 300°. (H. Rose.)

Ammonio-carbonate of Zinc, $NH^3.Zn^2CO^3$, or *Carbonate of Zinc and Zinc-ammonium*, $\left.\begin{matrix}(CO)''\\ Zn.NH^3Zn\end{matrix}\right\}O^2$.—Deposited in crystals from a solution of precipitated carbonate of zinc in a strong solution of carbonate of ammonium. (Favre, *Traité de Chimie par Pelouze et Frémy*, 2^me^ éd. iii. 47.)

Carbonate of Zinc and Potassium. $(Zn^{12}K^8H^2)C^{11}O^{33} + 7aq.$—Deposited in crystals from a solution of chloride of zinc mixed with sesquicarbonate of potassium. (Deville, Ann. Ch. Phys. [3] xxxiii. 75.)

Carbonate of Zinc and Sodium. $(Zn^{16}Na^6)C^{11}O^{33} + 8aq.$—Small shining crystals, apparently tetrahedrons and octahedrons, obtained in like manner. (Deville.)

CARBONATE OF ZIRCONIUM. Solutions of zirconium-salts, treated with excess of alkaline carbonate, yield a precipitate soluble in acid carbonates of alkali-metal, and containing, according to Hermann, 76·6 per cent. zirconia and 20·39 per cent. water, agreeing with the formula $2Zr^4O^3.CO^2 + 6aq.$ According to Klaproth, however, it contains 51·5 per cent., and, according to Vauquelin, 55·5 per cent. zirconia.

CARBONIC ACID and **ANHYDRIDE.** See CARBON, OXIDES OF (p. 770).

CARBONIC ETHERS. *Carbonates of Alcohol-radicles.*—These compounds are metacarbonates, M^2CO^3, in which one or both atoms of base are alcohol-radicles. Those which contain 2 at. of alcohol-radicle, the *neutral carbonic ethers*, are obtained: 1. By the action of carbonate of silver on the iodides of the alcohol-radicles.—2. By the action of potassium or sodium on the corresponding oxalates. This reaction is attended with evolution of carbonic oxide, and probably takes place in the manner represented by the following equation:

$$\underset{\text{Oxalate of ethyl.}}{2(C^2H^5)^2C^2O^4} + K^2 = \underset{\text{Carbonate of ethyl.}}{(C^2H^5)^2CO^3} + \underset{\text{Ethylate of potassium.}}{2C^2H^5KO} + 3CO.$$

3. By the action of water on the chlorocarbonates of the alcohol-radicles (produced by passing oxychloride of carbon into the alcohols), and by the dry distillation of these same products. In presence of water, the action is such as is represented by the equation,

$$\underset{\text{Chlorocarbonate of amyl.}}{2\left(\left.\begin{matrix}\overset{''}{CO}\\ C^2H^5\end{matrix}\right\}\begin{matrix}O\\ Cl\end{matrix}\right)} + H^2O = \underset{\text{Carbonate of amyl.}}{(C^5H^{11})^2CO^3} + CO^2 + 2HCl.$$

The decomposition of the chlorocarbonates by dry distillation is more complicated, a considerable quantity of charred matter remaining behind; but the principal reaction is doubtless the splitting up of 2 at. of the chlorocarbonate into a carbonic ether and oxychloride of carbon, *e. g.*:

$$2(CClO^2.C^5H^{11}) = (C^5H^{11})^2CO^3 + COCl^2.$$

The neutral carbonic ethers are ethereal oily liquids, insoluble in water, soluble in alcohol and ether. They are decomposed by alcoholic potash, yielding carbonate of potassium and the corresponding alcohols. Two volumes of the vapour of each of these ethers contain two volumes of alcohol-radicle, a fact which tends to establish the dibasicity of carbonic acid. (See ACIDS, p. 46.)

The *acid carbonic ethers* (carbonates of alcohol-radicles and hydrogen) are not known, but some of their salts have been prepared.

CARBONATE OF ALLYL. $C^7H^{10}O^3 = (C^3H^5)^2CO^3$.—Obtained by the action of iodide of allyl on carbonate of silver (Zeise, Ann. Ch. Pharm. xcvi. 361), or of potassium or sodium on oxalate of allyl (Cahours and Hofmann, Phil. Trans. 1857, p. 555). It is an ethereal liquid lighter than water. The alcoholic solution treated with hydrate of barium, yields carbonate of barium and allyl-alcohol.

CARBONATE OF AMYL. $C^{11}H^{22}O^3 = (C^5H^{11})^2CO^3$.—Prepared: 1. By saturating amylic alcohol with oxychloride of carbon, decomposing the product with water, treating it with oxide of lead to remove chlorine, drying over chloride of calcium, and rectifying (Medlock, Chem. Soc. Qu. J. i. 368).—2. By decomposing oxalate of amyl with potassium or sodium. The action begins immediately, but heat is required to complete it. By distillation, a yellow liquid is obtained, which begins to boil at 130° C., yielding amylic alcohol; afterwards carbonate of amyl passes over at 225°, the quantity amounting to about three-fourths of the original distillate. The residue contains a strong-smelling viscid matter. (Bruce, Chem. Soc. Qu. J. v. 132.)

Carbonate of amyl is a colourless liquid, having an agreeable odour, and specific gravity = 0·9144; it boils at 224°—225° C.

CARBONATE OF ETHYL. *Carbonic Ether.* $C^5H^{10}O^3 = (C^2H^5)^2CO^3$.—This ether is prepared: 1. By the action of potassium or sodium on oxalate of ethyl, the materials being heated in a retort to 130° C., and fresh potassium or sodium added, as long as carbonic oxide continues to escape. On cooling the residue and treating it with water, carbonate of ethyl rises to the surface: it is dried with chloride of calcium, and rectified over a small quantity of sodium, then heated alone till the boiling point becomes stationary, the portion which afterwards passes over being collected apart (Ettling, Ann. Ch. Pharm. xix. 17).—2. By distilling a mixture of ethyl-carbonate and ethyl-sulphate of potassium. (Chancel, Compt. rend. xxxi. 521.)

$$C^2H^5.K.CO^3 + C^2H^5.K.SO^4 = K^2SO^4 + (C^2H^5)^2CO^3.$$

Carbonate of ethyl is a colourless limpid oil, having a sweet ethereal odour, and burning taste. Specific gravity = 0·975 at 19° C. Boils at 125°, and volatilises without decomposition. Vapour-density = 4·243 (Ettling); 4·09 (Cahours); by calculation for a condensation to 2 vol. it is $\frac{60 + 10 + 48}{2} \times 0·0693 = 4·089$. It is inflammable, and burns with a blue flame. It is insoluble in water, but dissolves easily in alcohol and ether. With alcoholic potash, it yields alcohol and carbonate of potassium. Heated with sodium, it gives off carbonic oxide, and forms ethylate of sodium, together with carbonate (?) (Löwig, Pogg. Ann. l. 122). The reaction is perhaps: $C^5H^{10}O^3 + Na = 2C^2H^5NaO + CO$ (Gm. ix. 393). Chlorine decomposes carbonate of ethyl, abstracting hydrogen, and forming the two following substitution-products:

Tetrachlorocarbonic Ether, $C^5H^6Cl^4O^3$, commonly called *Bichlorocarbonic ether.*—Obtained by passing chlorine through carbonate of ethyl in diffused daylight, heating the liquid to 70°—80° C. in the latter part of the process, and expelling the excess of chlorine by a stream of carbonic anhydride. It is a colourless liquid having a saccharine odour, much heavier than water, and insoluble therein; soluble in alcohol. It is decomposed by dry distillation. (Cahours, Ann. Ch. Phys. [3] ix. 201.)

Perchlorocarbonic ether, $C^5Cl^{10}O^3$. (Cahours, *loc. cit.*; Malaguti, Ann. Ch. Phys. [3] xvi. 30.)—Produced by the continued action of chlorine on the preceding compound in direct sunshine. The resulting crystalline mass must be purified by pressing it between folds of bibulous paper, washing it rapidly with small quantities of ether, again pressing, and leaving it for some days in a dry vacuum. It cannot be purified by crystallisation from alcohol or ether.

It is a white mass, composed of small needles, and having a faint odour; melts between 86 and 88° C., and solidifies between 65° and 63°. At a higher temperature it partly distils unaltered, and is partly resolved into carbonic anhydride, chloride of trichloracetyl, and trichloride of carbon:

$$C^5Cl^{10}O^3 = CO^2 + C^2Cl^3O.Cl + C^2Cl^6.$$

When dissolved in alcohol, it changes to an oil which is a mixture of carbonate and trichloracetate of ethyl, a large quantity of hydrochloric acid being produced at the same time:

$$C^5Cl^{10}O^3 + 4C^2H^6O = (C^2H^5)^2CO^3 + 2(C^2H^5.C^2Cl^3O^2) + 4HCl.$$

Heated with potash-ley, it yields formate, chloride and acid carbonate of potassium, together with hydrochloric acid:

$$C^5Cl^{10}O^3 + 10KHO = 2CHKO^2 + 5KCl + 5HCl + 3KHCO^3.$$

With gaseous ammonia, it forms sal-ammoniac, chlocarbethamide (trichloracetamide, according to Gerhardt, *Traité*, i. 16·6), and an unknown substance, which crystallises in long needles (Malaguti). When thrown into aqueous ammonia, it makes a hissing noise, like red-hot iron in water, and forms trichloracetamide, together with carbonate, formate, and chloride of ammonium, and probably also other ammoniacal salts. (Malaguti.)

Carbonate of Ethyl and Potassium. *Ethyl-carbonate* or *Carbovinate of of Potassium*, $C^3H^5KO^3 = C^2H^5.K.CO^3$. (Dumas and Péligot, Ann. Ch. Phys. [2] lxxiv. 6.)—Obtained by passing carbonic anhydride into a solution of perfectly dry hydrate of potassium in absolute alcohol, the liquid being carefully kept cool, which is best effected by introducing from time to time small portions of anhydrous ether. A crystalline deposit then forms, consisting of ethyl-carbonate of potassium, together with neutral and acid carbonate. The ethyl-carbonate is formed as represented by the equation:

$$C^2H^6O + KHO + CO^2 = C^2H^5.K.CO^3 + H^2O;$$

the acid carbonate results from the action of the water thus formed on a portion of the ethyl-carbonate, and the neutral carbonate from that of the excess of potash on the acid carbonate. To separate the ethyl-carbonate, the mass is treated with an equal volume of ether, which dissolves the excess of free potash, and leaves the two other salts undissolved: the ethyl-carbonate is then dissolved out by alcohol, precipitated by ether, and rapidly dried. It might doubtless be more easily prepared from anhydrous ethylate of potassium, C^2H^5KO.

Ethyl-carbonate of potassium is a white nacreous salt, which burns with flame on platinum-foil, leaving a carbonaceous residue, and yields by distillation an inflammable gas, a small quantity of ethereal liquid, and a residue of carbonate mixed with charcoal. Water transforms it into alcohol and acid carbonate of potassium:

$$C^2H^5.K.CO^3 + H^2O = C^2H^5.H.O + KHCO^3.$$

Ethyl-carbonic acid, $C^2H^5.H.CO^3$, has not yet been obtained; neither has *Carbonate of methyl*, $(CH^3)^2CO^3$, nor *Methyl-carbonic acid*, $CH^3.H.CO^3$.

Carbonate of Methyl and Barium. *Methyl-carbonate of Barium.* $CH^3.Ba.CO^3$ (Dumas and Péligot, *loc. cit.*)—A solution of anhydrous baryta in anhydrous methylic alcohol, subjected to the action of carbonic anhydride, yields a white precipitate, which after washing with methylic alcohol, consists entirely of methyl-carbonate of barium:

$$CH^3.H.O + Ba^2O + CO^2 = CH^3.Ba.CO^3 + BaHO.$$

The salt is insoluble in methylic or ethylic alcohol, but dissolves easily in cold water. The solution soon however becomes turbid, depositing a considerable quantity of carbonate of barium and giving off carbonic anhydride. The action is greatly assisted by a gentle heat, and at the boiling-point it is instantaneous.

Carbonate of Methyl and Ethyl. $C^4H^8O^3 = CH^3.C^2H^5.CO^3$ (Chancel, Compt. rend. xxxi. 521).—Obtained by distilling a mixture of methyl-carbonate and ethyl-sulphate of potassium:

$$CH^3.K.CO^3 + C^2H^5.K.SO^4 = K^2SO^4 + CH^3.C^2H^5.CO^3.$$

Carbonate of Phenyl and Hydrogen. $C^6H^5.H.CO^3$.—Salicylic acid (*q. v.*) may be regarded as constituted in this manner. When subjected to dry distillation, it splits up into carbonic anhydride and hydrate of phenyl.

Carbonate of Tetryl. *Carbonate of Butyl.* $C^9H^{18}O^3 = (C^4H^9)^2.CO^3$.—Produced: 1. By the action of iodide of tetryl on carbonate of silver, the materials (12 grammes of each) being enclosed together in a sealed flask, and heated for two days in the water-bath,—distilling the product, collecting apart that which passes over above 180° C., and rectifying (Ph. de Clermont, Ann. Ch. Phys. [3] xliv. 336).—2. By the action of chloride of cyanogen, either gaseous or liquid, on tetrylic alcohol, in presence of water. (Humann, *ibid.* xliv. 340):

$$2(C^4H^9.H.O) + CNCl + H^2O = (C^4H^9)^2CO^3 + NH^4Cl.$$

It is a colourless limpid liquid, lighter than water, and having an agreeable odour like that of carbonate of ethyl. It boils at 190° C. Aqueous ammonia converts it into tetrylic alcohol and carbonate of tetryl.

CARBONITROTOLUYLIC ACID, also called *Nitrodracylic acid.*—An acid crystallising in white slender needles, obtained by treating toluene with excess of strong nitric acid. Glenard and Boudault (Compt. rend. xix. 505), who discovered it, assigned to it the formula $C^8H^6NO^4$; it is more probably isomeric with nitrotoluylic acid, $C^8H^7NO^4$; or perhaps, as suggested by List (Gm. xiii. 24), the product was merely nitrobenzoic acid containing nitrostyrol.

CARBONYL. CO.—The diatomic radicle of the carbonates, carbamates, carbamides, &c.

CARBOPYRROLIC ACID. $C^5H^5NO^3 = \left.\begin{matrix}NH^2(C^5H^2O)''\\ H\end{matrix}\right\}O.$ (Schwanert, Ann. Ch. Pharm. cxiv. 63.)—An amic acid, obtained by heating Malaguti's pyromucamide, $C^5H^6N^2O$ (*q. v.*), which Schwanert regards as carbopyrrolamide, $N^2.H^4.(C^5H^2O)''$, with baryta-water in sealed tubes. Ammonia is then formed, together with carbopyrrolate of barium, $C^5H^4BaNO^3$, which crystallises in nacreous laminæ, and is not decomposed by heating with potash-ley. The concentrated aqueous solution treated with hydrochloric acid, deposits carbopyrrolic acid as a white crystalline precipitate. The *lead-salt*, $C^5H^4PbNO^3$. forms sparingly soluble nacreous laminæ.

When the aqueous solution of carbopyrrolic acid is heated to 60° C. or above, pyrrol, C^4H^5N, separates from it as a brown flocculent substance.

CARBOSTYRIL. $C^9H^7NO = N(C^8H^7)(CO)''$.—Produced by the action of sulphide of ammonium on nitrocinnamic acid. Probably an acid, $C^9H^9NO^2$, is first produced and afterwards converted into carbostyril by loss of 1 at. water, thus:

$$\underset{\text{Nitrocinnamic acid.}}{C^9H^7(NO^2)O^2} + 2H^2S = C^9H^9NO^2 + 2H^2O + S^2$$

$$\text{and}\quad C^9H^9NO^2 - H^2O = \underset{\text{Carbostyril.}}{C^9H^7NO.}$$

The liquid is supersaturated with hydrochloric acid, filtered, and evaporated. It then deposits crystals of carbostyril, coloured brown by a resin, which may be removed by recrystallising the product several times from boiling water.

Carbostyril forms beautiful colourless silky needles, moderately soluble in boiling water, easily in alcohol and ether; melts when heated, and at a higher temperature sublimes in shining needles; dissolves in hydrochloric acid, also in boiling potash, not in ammonia or in sulphuric acid. Heated with solid potash, it yields an oil which appears to be a peculiar alkaloïd (C^8H^7N ?) Boiled with oxide of silver, it forms a compound insoluble in boiling water, from which it is separated by acids in its original state. (Chiozza, Compt. rend. xxxiv. 598.)

CARBOTHIACETONINE. $C^{10}H^{18}N^2S^2$.—The sulphydrate of this base is deposited in yellow crystals on mixing acetone with ammonia and sulphide of carbon:

$$3C^3H^6O + CS^2 + 2NH^3 = C^{10}H^{18}N^2S^2 + 3H^2O.$$

(Städeler, Pharm. Centr. 1853, p. 433; see also Acetone, p. 28.)

CARBOTHIALDINE. $C^5H^{10}N^2S^2$.—A colourless crystalline body, produced by adding sulphide of carbon to an alcoholic solution of aldehyde-ammonia. It is insoluble in cold water and in ether, sparingly soluble in cold alcohol, easily in boiling alcohol. Dissolves in hydrochloric acid, and is reprecipitated by ammonia. Boiled with excess of hydrochloric acid, it is resolved into sulphide of carbon, sal-ammoniac, and aldehyde. On adding oxalic acid and then ether to the alcoholic solution of carbothialdine, crystals of oxalate of ammonium are formed. The alcoholic solution forms, with *nitrate of silver*, a greenish-black precipitate, which gradually changes into sulphide of silver; with *mercuric chloride* it forms a thick white curdy precipitate, and with *copper-salts* a green precipitate. (Redtenbacher and Liebig, Ann. Ch. Pharm. lxv. 43.)

CARBOTRIAMINE. $N^3\left\{\begin{matrix}\overset{''''}{C}\\ H^5\end{matrix}\right.$—Guanidine, a base obtained by the action of oxidising agents on guanine, may be viewed as a triple molecule of ammonia (N^3H^9), in which 4 at. H are replaced by the tetratomic radicle carbon. Several substitution derivatives of carbotriamine are also known, viz.:

Carbomethyltriamine. $N^3.\overset{''''}{C}.(CH^3)H^4$.—This constitution may be ascribed to methyluramine, a base resulting from the action of oxidising agents on creatine.

Carbotriethyltriamine. $N^3.\overset{''''}{C}.(C^2H^5)^3H^2$.—Produced by heating cyanurate of ethyl with ethylate of sodium. (Hofmann, Proc. Roy. Soc. xi. 282.)

Carbodiphenyltriamine. $N^3.\overset{''''}{C}.(C^6H^5)^2.H^3$.—This is the composition of melaniline.

Carbotriphenyltriamine. $N^3.\overset{''''}{C}.(C^6H^5)^3.H^2$.—This base is produced by the action of tetrachloride of carbon on phenylamine (p. 765).

All these bases may likewise be regarded as diamines containing 1 at. cyanogen in place of 1 at. hydrogen; thus, carbotriamine = cyan-diamine = $N^2(CN).H^5$. (See Ethyl-, Methyl-, and Phenyl-Diamines and Triamines.)

CARBOVINIC ACID. Syn. with Carbonate of Ethyl and Hydrogen. (See Carbonic Ethers, p. 801).

CARBOVINOMETHYLIDE. Carbonate of Ethyl and Methyl (p. 801).

CARBUNCLE. A gem highly prized by the ancients, probably the almandin or noble garnet.

CARBUREIC ACID. Syn. with Allophanic Acid.

CARBYL, SULPHATE OF. $C^2H^4S^2O^6$.—Syn. with Ethionic Anhydride.

CARDAMINE AMARA. The dried herb of this plant contains an azotised and sulphuretted organic acid, either identical with or very similar to the myronic acid of black mustard seed, in combination with an organic (probably basic) compound. Moreover this acid, either free or in combination with bases, develops, under the influence of myrosyn, but not under that of the emulsion of bitter almonds, an acrid volatile oil, very much like oil of horse-radish or scurvy grass. The decided bitterness and lower degree of pungency of the fresh herb appear to be due to the absence of myrosyn or of some analogous compound capable of developing the pungent oil. (Winckler, Jahrb. pr. Pharm. xviii. 89.)

CARDAMOM OIL. An essential oil extracted by distillation from the seeds of several kinds of cardamom, especially *Alpinia cardamomum* and *Amomum repens.* It is pale, aromatic, and has a burning taste. Specific gravity, 0·945. Soluble in ether, alcohol, and oils, also in acetic acid and caustic potash. It detonates with iodine, and is set on fire by strong nitric acid. The oil amounts to 4·9 per cent. of the seed-kernels of amomum repens.

Crystals deposited from old cardamom oil were found by Dumas and Peligot (Ann. Ch. Phys. [2] lvii. 334) to have the formula of a hydrate of camphene, $C^{10}H^{16}.3H^2O$.

Cardamom also contains a fixed non-drying oil, which has a rancid bitter taste, and saponifies by boiling with potash.

CARDOL. An oily liquid contained, together with anacardic acid (p. 209), in the pericarp of the cashew-nut (*Anacardium* or *Cassuvium occidentale*). To obtain, it the pericarp is exhausted with ether, the ether distilled off, the residue washed with water to remove tannin, then dissolved in 15 to 20 pts. of alcohol, and digested with recently precipitated hydrate of lead, which takes up the anacardic acid, while the cardol remains in solution. The greater part of the alcohol is removed from the filtered liquid by distillation, water added to the remaining liquid till it becomes turbid, and afterwards acetate and subacetate of lead till it is decolorised. Lastly, the lead is precipitated by sulphuric acid.

Cardol is a yellow oily liquid, insoluble in water, very soluble in alcohol and ether; the solutions are neutral to litmus. It is not volatile, but decomposes when heated. It blisters the skin strongly. According to Städeler, it contains 60 per cent. carbon and 8·8 or 8·9 hydrogen, whence he deduces the formula $C^{42}H^{31}O^4$; it should perhaps be $C^{21}H^{30}O^2$.

Cardol precipitates basic, but not neutral acetate of lead. Strong sulphuric acid dissolves it with red colour. Nitric acid appears to form with it under certain circumstances, the same products as with anacardic acid. Strong potash-ley colours it yellow, and ultimately dissolves it; and the solution, in contact with the air, acquires a deep red colour, and then forms red or violet precipitates with most metallic salts. (Städeler, Ann. Ch. Pharm. lxiii. 137.)

CAREX. The ashes of *Carex remota* and *C. acuta* have been examined by E. Witting. (J. pr. Chem. lxix. 149.)

The fresh plants contained in 100 pts.:

	Water.	Organic matter.	Ash.
Carex remota	52·75	45·18	2·07
„ *acuta*	69·60	29·28	1·12

The ash contained:

	KCl	NaCl	K^2O	Na^2O	Ca^2O	Mg^2O
C. remota . .	2·81	10·23	23·52	0·72	7·86	9·22
C. acuta . .	4·90	7·28	37·94	0·35	7·90	7·36
	Fe^4O^3	Mn^2O	P^2O^5	SO^3	CO^2	SiO^2
C. remota . .	2·23	1·45	4·95	1·93	4·75	30·33
C. acuta . .	1·39	2·02	7·66	1·36	4·86	16·98

The quantities of soluble and insoluble constituents of the ash were as follows:—

Soluble in water.	Soluble in nitric acid.	Insoluble.
49·15	29·45	21·40
57·56	31·59	10·85

CARICA PAPAYA. *Papaw Tree.*—Every part of the papaw tree, except the ripe fruit, affords a milky juice, which is used in the Mauritius as an effectual remedy for the tape-worm. In Europe, however, whither it has been sent in the concrete state, it has not answered. The milky juice is said to make meat washed in it very tender, and the leaves and fruit are said to have the same effect upon the flesh of old hogs and poultry which are fed with them; the flesh, however, soon becomes putrid. The juice yields a substance resembling the flesh or fibre of animals. U.

CARIES. See Bone (p. 623).

CARINTHIN. A sub-species of augite. Colour black. Occurs massive and disseminated. Internally splendent. Resino-vitreous. Distinct cleavage of 124° 34′. Fracture conchoïdal. Greenish-black variety: translucent on the edges, velvet-black, opaque. Occurs on the Saualp in Carinthia, in a bed of primitive rock, associated with quartz, kyanite, garnet, and zoisite. (*Jameson's Mineralogy.*) U.

Dana (ii. 172) enumerates it as a variety of hornblende.

CARMIDINE. An organic base produced by passing lutidine over red-hot lime. Its composition has not been ascertained. It produces a fine red colour with pine-wood and hydrochloric acid, and pale green with bleaching powder; hence it is probably a mixture of pyrrhol and vertidine. (Gr. Williams, Chem. Soc. Qu. J. vii. 97.)

CARMINAPHTHA. $C^{10}H^{6}O^{3}$ (?)—A red colouring matter obtained by heating naphthalene with a solution of acid chromate of potassium, and adding sulphuric or hydrochloric acid. It is dissolved by alkalis and precipitated in its original state by acids. (Laurent, Rev. scient. xiv. 560.)

CARMINDIN. A product which Laurent obtained by the action of ammonia on dibromisatin. (See Isatin.)

CARMINE. CARMINIC ACID. (Pelletier and Caventou, Ann. Ch. Phys. [2] viii. 250, li. 194; Warren de la Rue, Ann. Ch. Pharm. lxiv. 1, 23; Gerh. iii. 750.)—The colouring matter of cochineal (*Coccus cacti*). To separate it, cochineal is exhausted with boiling water; the extract is precipitated by subacetate of lead slightly acidulated, care being taken not to add the lead-solution in excess; the precipitate is washed with distilled water till the wash-water no longer gives a precipitate with a solution of mercuric chloride, then decomposed by sulphuretted hydrogen; the filtrate is evaporated to a syrupy consistence and dried over the water-bath; and the dark purple product thus obtained is treated with alcohol, which extracts the carminic acid.

This acid forms a purple mass, fusible and soluble in all proportions in water and in alcohol. Sulphuric and hydrochloric acid dissolve it without alteration. It bears a heat of 136° C. without decomposition. It is very hygroscopic. Its solution forms red precipitates with the alkaline earths, also with the acetates of lead, zinc, copper, and silver.

According to De la Rue's analysis, carminic acid contains 54·1 per cent. carbon and 4·6 hydrogen, agreeing nearly with the formula $C^{14}H^{14}O^{8}$.

Schützenberger (Ann. Ch. Phys. [3] liv. 52) regards De la Rue's carminic acid as a mixture, and assigns to pure carminic acid the formula $C^{9}H^{8}O^{5}$; he states also that it is mixed in cochineal with an oxycarminic acid, $C^{9}H^{8}O^{7}$, and perhaps also with other acids of intermediate composition. These statements do not appear, however, to be borne out by the results of his analyses.

Carminic acid is decomposed by chlorine and bromine. The bromine-compound is yellow and soluble in alcohol.

Carminic acid treated with nitric acid yields *nitrococcusic acid;* a compound which is isomeric with trinitranisic acid, and crystallises in yellow rhomboïdal tables, soluble in cold but more soluble in hot water; soluble also in alcohol and ether. All its salts are soluble in water.

The mother-liquor of the preparation of carminic acid contains a crystalline substance, insoluble in alcohol and ether, soluble in ammonia, and identical with *tyrosine.* (Warren de la Rue.)

The colouring principle of cochineal (carmine) was previously obtained in an impure state by Pelletier and Caventou (Ann. Ch. Phys. viii. 250), by treating the cochineal with ether to extract the fatty matter, and digesting the residue in alcohol.

The fine red pigment known in commerce as carmine, is prepared by treating a solution of cochineal with cream of tartar, alum, or acid oxalate of potassium. The fatty and albuminous matters then coagulate and carry down the colouring matter with them.

By treating a solution of cochineal with an alkaline carbonate and alum, a compound of the colouring matter with alumina is obtained, known by the name of *carmine-lake.*

For this purpose, the coarser sediment deposited from a decoction of cochineal, after the finer particles have been separated by decantation, is generally used. For cheaper sorts, extract of Brazil wood is sometimes mixed with the cochineal.

Cochineal colours are used for dying wool and silk crimson or scarlet; but the colours it produces are remarkable more for brilliancy than for durability, and are easily stained by water or alkalis. The mordants used are alum, cream of tartar, and tin-salt. (See *Ure's Dictionary of Arts, Manufactures and Mines*, i. 616.)

CARMINITE, or *Carmine-spar.*—A mineral, probably consisting of anhydrous arsenate of lead and iron, from Hornhausen in Saxony, where it occurs, with Beudantite, in quartz and brown iron ore. It occurs in clusters of fine needles, and in spheroïdal forms with columnar structure, cleaving parallel to the faces of a rhombic prism. Hardness = 2·5. Lustre vitreous, but pearly on the cleavage faces. Colour carmine to brick-red; powder reddish-yellow. Translucent. Brittle. Before the blowpipe it gives the reactions of arsenic, lead, and iron. (Dana, ii. 410.)

CARMUFELLIC ACID. An acid obtained by Muspratt and Danson (Phil. Mag. [4] ii. 293), by the action of nitric acid on the aqueous extract of cloves. It separates from the concentrated solution in yellow micaceous scales; and by precipitation with acetate of lead, decomposition of the lead-precipitate with sulphuretted hydrogen, and evaporation, it may be obtained in white crystals. It is insoluble in alcohol, ether, and cold water, soluble in hot water, ammonia, and potash. When heated, it yields a yellow oil and emits an odour of burnt sugar. Strong sulphuric acid does not act upon it in the cold, but carbonises it when heated. A moderately concentrated solution of the acid precipitates the salts of the alkaline earths, forming a very thick gelatinous mass. With copper-salts it forms a green, with silver and ferrous salts a white, and with ferric salts a yellow precipitate, all of flocculent character.—Muspratt and Danson assign to the barium and lead-salts of this acid, the doubtful formula, $C^{34}H^{30}MO^{33}$.

CARNALLITE. $KCl.2MgCl.6H^2O$.—A salt which sometimes separates in coarse-grained masses, often coloured by oxide of iron, from the mother-liquor of rock-salt, also of certain brine-springs; it may also be obtained by careful evaporation of the mother-liquor of sea-water. (Jahresber. d. Chem. 1856, p. 884; 1858, p. 739.)

CARNAUBA WAX. A wax which coats the leaves of the *Corypha cerifera*, a palm growing in Brazil, and is obtained by drying the leaves and melting the coating, which separates in scales. It forms hard, brittle lumps of yellowish-white colour, inclining to green, and has an odour of melilot, but no taste. It melts at 97° C., or according to Lewy (Ann. Ch. Phys. [3] xiii. 438) at 83·5°. According to Brande (Phil. Trans. 1811, p. 261), it is insoluble in cold, sparingly soluble in hot alcohol, forming a greenish solution. Similarly with ether. With fixed oils it mixes in all proportions. With caustic potash it forms a pale rose-coloured mass without actually saponifying. Nitric acid converts the wax into a yellow friable mass. Chlorine bleaches it. In other respects it behaves like beeswax. According to Lewy, it contains 80·3 per cent. carbon and 13·0 hydrogen. (Handw. d. Chem. 2te Aufl. ii. [2] 807.)

CARNAT. A variety of lithomarge from Rochlitz. (Breithaupt.)

CARNELIAN. A subspecies of chalcedony, of white, yellow, brown, and red colour. It has a conchoïdal fracture. Specific gravity 2·6. Semitransparent, with glistening lustre. The finest specimens come from Cambay and Surat in India. It is found in peculiar strata, thirty feet below the surface, in nodules of a blackish-olive colour, passing into grey. These, after two years' exposure to the sun, are boiled for two days, and thereby acquire the lively colours for which they are prized in jewellery. Carnelian is softer than common chalcedony. It consists mainly of silica (about 94 per cent.) with alumina, and a small quantity of sesquioxide of iron. According to Gauthier de Claubry, the colour proceeds, not from oxide of iron, but from an organic substance. This, however, is denied by Heintz. (Pogg. Ann. lx. 519.)

CAROLATHIN. A mineral containing organic matter, found in a coal-mine in Upper Silesia. It has the aspect of honey-stone; colour, honey-yellow to wine-yellow: translucent on the edges; has a faint unctuous lustre; very brittle. Specific gravity 1·515. Hardness 2·5. It is decomposed by hydrochloric acid. It contains about 15·10 per cent. water, 47·25 alumina, 29·52 silica, and 1·33 carbon. The water is not completely given off below 290° C., at which temperature the organic matter begins to decompose. The organic matter appears to be allied to humic acid. (Sonnenshein, J. pr. Chem. lx. 268.)

CAROTIN. $C^{18}H^{24}O$.—The colouring matter of the carrot (*Daucus Carota*). It was first isolated by Wackenroder in 1831 (Geiger's Mag. xxxiii. 144), afterwards examined by Zeise (J. pr. Chem. xl. 297), and recently with greater exactness by Husemann (Ann. Ch. Pharm. cxvii. 200).

Carrots also contain a colourless substance, hydrocarotin, $C^{18}H^{30}O$, containing 6 at. H more than carotin; and as they are colourless in the early stages of their growth, Husemann considers it probable that they at first contain only hydrocarotin, which gradually changes to red carotin by oxidation.

Preparation.—The expressed juice of bruised carrots is precipitated with sulphuric acid, to which a small quantity of tincture of galls is added; the half-dried coagulum is repeatedly boiled with five or six times its volume of 80 per cent. alcohol, which extracts the hydrocarotin; the residue, after drying at a gentle heat, is exhausted with sulphide of carbon; and the filtrate is mixed with an equal volume of absolute alcohol The solution, when left to itself, deposits the carotin in crystals of the dimetric system, which, while in the liquid, exhibit a golden-green lustre by reflected light; if, however, the sulphide of carbon was mixed with much alcohol, or if the solution was too much concentrated, the crystals are microscopic, and of a ruby-colour. The crystals are washed on a water-bath funnel with boiling 80 per cent. alcohol, afterwards with absolute alcohol, till the wash-liquid exhibits only a faint yellow colour, and when evaporated on a watch-glass, leaves small octahedral crystals.

The pure carotin which remains, exhibits, after drying in the air at mean temperature, a red-brown colour with velvet lustre, becoming bright red when dried at 100° C. It smells like Florentine violet-root, especially when heated. It is rather heavier than water; dissolves sparingly in alcohol, ether, and chloroform, easily in sulphide of carbon, benzene, and volatile oils; fixed oils dissolve it slowly, with red colour. It becomes soft at 126° C., and melts at 168° to a thick dark red liquid.

Carotin forms at low temperatures a colourless crystalline hydrate, which may be obtained by placing a concentrated solution of carotin in sulphide of carbon (not anhydrous) in a watch-glass, over a freezing mixture producing a temperature of $-10°$ C. It then separates as a white efflorescence made up of small needles; but as soon as it is taken out of the freezing mixture, it gives up its water, and is converted into red carotin. The same phenomenon is exhibited by a solution of carotin in benzene, excepting that the hydrate is then slightly yellow. Another hydrate is sometimes formed by adding to a dilute solution of carotin in sulphide of carbon, so much absolute alcohol, that the turbidity at first produced shall disappear, at least on heating the liquid. It separates in thin, iridescent, six-sided laminæ, and appears to be more stable than the first-mentioned hydrate. The composition of these hydrates has not been determined.

Carotin is very unstable; during the evaporation of its solution, it often separates in a light yellow amorphous modification, which is but sparingly soluble in sulphide of carbon. The red crystals gradually become colourless from without inwards, when exposed to daylight, and more quickly in sunshine; the new substance thus formed is inodorous, dissolves readily in alcohol or ether, but with difficulty in sulphide of carbon or benzene, and separates from these solutions in the amorphous state. The same change takes place when carotin is exposed for a long time to a heat of 150° C. Whether the new substance thus formed has the same composition as carotin, is not yet made out. Carotin heated to 250° C. forms a mobile liquid, which on cooling solidifies to a soft yellowish-red mass. At higher temperatures, it carbonises and gives off empyreumatic vapours.

Fuming nitric acid dissolves carotin with yellow colour, and water separates from the solution a yellow nitro-compound. *Strong sulphuric acid* dissolves carotin with purple colour; and on carefully adding water, the colour disappears, and a somewhat modified carotin separates in dark green flocks, which, like carotin altered by light, are coloured brown by sulphuric acid.—*Sulphurous anhydride* changes the colour of carotin to dark indigo, but does not alter it further; the blue substance crystallises from benzene in red cubes, and is also converted into red carotin by boiling with potash.

Dry chlorine gas converts carotin into tetrachloro-carotin, a white substance soluble in ether and in sulphide of carbon, becoming soft and dark-red at 100° C., melting at 120°. Another substitution-product containing less chlorine appears also to be formed.

Bromine and *iodine* likewise decompose carotin, forming substitution-products which are more fusible than carotin itself.

Carotin is not decomposed by dilute acids, by hydrochloric acid gas, sulphuretted hydrogen, sulphide of ammonium, or by alkalis, either in aqueous or in alcoholic solutions. Solutions of carotin are not precipitated by metallic salts; the alcoholic solution is coloured greenish by ferric chloride.

A substance having the same colour and composition as carotin, is obtained by treating tribromhydrocarotin, $C^{18}H^{27}Br^{3}O$, with potash; but the identity of the two has not yet been completely established. (See HYDROCAROTIN.)

CARPHOLITE. A silicate of manganese, aluminium, and iron, found near Schlackenwald in Bohemia, in radiated and stellated tufts, sometimes also in rhombic prisms of 111° 27′, and 68° 33′, with the lateral edges truncated. Specific gravity =

2·935. Hardness = 5 to 5·5. It is opaque, with straw-yellow or wax-yellow colour (hence the name, from *καρφος*, straw), and vitreous lustre. Its analysis gives—

SiO^2	Al^4O^3	Mn^4O^3	Fe^4O^3	Ca^2O	H^2O	F.		
37·53	26·47	18·33	6·27	—	11·36	—	= 99·961	(Steinmann).
36·15	28·67	19·16	2·54	0·27	10·78	1·40	= 98·97	(Stromeyer).
36·15	19·74	20·76	9·87	2·56	11·35	—	= 100·43	(Hauer).

Hence the formula $2R^4O^3.3SiO^2 + 3\,aq.$, the sesquioxides of aluminium, manganese, and iron being supposed to replace each other isomorphously.

By reducing the sesquioxides to protoxides (substituting $r = \frac{2}{3}R$), the formula becomes that of an orthosilicate, $2r^2O.SiO^2 + aq. = r^4SiO^4 + aq.$ According to Kobell, the manganese and iron are in the state of protoxides, and the formula is $(Mn^2O.Al^4O^3) + 2(H^2O.SiO^2)$. (*Rammelsberg's Mineralchemie*, p. 587.)

CARPHOSIDERITE. A hydrated phosphate of iron, containing small quantities of manganese and zinc, occurring in reniform masses and incrustations of straw-yellow colour and resinous lustre. Specific gravity 2·5; hardness 4 to 4·5. It is found in fissures in mica slate, and was first distinguished by Breithaupt, among some specimens from Labrador. (Dana, ii. 431.)

CARPHOSTILBITE. A straw-yellow variety of Thomsonite, from Bernflord, Iceland.

CARPOBALSAMUM. A commercial name of the volatile oil obtained from pimento, the fruit of *Myrtus pimenta.* It is yellowish, heavier than water, and smells like cloves.

CARROLITE. (W. L. Faber, Sill. Am. J. (2) xiii. 418; Smith and Brush, *ibid.* xvi. 366; Genth, *ibid.* xxiii. 115.)—A sulphide of cobalt and copper, from Finksburg, Carrol County, Maryland, U. S. Forms homogeneous, very friable masses, with indistinct cleavage; tin-white to steel-grey colour; metallic lustre; iron-black streak; uneven fracture, approaching to the conchoïdal. Hardness 5·5. Specific gravity 4·58. The mineral has not been found in distinct crystals, but appears to belong to the regular system.

S	As	Cu	Co	Ni	Fe	Quartz		
27.04	1·82	32·99	28·50	1·50	5·31	2·13	= 99·30	(Faber).
41·29	–	18·15	37·70	1·54	1·26	–	= 100·08	(Smith and Brush).
41·71	–	17·55	38·70	1·70	0·46	0·97	= 100·19	(Genth).

Faber deduces from his analysis (after deducting the nickel, arsenic, and iron, together with 3·468 per cent. sulphur required to form copper-nickel and magnetic pyrites), the formula $Co^2S.Cu^4S$ or CoCcuS. Smith and Brush regard the mineral as cobalt pyrites (Co^3S^2), in which part of the cobalt is replaced by copper.

CARRAGHEEN MOSS. See Caragheen Moss (p. 747).

CARROT. *Daucus Carota.*—The ashes of the root, leaves, and seed of the carrot have been analysed by Way and Ogston (Jahresber. f. Chem. 1849, Table E to page 656, and 1850, Table B to p. 660) with the following percentage results:

	White Belgian		Long red Surrey (on poor sandy soil)		
	Root.	Leaves.	Root.	Leaves.	Seed.
Potash	21·40—41·97	6·55— 7·53	43·73	17·10	16·21

CARROT, OIL OF. The root of the carrot contains a very small quantity (0·0114) per cent. of a volatile oil, of specific gravity 0·8863 at 12° C., which may be obtained by distilling the fresh roots with water. It has a very strong pungent taste and smell, dissolves sparingly in water, freely in alcohol and in ether. (Wackenroder, Mag. Pharm. xxxiii. 145.)

CARTHAMIN. The colouring principle of safflower (*Carthamus tinctorius*), first examined by Chevreul, afterwards more fully by Schlieper (Ann. Ch. Pharm. lviii. 362.)

The flowers of *Carthamus tinctorius* contain two coloured principles, one yellow, soluble in water, and of no use in dyeing, the other red, soluble in alkalis and precipitable by acids from its alkaline solutions: this is *carthamin*. To prepare it, safflower is first washed repeatedly with water, to free it from the yellow substance, then treated with solution of carbonate of sodium; the liquid is saturated with acetic acid; and pieces of cotton are immersed in it, on which the carthamin is deposited. After twenty-four hours, the cotton is removed and treated with solution of carbonate of sodium, which redissolves the colouring matter; the solution is mixed with citric acid, whereby the carthamin is precipitated in red flocks; and, lastly, these flocks are dissolved in alcohol. The solution evaporated in vacuo yields the carthamin in the form of a powder, having a deep red colour with greenish iridescence. It is sparingly soluble in water, insoluble in ether, but easily soluble in alcohol, yielding a fine purple solution.

According to Schlieper, carthamin contains 56·9 per cent. carbon and 5·6 hydrogen, agreeing with the formula $C^{14}H^{16}O$.

The yellow colouring matter of carthamus is acid. It has a bitter taste and great colouring power. It combines readily with oxygen, and is converted into a brown substance. It unites with oxide of lead, forming the compound $(Pb^2O)^3.C^8H^{10}O^8$.

The red colouring matter of carthamus is used in dyeing, and for the preparation of rouge. The flowers, after being freed as much as possible from the yellow dye by repeated washing with water, are pressed and dried, and sent into the market in the form of cakes, known in commerce as *safflower*, *Spanish red*, or *China cake*.

For the preparation of rouge, the red colour is extracted by a solution of carbonate of sodium, and precipitated by sulphuric acid or by lemon juice previously depurated by standing. This precipitate is dried on earthen plates, mixed with talc or French chalk, reduced to a powder by means of the leaves of shave-grass triturated with it till they are both very fine, and then sifted. The fineness of the powder and proportion of the precipitate constitute the difference between the finer and cheaper rouge. It is likewise spread very thin on saucers, and sold in this state for dyeing.

Carthamus is used for dyeing silk or cotton of a poppy, cherry, rose, or bright orange-red. The cakes of safflower having been disintegrated by steeping in water, the red fibre is washed in sieves as long as the water which runs through acquires a yellow colour. It is then put into a deal trough, and sprinkled at different times with pearl ashes, or rather soda, well powdered and sifted, in the proportion of 6 lbs. to 100, mixing the alkali well as it is put in. The alkali should be saturated with carbonic acid. The carthamus is then put on a cloth in a trough with a grated bottom, placed on a larger trough, and cold water poured on till the larger trough is filled; and this treatment is repeated, with addition of a little more alkali toward the end, till the carthamus is exhausted and become yellow. Lemon juice or sulphuric acid is then poured into the bath, till it is turned of a fine cherry colour, and after it is well stirred, the silk is immersed in it. The silk is wrung, drained, and passed through fresh baths, washing and drying after every operation, till it is of a proper colour; after which it is brightened in hot water and lemon juice. For a poppy or fire colour, a slight annotto ground is first given; but the silk should not be alumed. For a pale carnation, a little soap should be put into the bath. All these baths must be used as soon as they are made, and cold, because heat destroys the colour of the red fecula. The colours produced by carthamus are very beautiful, but fugitive. (See *Ure's Dictionary of Arts, Manufactures and Mines*, i. 624.)

CARTILAGE. The cartilages consist of a dry flexible tissue, which contains but a small quantity of inorganic matter, and when boiled with water yields chondrin (*q. v.*), a substance resembling gelatin, but differing in certain reactions.

According to Scherer, the cartilage of the ribs contains 40·5 to 50·9 per cent. carbon, 7·0 to 7·1 hydrogen, 14·9 nitrogen, and 27·2 to 28·5 oxygen. (See BONE.)

CARVENE, CARVOL, and **CARVACROL.** (Völckel, Ann. Ch. Pharm. xxxv. 308; lxxxv. 246; Schweizer, *ibid.* l. 329; Gm. xiv. 283, 414.)—Essence of caraway consists of two essential oils, *carvene*, $C^{10}H^{16}$, and *carvol*, $C^{10}H^{14}O$, which may be separated by fractional distillation. The latter, however, is more easily prepared by agitating oil of caraway with an alcoholic solution of sulphide of ammonium: *sulphydrate of carvol*, $(C^{10}H^{14}O)^2.H^2S$ is then formed, and this compound, decomposed by ammonia yields carvol. (Varrentrapp, Handw. d. Chem. 2te Aufl. ii. [2] 812.)

Carvene is a colourless mobile oil, lighter than water, having a slight agreeable odour and aromatic taste. Boils at 73° C. It is nearly insoluble in water; very soluble in alcohol and ether; it absorbs hydrochloric acid, and forms a crystalline compound, which melts at 50·5 C. and consists of $C^{10}H^{16}.2HCl$.

Carvol is a liquid boiling at 250° C. Specific gravity 0·953. It is resinised by strong nitric or sulphuric acid, and forms with hydrochloric acid an oily compound containing $C^{10}H^{14}O.HCl$. *Sulphydrate of carvol*, $2C^{10}H^{14}O.H^2S$, crystallises from solution in alcohol in long needles having the lustre of satin; they are fusible, and when cautiously heated, sublime almost unaltered (Varrentrapp). *Sulphydrate of sulphocarvol*, $2C^{10}H^{14}S.H^2S$, is produced by passing sulphuretted hydrogen for a long time through alcohol in which the preceding compound is suspended. It then separates as a thick oil, which dissolves in ether, and is deposited therefrom in white flocks. The ethereal solution precipitates chloride of mercury and dichloride of platinum; but the precipitates have not a constant composition. (Varrentrapp.)

Carvacrol, a substance isomeric with carvol, is obtained by treating oil of caraway with potash, or again by treating the same oil with iodine, cohobating several times, and washing the product with potash; as thus obtained, however, it is mixed with carvene. Carvacrol is also found among the products of the action of iodine on camphor (p. 729), $C^{10}H^{16}O + 2I = 2HI + C^{10}H^{14}O$. Carvacrol when pure is a colourless viscid oil lighter than water, and soluble in water to a small amount. It has an unpleasant odour, and an acrid very persistent taste. Boils at 232° C., giving off vapours which irritate the organs of respiration. It burns with a bright very smoky flame.

CARYOPHYLLIC ACID. Syn. with Eugenic Acid.

CARYOPHYLLIN. $C^{10}H^{16}O$.—This substance, isomeric with common camphor, is contained in considerable quantity in *cloves*, the dried flower-buds of the clove-tree, *Caryophyllus aromaticus*, which is indigenous in New Guinea and the Moluccas, and cultivated in Sumatra, in the isles of Mauritius and Bourbon, and in Brazil. It may be extracted by treating cloves with cold alcohol; the liquid in about fifteen days becomes covered with crystals, which may be purified with solution of soda. The cloves may also be exhausted with ether, and the caryophyllin separated by agitating the ethereal solution with water. Crude oil of cloves also deposits caryophyllin on standing.

Caryophyllin forms silky colourless needles arranged in radiating groups, destitute of taste and smell. It melts with difficulty and with partial decomposition (Dumas); sublimes at about 2 5° C. (Muspratt). It dissolves sparingly in cold alcohol, easily in boiling alcohol and in ether; also in hot caustic alkalis. Strong sulphuric acid dissolves it in the cold without blackening, but the liquid blackens when heated. Nitric acid converts it into a resinous substance. (Gerh. iv. 278.)

CASCALHO. The alluvial soil, consisting of ferruginous sand and clay, in which Brazil diamonds are found.

CASCARILLA BARK. The bark of cascarilla, *Croton eleutheria* and *Cr. cascarilla*, shrubs indigenous in the West Indies. It contains albumin, tannin, a red colouring matter, a fatty substance, an essential oil having an agreeable odour, wax, resin, a gummy substance, starch, pectic acid, wood, fibre, and cascarillin, together with a calcium-salt and chloride of potassium. It possesses tonic and aromatic properties.

CASCARILLA, OIL OF. Cascarilla bark contains a volatile aromatic oil, amounting to 0·37 per cent. (Bley), 0·87 (Trommsdorf). It is dark yellow, sometimes with a bluish tinge; of specific gravity 0·909—0·938; boils at 180° C. or higher (Trommsdorf). According to Völckel, the first distillate is colourless, of specific gravity 0·862, and boils at 173° C. (Gm. xiv. 363.)

CASCARILLIN is obtained by treating the aqueous extract of cascarilla bark with acetate of lead, filtering, and precipitating the excess of lead with sulphuretted hydrogen. The liquid evaporated at a gentle heat deposits an amorphous mass, from which, after washing with cold alcohol, the cascarillin may be extracted by boiling alcohol. It is purified by recrystallising several times, after decolorising with animal charcoal. It crystallises in needles or in hexagonal plates, which are colourless, bitter, fusible, decomposible by heat, sparingly soluble in water, more soluble in alcohol, ether, hydrochloric acid, and sulphuric acid. The aqueous solution is not precipitated by alkalis, tannin, acetate, or subacetate of lead. (Duval, J. Pharm. [3] viii. 91.)

CASE-HARDENING. Steel when hardened is brittle, and iron alone is not capable of receiving the hardness which steel may be brought to possess. There is, nevertheless, a variety of articles in which it is desirable to obtain all the hardness of steel together with the toughness of iron. These requisites are united by the art of case-hardening, which does not differ from the making of steel, except in the shorter duration of the process. Tools, utensils, or ornaments intended to be polished, are first manufactured in iron and nearly finished, then put into an iron box, together with vegetable or animal charcoal in powder, and cemented for a certain time. This treatment converts the external part into a coating of steel, which is usually very thin, because the time allowed for the cementation is much shorter than when the whole is intended to be made into steel. Immersion of the heated pieces in water hardens the surface, which is afterwards polished by the usual methods. Moxon (*Mechanic Exercises*, p. 56) gives the following receipt: — Cow's horn or hoof is to be baked or thoroughly dried, and pulverised. To this add an equal quantity of bay salt: mix them with stale chamber ley, or white wine vinegar: cover the iron with this mixture, and bed it in the same in loam, or enclose it in an iron box: lay it then on the hearth of the forge to dry and harden: then put it into the fire, and blow till the lump have a blood-red heat, and no higher, lest the mixture be burnt too much. Take the iron out, aud immerse it in water to harden.

The same end is now more effectually attained by heating the tool red-hot, and sprinkling over it ferrocyanide of potassium (yellow prussiate) in fine powder, then quenching it in water. Some prefer smearing the surface of the bright iron with loam made into a thin paste, with solution of the yellow prussiate, drying it slowly, then heating it nearly to whiteness, and plunging it into cold water, when the heat has fallen to dull redness. (See *Ure's Dictionary of Arts, Manufactures and Mines*, i. 630.) U.

CASEIN constitutes the chief part of the nitrogenised matter contained in the milk of mammiferous animals. It takes its name from *caseus*, the Latin name of cheese, which is principally composed of casein mixed with fatty matters (butter) and decomposition products of casein (carbonate of ammonium and ammoniacal salts of acetic, butyric, valeric acids, &c.).

Preparation.—According to the views of Berzelius, Braconnot, and others, two modifications of casein are supposed to exist, the one *soluble* in water, the other coagulated and *insoluble* in water. *Soluble* casein has, however, never been prepared free from alkali, and is most probably identical with albuminate of potassium or sodium (Lehmann). *Insoluble* casein has nearly the same properties and composition as insoluble albumin.

Soluble casein may be prepared as follows: Fresh milk, from which the cream has been removed, is evaporated at a gentle heat, a portion of the casein becoming coagulated, while the rest remains dissolved. The residue is exhausted with ether, in order to extract fatty substances, and treated with water, which dissolves casein and lactin (sugar of milk); a little alcohol is next added to the aqueous solution, whereby most of the lactin is precipitated, the precipitate is washed with weak alcohol, and a solution of casein is obtained which always contains lactin and alkali. (Gerh. iv. 484.)

Insoluble casein may be obtained by simply heating creamed milk near to the boiling point, coagulating the liquid with a few drops of acetic acid, completely exhausting the coagulum with water, treating with alcohol and ether, drying and powdering the residue, and repeatedly digesting it with ether (Dumas and Cahours). Perhaps the best method is that of Bopp (Ann. Ch. Pharm. lxix. 16). Milk is coagulated with hydrochloric acid, the coagulum washed, first with distilled water, and then with water containing 2 or 3 per cent. hydrochloric acid, and finally with cold distilled water. A jelly is thus obtained, dissolving at 40° C. in a large quantity of water. This solution is filtered and carbonate of ammonium cautiously added, and the precipitate is well washed and exhausted with ether-alcohol. Whatever acid be employed in the coagulation, the casein, when treated in the manner described, never contains any trace of acid, and has always the same composition. (Gerh. *loc. cit.*)

Chemical Properties.—Soluble casein, when prepared in the manner described, leaves, after evaporation, an amorphous residue, inodorous, but having a sickly taste. It does not redissolve completely in water, nor does the solution coagulate by heat, but merely becomes covered with a film, which forms again as often as it is removed. Soluble casein is coagulated by alcohol, a portion at the same time entering into solution; a larger quantity is dissolved by boiling alcohol. The coagulum produced by *absolute* alcohol is completely insoluble in water. Solution of casein is precipitated by all *acids* (except carbonic acid); the precipitates redissolve in an excess of acid, and the solutions become covered with a film when evaporated in an open vessel. Mineral acids precipitate casein from its acetic acid solution. After the coagula thus obtained have been well washed with water, they still redden litmus, although they do not impart an acid reaction to water, even on boiling. The spontaneous coagulation of milk is due to the formation of lactic acid (produced by the fermentation of lactin) the acid neutralising the alkali in which the casein was dissolved, and thus rendering the casein insoluble.

Soluble casein always contains a large amount of mineral matter (when coagulated by alcohol, 8 to 10 per cent.). Casein coagulated by an acid yields from 1 to 5 per cent. ash, and the ash is never alkaline (Scherer). Casein contains phosphate of calcium as a constituent part. Mulder (Arch. f. 1828, p. 155) found in casein 6 per cent. phosphate of calcium, which is precipitated on coagulating any caseous liquid with an acid, although enough free acid be added to dissolve any uncombined phosphate of calcium.

When moist casein is exposed to the air, it soon begins to putrefy, yielding sulphide and carbonate of ammonium, a neutral oily body, having a disagreeable smell, together with butyric and valeric acids; at the same time the undecomposed casein dissolves in the ammonia formed (Iljenko, Ann. Ch. Pharm. lxiii. 264). According to Bopp, a crystalline body possessing a most powerful odour, is formed under the same circumstances. When casein putrefies out of contact with the air, it yields acetic, butyric, valeric, and capric acids, as well as ammonia.

The following are the results of the analysis of coagulated casein, deducting ash:

	Scherer.			Rochleder.	Walther.	Verdeil.
	By alcohol.	By the turning of milk.	By acetic acid.	By sulphuric acid.		
Carbon . .	53·7	54·0	53·8	53·8	—	—
Hydrogen . .	7·2	7·2	7·4	7·1	—	—
Nitrogen . .	15·6	15·7	15·7	—	—	—
Sulphur . .	—	—	—	—	1·0	0·9
Oxygen . .	—	—	—	—	—	—

	Dumas and Cahours.*					
	From cow's milk by acetic acid.	From goat's milk, by acetic acid.	From asses' milk, by acetic acid.	From sheep's milk, by acetic acid.	From human milk, by alcohol.	From blood by weak boiling alcohol †
Carbon . .	53·5	53·6	53·7	53·5	53·5	53·8
Hydrogen . .	7·1	7·1	7·1	7·1	7·1	7·1
Nitrogen . .	15·8	15·8	16·0	15·8	15·8	15·9
Sulphur . .	—	—	—	—	—	—
Oxygen . .	—	—	—	—	—	—

(Gerh. iv. 487.)

These numbers agree very closely with those obtained by the same chemists in the analysis of albumin, except that casein appears to contain less sulphur than albumin (2·16, Verdeil). Casein does not appear to contain any phosphorus, except in the form of phosphate of calcium.

Coagulated casein is readily soluble in caustic potash; after boiling, the solution contains sulphide of potassium. When casein is fused with caustic potash, ammonia is first evolved, then hydrogen; the mass, at first dark brown, gradually clears and becomes yellow; it is then completely soluble in water, and contains tyrosin, leucin, valerate (sometimes butyrate), and oxalate of potassium, as well as the potassium-salt of a volatile acid having an excrementitious odour (Liebig). If a very weak solution of alkali is saturated with casein, the alkaline reaction completely disappears; the solution thus obtained is precipitated by all acids except carbonic. Casein dissolves in a solution of phosphate of sodium, and neutralises it at the same time. It also dissolves largely in solutions of the alkaline carbonates, of common salt, chloride of ammonium, nitrate of potassium, &c. These solutions do not coagulate by heat, but become gradually covered with a film which is insoluble in dilute alkalis and acids. The same film is formed when milk is heated.

The solutions of casein are precipitated by all *earthy and metallic salts*. The precipitates with chloride, sulphate, and acetate of calcium and sulphate of magnesium, are thrown down only on heating the liquid. Compounds insoluble in water and hardening on exposure to the air, are obtained by heating casein with carbonate of calcium or of barium. The compound of casein and lime, prepared from clotted milk, is imputrescible, and is employed in distemper painting. (Gerhardt, *loc. cit.*)

If well washed casein, while still moist, be digested with water containing 0·0005 per cent. hydrochloric acid, it dissolves completely. The liquid, filtered from a trace of fat, deflects the rays of polarised light to the left, and has all the characteristics of a solution of albumin. (Bouchardat.)

---

* The ashes varied between 1·5 and 5·4 per cent. The substance was dried 150° C.

† See "Physiological Sources of Casein." (p. 812.)

Ozone acts energetically upon casein, the casein being apparently first converted into a substance resembling albumin, which is again destroyed on prolonging the action of the ozone (Gorup-Besanez, Jahresb. d. Chem. 1858, p. 63). O. Maschke says that he obtained by this reaction a crystallised compound of casein with a new acid (*ibid.* p. 543). Concentrated *hydrochloric acid* turns casein blue or violet, forming the same products of decomposition as with albumin. *Tannin*, from gall-nuts, precipitates the most dilute alkaline solutions of casein. *Mercuric chloride* yields with soluble casein a bulky white precipitate, soluble in acetic acid and in excess of alcohol: the precipitate does not contain chlorine, and is probably identical with albuminate of mercury (Elsner). Soluble casein is also precipitated by *acetate* and *subacetate of lead*, by *alum*, *mercurous nitrate*, and *sulphate of copper*. The acetic acid solution of casein is moreover precipitated by *ferrocyanide*, *chromate*, and *iodate of potassium.*

Casein yields the same products as albumin with sulphuric acid and acid chromate of potassium or peroxide of manganese (Guckelberger). When chlorine is passed through ammoniacal solution of casein, a product is likewise obtained analogous to that produced in the same way from albumin.

The coagulation of milk by rennet (the mucous membrane of the fourth stomach of young calves), is supposed by Liebig to result from the animal matter acting as a ferment, and transforming the lactin of the milk into lactic acid; since milk coagulated by rennet at a temperature of 40° C. always has an acid reaction. It appears, however, that milk may be coagulated by rennet, even when rendered alkaline by the addition of small quantities of carbonate of soda, so that after coagulation the liquid still remains alkaline: it is only necessary to operate at a higher temperature (between 50° and 60° C.) (Gerh. iv. 490.)

Sources and physiological nature of Casein.—When morbid bile is evaporated, a film of coagulated mucus and of a caseous substance is formed (Frerichs, Hann. Ann. v. pp. 1 and 2). Moleschott (*Physiologie des Stoffwechsels*, Erlangen, 1851. p. 366, &c.) found casein in the fluid filling the interstices of *cellular tissue*, also in the interstitial fluid of the *neck-band*. M. S. Schultze found casein in the liquid impregnating the middle lining of the arteries: in 100 pts. of the dried fibrous lining membrane of the *aorta thoracica*, out of 17·4—23·1 pts. soluble constituents, 7·24 pts. casein; and in the middle lining of the *carotid*, which contains more contractile fibrous cells than the *aorta*, in 39 per cent. soluble pts. 21 pts. of casein were found. The juice of flesh appears to contain casein; at least this substance has been found in the liquid pressed from flesh. It is not certain that blood contains casein. Dumas and Cahours have extracted from the coagulum of blood, a substance which has the same composition as casein (see analysis of casein), but is soluble in warm alcohol (Ann. Ch. Phys. [3] vi. 416). Frerichs almost always observed in the soluble constituents of the contents of the *small intestine*, albuminous compounds sometimes having the properties of albumin, sometimes of casein. A substance resembling casein is extracted by boiling alcohol from the contents of the small intestine of the human fœtus, from the fifth to the sixth month (Lehmann). The presence of casein in the *chyle* is exceedingly improbable. (Lehm.)

When yoke of egg is treated with ether and water, a coagulum collects under the yellow stratum of ether. If, after removing the ether, the coagulum be filtered off and washed until the wash-water becomes only opaline by heat, a substance remains on the filter identical with casein prepared by Rochleder's or Bopp's method (Ann. Ch. Pharm. xiv. 253—6; Bopp, *ibid.* lxix. 16—37), only that it contains a little albumin poor in salts; the albumin was precipitated by diluting the yoke solution with water (Gmelin, *Handbuch*, viii. 2, 282). Casein has been said to exist in *urina chylosa.* Reveil says that the urine of a child twenty-two weeks old, collected in his presence, concontained all the constituents of milk. Lehmann and Chevalier were unable to confirm this statement. Lehmann does not deny that albuminoïdal substances may pass into the urine, but with their properties so changed as not to agree with those of any known albuminoïdal compound.

Coagulable albuminate is sometimes found in the discharge of *serous* skin. Casein is not contained in normal *pus*, nor has it been detected with certainty in abnormal pus.

The casein of *human milk* is stated by Simon to be yellowish-white and very friable; it absorbed moisture from the air, and was but incompletely precipitated by alum or by acetic acid, from its aqueous solution. Casein from *cow's milk* is less soluble in water, and becomes viscid and horny on drying. *Canine milk* gives a casein which does not become viscid and horny when dried, and is less soluble in water.

The following are the percentages of casein in milk from various sources. (Gmelin, Handb. viii. [2] 254, 5.)

HUMAN.	COW.	BITCH.	ASS.

The soluble casein of milk is rapidly coagulated by the gastric juice, and then gradually digested. Milk is the most indigestible of albuminous bodies. A dog digests 100 grammes of cheese in 3—3·5 hours; boiled casein in 7 hours. E. v. Schröder remarked that in the human stomach, 2·5 hours after fresh milk had been taken, casein still remained in the form of amorphous or filmy transparent lumps; and even after the lapse of 3½ hours, undissolved milk globules, adhering to small coagula of casein, were almost always found, although the greater part of the milk seemed to have passed from the stomach. Cheeses which are hard, fat, and poor in salts, are more difficult of digestion than loosely coagulated, moist, and fresh cheeses (Gmelin, Handb. iv. [2] 616). The digestibility of casein naturally depends upon its state of aggregation; the casein of human milk, which coagulates with great difficulty, is more readily digested than that of cow's milk, which is more viscid. C. E. L.

CASEIN, VEGETABLE. See LEGUMIN.

CASSAVA. *Mousache, Cassave, Cassava Bread*, is a kind of starch, obtained from the root of the *maniock* (*Jatropha manihot, L.*) in the West Indies, where this plant is indigenous. The root is grated to a pulp, which is strongly squeezed in bags by a press. The juice contains nearly one-half per cent. of an exceedingly poisonous matter, volatile, and therefore entirely dissipated by the heat on iron plates, to which the pressed and crumbled pulp is exposed. Of that poison, as obtained by distillation, 35 drops served to kill, with horrible convulsions, in six minutes, a negro who had been convicted of murder by poison. Cassava may be freed from woody particles by solution, filtration, and evaporation. If in this state it is exposed to heat on an iron plate, it concretes into mammellated small lumps, called *tapioca*, an agreeable food, which is often imitated by means of potato-starch.

Cassava flour may be distinguished, by the microscope, from arrow-root, potato-starch, and wheat-starch, by the shape of its particles, which are spherules of $\frac{1}{1000}$ of an inch in diameter, while those of the second and third farina are ellipsoids, varying in size; and those of the fourth are spherules, clustered more or less together. U.

CASSEL YELLOW. See LEAD, OXYCHLORIDE OF.

CASSIA CARYOPHYLLATA. The bark of *Dicyphellium caryophyllatum* (Nees), a lauraceous tree growing in Brazil. It has an agreeable taste of cloves, an aromatic odour, and contains, according to Trommsdorff, 19 per cent. resin, 8·0 tannin, 10 gum and phosphate of calcium, and 59 woody fibre. It also yields an aromatic volatile oil containing eugenic acid. (Handw. d. Chem. 2te Aufl. ii. [2] 820.)

CASSIA CINNAMONEA, *Cinnamon Cassia, Chinese Cassia bark*, is the bass or inner bark of *Cinnamonum aromaticum*, a lauraceous tree indigenous in China, and cultivated in Java. It has a burning taste and aromatic odour, and contains, according to Bucholz, 4·0 per cent. soft resin, 14·6 extractive matter, 64·3 woody fibre, and bassorin; volatile oil, &c. According to Mulder, it also contains tannic acid (Handwört.) By distillation with salt water, it yields *oil of cassia*, an oil mainly consisting of cinnamic aldehyde, and nearly identical with the oil obtained from Ceylon cinnamon.

CASSIA FISTULA. The fruit of *Bactyrilobium fistula*, a leguminous plant growing in India and in the interior of Africa. According to Vauquelin, it contains 14·8 per cent. sugar, and 1·5 gum, together with pectin, gluten, &c.; according to Caventou, it contains cassiin. The legume is divided into a number of transverse cells, filled with a sweet, slight acid pulp, 100 pts. of which contain, according to Henry:

	Sugar.	Gum.	Tannin.	Yellow colouring matter and mucus.	Water.
West Indian .	69·2	2·6	3·9	1·3	23·2
African . .	61·0	6·7	13·2	—	19·0

CASSIA BUDS. The undeveloped flowers of *Cinnamonum Louresii* (Nees). By distillation with salt water, they yield oil of cassia. (Handw.)

---

* Casein and extractive matter: average of 89 persons (1·932—7·092).

CASSIIN. A bitter principle obtained from *Cassia fistula*. It is soluble in water and in alcohol, and is precipitated therefrom by sulphuric, nitric, or hydrochloric acid. (Caventou, J. Pharm. xiii. 340.)

CASSITERITE. Native oxide of tin. (See TIN.)

CASSITEROTANTALITE. Tantalite from Broddbo in Finland, containing oxide of tin. (See TANTALITE.)

CASSIUS, PURPLE OF. A purple compound of the oxides of gold and tin. (See GOLD.)

CASSONIC ACID. A syrupy uncrystallisable acid, obtained, together with oxalic and saccharic acid, by oxidising cane-sugar with nitric acid. It forms a speculum with nitrate of silver. The barium-salt appears to contain $C^6H^6Ba^2O^7$. (Siewert, Institut. xxi. 78.)

CASTELNAUDITE. A mineral from the diamond sands of Bahia in Brazil. It consists mainly of hydrated phosphate of yttrium, and occurs in imperfect crystals or irregular grains, probably trimetric, of greyish-white or pale yellow colour, unctuous adamantine lustre, harder than fluorspar, but scratched by a steel point. (Damour, Institut. 1853, p. 78.)

CASTILLOYA ELASTICA. A Mexican scrophulariaceous plant, which yields caoutchouc.

CASTINE. A crystalline basic substance, obtained from the seed of *Vitex Agnus castus, L.* It is bitter, insoluble in water, soluble in alcohol, ether, and acids; forms a crystalline hydrochlorate. (Landerer, Buchner's Repert. liv. 90.)

CASTOR. A variety of PETALITE (*q. v.*)

CASTOREUM. *Bibergeil.*—A substance found in a pair of small sacs situated in the genital organs of the beaver (*Castor Fiber* and *Castor americinus*). There are three sorts of it, Russian, Bavarian, and American or Canadian. Of these, the Russian is most valued, though the Bavarian is considered nearly equal to it. Castoreum when fresh, is soft and unctuous, but becomes hard and firm when dry; it has a black or brownish-black colour, and is somewhat shining. It has a peculiar pungent odour, and a bitterish spicy taste, which irritates the throat; it is used in medicine as an antispasmodic.

According to Brandes, Russian and Canadian castoreum differ considerably in composition, as shown by the following table:

Volatile oil	1·00	2·00
Castoreum resin	13·85	58·60
Cholesterin	—	1·20
Castorin	0·33	2·50
Albumin	0·05	1·60
Glutinous substance	2·30	2·00
Extract soluble in water and alcohol	0·20	2·40
Carbonate of ammonium	0·82	0·80
Phosphate of calcium	1·44	1·40
Carbonate of calcium	33·60	2·60
Sulphates of potassium, calcium, and magnesium	0·20	—
Gelatinous substance extracted by potash	2·30	8·40
Gelatinous substance, extractable by potash, soluble in alcohol	—	1·60
Membranes, skin, &c.	20·03	3·30
Water and loss	22·83	11·70
	98·95	100·10

Wöhler by distilling Canadian castoreum with water, obtained phenic acid, together with benzoic acid and salicin; he suspected also the presence of ellagic and salicylic acid. Lehmann found bile in fresh castoreum, by Pettenkofer's test; also alkaline sebates and urates, and an albuminoïdal substance. Laugier, Brandes, Batka, and Riegel, found benzoic acid. Lehmann found, as the mineral constituents of castoreum, a small quantity of chloride of sodium, sal-ammoniac, and other soluble salts, also phosphate of sodium and ammonium, and an abundance of phosphate of calcium and phosphate of magnesium.

A substance resembling castoreum is likewise secreted by the prepuce (*Præputium penis* and *clitoridis*) of man and of the horse. Lehmann gives the following table of the composition of: A. Fresh German castoreum; B. Smoked Russian; C. Canadian; D. *Smegma præputii* of the horse; E. of man:

	A.	B.	C.	D.	E.
Ethereal extract	7·4	2·5	8·2	49·9	52·8
Alcoholic extract	67·7	64·3	41·3	9·6	7·5
Water extract	2·6	1·9	4·8	5·4	6·1
Acetic acid extract	14·2	18·5	21·4	5·4	9·7
„ „ consisting of carbonate of calcium and albuminoïdal substance . .	2·4	3·4	5·8	2·8	5·6
Portions of skin	5·7	9·4	18·4	26·8	18·5
	100·0	100·0	99·9	99·9	100·2

The ethereal extracts contained saponifiable fats, cholesterin, and castorin, and a fat which became very finely divided in water.

Castoreum resin is obtained by evaporating the mother-liquor of castorin (*vid. inf.*) to dryness, exhausting the residue with water, then dissolving in alcohol, and evaporating. It is black-brown, shining, brittle, nearly insoluble in ether, soluble in aqueous alkalis, and precipitated therefrom by acids.

Castoreum-oil, obtained by distilling castoreum with water, is pale yellow, viscid, sparingly soluble in water, easily in alcohol, and has a sharp bitter taste. Russian castoreum yields 2 per cent. of this oil; Canadian 1 per cent. (Handw. d. Chem. 2te Aufl. ii. [2] 1034.)

CASTORIN. A fatty substance obtained from castoreum. A solution of castoreum in 6 pts. of alcohol saturated while warm, yields on cooling a deposit of ordinary fat, and the mother-liquor deposits crystals of castorin by slow evaporation. This substance, when purified by repeated crystallisation, forms delicate, transparent, four-sided needles, having a faint taste and smell of castoreum. It melts in boiling water, and solidifies on cooling to a hard translucent, pulverisable mass. It is but sparingly soluble in cold alcohol; ether dissolves it readily; volatile oils only when warm. It appears to volatilise with vapour of water. It dissolves without alteration in boiling dilute sulphuric acid, in strong acetic acid, in caustic alkalis. According to Brandes, it forms a peculiar compound with nitric acid. (Gerh. iv. 280.)

CASTOR OIL. This oil, much used in medicine as a purgative, is extracted from the seed of *Ricinus communis*, a euphorbiaceous plant cultivated in the West Indies and other warm climates. It is viscid, yellowish, odourless, and has a faint taste, which becomes acrid when the oil is rancid. It solidifies at − 18° C. Specific gravity 0·969 at 12° C. It is distinguished from other oils by its easy solubility in alcohol and ether. It is a mixture of several glycerides. When saponified by an alkali, it yields a soap perfectly soluble in water, and from which mineral acids separate a mixture of acids, oily at common temperatures, and consisting mainly of ricinoleic acid, $C^{18}H^{34}O^3$. When this oily mixture is dissolved in a third of its volume of alcohol, and the solution is cooled to − 15° or − 12° C., it deposits a small quantity of nacreous scales, apparently consisting of stearic and palmitic acids.

Castor-oil gives by analysis:

	Saussure.	Ure.	Lefort.	
Carbon . . .	74·18	74·00	74·58	74·35
Hydrogen . .	11·03	10·29	11·48	11·35
Oxygen . . .	14·79	15·71	13·94	14·30
	100·00	100·00	100·00	100·00

Ammonia converts castor-oil into ricinolamide, $N.H^2.C^{18}H^{33}O^2$. When castor oil is distilled with potash, sebate of potassium remains in the retort, and an oily liquid passes over, consisting of caprylic or œnanthylic alcohol, and methyl-œnanthyl (see ALCOHOLS, p. 98). Castor-oil treated with a mixture of sulphuric acid and acid chromate of potassium, yields œnanthylic acid and hydride of valeryl. Nitric acid attacks it with violence, and converts it into œnanthylic acid. Peroxide of nitrogen causes it to solidify. Castor-oil dissolved in absolute alcohol, and exposed to the action of gaseous hydrochloric acid, is converted into glycerin, and contains ethyl-compounds formed by the fatty acids previously in combination with the glycerin. Castor-oil subjected to dry distillation, yields hydride of œnanthyl and œnanthylic acid, together with small quantities of acrolein and solid fatty acids. (Gerh. ii. 903.)

CATALYSIS, or *Contact action.*—Terms applied by Berzelius and Mitscherlich to those cases of chemical action in which a substance appears to induce decomposition in another body, without itself undergoing perceptible alteration, or at all events without entering into combination with either of the elements of that compound. (See CONTACT ACTION.)

CATAPLEIITE. A silicate containing zirconium, from the island Lamö, near

Brevig, Norway, together with zircon, leucophane, mosandrite, and tritomite. Imperfect prismatic crystals, with perfect basal cleavage. Specific gravity 2·8. Hardness near 6. Opaque, with light yellowish-brown colour, and little lustre. Melts easily to a white enamel before the blowpipe on platinum; gives a colourless glass with borax; blue with cobalt-solution. Dissolves easily in hydrochloric acid without gelatinising. Mean of analyses:

SiO^2	Zr^4O^3	Al^4O^3	Na^2O	Ca^2O	Fe^2O	H^2O	
46·67	29·57	0·92	10·45	4·13	0·56	8·96	= 101·26

agreeing nearly with the formula $3(M^2O.SiO^2) + 2(Zr^4O^3.3SiO^2) + 2aq.$, which if zirconia be regarded as a protoxide ($zr = \frac{2}{3}Zr$), may be reduced to that of a metasilicate $(M^2zr^4)Si^3O^9 + aq.$ (Weibye and Sjögren, Pogg. Ann. lxxix. 299; Dana, ii. 308.)

CATAWBARITE. A name given by Lieber (Sill. Am. J. xxviii. 148), to a rock which accompanies itacolumite, and appears to stand, as a magnesium rock or slate, between itacolumite and itabirite.

CATECHU, formerly called also *Terra japonica*, is an extract rich in tannin, obtained by boiling in water the parts of several plants growing in India, and is distinguished into three sorts in commerce. 1. Bombay Catechu, from the *Areca catechu*, is prepared by boiling the fruit of the *areca* palm in water, the first portions of the decoction being the strongest, and affording the quality called *Cassu*, the latter portions, the weaker sort called *Coury*. The best occurs in dense irregular lumps of a dark brown colour. It is opaque, with an even, slightly unctuous, shining fracture. Another variety called *catechu verum* has a somewhat reddish-brown colour, a fatty lustre, a splintery conchoïdal fracture, and is translucent on the edges. Bombay catechu is almost entirely soluble in boiling water, yielding a dark brown liquor, very rich in tannic acid, and affording copious precipitates with solution of glue and with sulphuric acid.

2. Bengal Catechu, is obtained from the *Acacia* (*Mimosa*) *Catechu*, by boiling the twigs and unripe pods in water. It has a lower specific gravity, is of a pale brown colour, with a yellowish cast. It is opaque, with a glimmering lustre on the fractured surface only, and traversed by dark brown shining stripes. When treated with cold water, it leaves a large residuum, but boiling by water it is mostly taken up; the solution contains less tannin, but more *catechin*, than the Bombay sort.

3. The third kind, called Gambir Catechu, is referred to the *Nauclea* (*Uncaria*) *Gambir*, from which also kino is obtained. It occurs in cubical pieces of 1 to 1½ inches, opaque, and of a brown yellow or bright yellow colour. Their fracture is even and dull. It is little soluble in cold water, but almost completely in boiling water, the solution affording copious precipitates with glue and sulphuric acid.

4. A fourth kind called Egyptian or Nubian Catechu, is said by Landerer to be obtained by the collectors of gum by boiling the fruits of gummiferous acacias, and to be exposed for sale in the bazaars of Smyrna, and at Constantinople. It is for the most part soluble in water, but differs from the other varieties in many respects.

All kinds of catechu dissolve in great measure in alcohol; and soften with heat. The specific gravity of good Bombay catechu is 1·39; of Bengal catechu 1·28; and of the Gambir variety, 1·40. Catechu is used as an astringent in medicine, and for tanning leather, either alone or mixed with oak bark. The comparative value of catechu for tanning may be measured by the proportion of gelatin which is required to precipitate all its tannin. Catechu is also used in dyeing, especially for silk and wool. When treated with nitric acid at 45° C., it yields a bright yellow powder, possessing all the properties of picric acid, but much more soluble in water. Silk and wool may be easily dyed in the aqueous solution.

Catechu has lately been much used to prevent the formation of boiler incrustations, or to remove them when formed; the quantity required is such as will slightly colour the water. (Newton, Rep. of Patent Inventions, 1858; Dingl. pol. J. cxlviii. 315.)

Catechu is *mainly* composed of two principles, *catechin* and *catechutannic acid*, together with a brown colouring matter.

CATECHIN, *Catechucic acid*, or *Tanningenic acid*, is obtained from Bengal catechu, by digesting it for 24 hours in cold water to extract the tannin, and then boiling the residue several times with water. The yellow catechucic acid which deposits itself during the cooling is to be collected upon a filter, washed repeatedly with cold water, and finally dissolved in six times its weight of water with purified bone-black to decolorise it. White catechucic acid separates from the hot filtered solution as it cools. It is now to be washed on a filter with cold water, quickly dried on bibulous paper, and more completely under the receiver of the air-pump. Other processes, but less simple, have been prescribed.

Pure catechin is a white powder composed of very small silky needles. It dissolves in 1133 pts. of water at 17° C., forming a colourless tasteless solution, which has no effect on the colour of litmus; it dissolves in 3 pts. of boiling water (forming a solution said to have an acid reaction), in 5 or 6 pts. of cold alcohol, 2 or 3 pts. boiling alcohol 120 pts. of cold ether and 7 to 8 pts. boiling ether. According to Zwenger's analysis it contains 61·3 per cent. carbon and 4·8 hydrogen, whence Zwenger deduces the formula $C^{20}H^{18}O^{8}$.

Catechin melts at 217° (Zwenger), and solidifies to a translucent, amorphous, brittle mass. After drying at 100° C. it gives off 4·4 per cent water when melted. When heated above its melting point, it turns brown, and intumesces, giving off water and carbonic acid. By dry distillation it yields an empyreumatic oil and an acid watery liquid, which yields by evaporation crystals of pyrocatechin or oxyphenic acid (*q. v.*)

Dilute mineral acids dissolve catechin without altering it; strong acids decompose it; with strong sulphuric acid it forms a deep purple liquid.

Catechin does not form definite compounds with bases. It absorbs ammonia, but gives it up again in vacuo. The fixed alkalis colour it yellow, brown, and black. It does not decompose alkaline carbonates, or precipitate the solutions of hydrate or acetate of calcium or barium. It forms a white precipitate with acetate and subacetate of lead; dark green with ferric chloride; greenish-black or violet with ferroso-ferric sulphate; brown or black with sulphate of copper; brown or black with salts of silver, gold, and platinum, the metals being reduced. These decompositions often take place after a time only, or on heating the liquid, and are always accompanied by decomposition of the catechin. Solutions of gelatin, starch, tartar-emetic, and salts of quinine or morphine, are not precipitated by catechin. (Gerh. ii. 882).

CATECHU-TANNIC ACID. *Cachoutannic acid. Tannin of Catechu.* To obtain this acid, the aqueous infusion of catechu is heated with dilute sulphuric acid, and after the liquid has been clarified from the colouring matter, &c., thereby thrown down, strong sulphuric acid is added as long as a precipitate continues to form. This precipitate is washed on a filter with dilute sulphuric acid, pressed between paper, and dissolved in pure water, the solution digested with carbonate of lead, the solid matter thrown on a filter, and the filtrate evaporated in vacuo. The product thus obtained is purified by re-solution in ether containing alcohol. Another mode of preparation is to exhaust powdered catechu with ether in a displacement-apparatus and evaporate the ethereal solution. A yellowish porous mass then remains resembling gallotannic acid.

Cachoutannic acid has a purely astringent taste, and resembles gallotanic acid in many of its properties, but is distinguished therefrom by not precipitating tartar-emetic, and by forming a greyish-green precipitate with ferric salts. It does not precipitate ferrous salts. It is soluble in water, alcohol, or ether, insoluble in oils both fixed and volatile; its solutions are precipitated by gelatin. It is but slightly soluble in water acidulated with sulphuric acid, though more so than gallotannic acid.

According to Pelouze, catechutannic acid contains $C^{18}H^{18}O^{8}$.

Catechutannic acid softens when heated, and yields by distillation a yellow empyreumatic oil, together with a watery liquid which gives a greenish-grey precipitate with ferric salts, and is coloured brown by alkalis.

The solution of catechu-tannic acid alters quickly by exposure to the air, becoming red, and leaving on evaporation a substance which no longer re-dissolves completely in water. According to Delffs, catechin is one of the products of the decomposition.

The salts of catechutanuic acid are too unstable to be prepared in the pure state. The *potassium-salt* is very soluble, and precipitates gelatin after addition of an acid. The catechutannates of the earth-metals and heavy metals form sparingly soluble precipitates.

CATHA EDULIS. The leaves of this plant, called *Kât* by the Arabs, are brought from the interior to Aden; they are said to produce sleeplessness and an agreeable state of excitement.

CATHARTIN. The purgative principle of senna (the leaves and fruits of several shrubs of the genus *Cassia*, order *Leguminosæ*). It is prepared by evaporating the alcoholic extract of senna, redissolving in water, precipitating with acetate of lead, separating the excess of lead from the solution by sulphuretted hydrogen, and evaporating the filtrate. It is a brownish yellow, uncrystallisable, diaphanous mass, soluble in water and alcohol, insoluble in ether; its taste is bitter and disgusting. By dry distillation it yields products free from nitrogen. Alkalis turn it brown; with subacetate of lead and tincture of galls, it forms yellow precipitates (Lassaigne and Feneuille, Ann. Ch. Phys. [2] xvi. 18). Winckler (Jahrb. pr. Pharm. xix. 223) applies the term *cathartin* to a bitter substance contained in the berries of the buckthorn (*Rhamnus catharticus*). (See RHAMNO-CATHARTIN.)

CATHODE, or *Kathode.*—Faraday's term for the negative pole or electrode in the voltaic circuit, the elements there eliminated being called *cations*, or *kations*. (See ANION, p. 296.)

CATLINITE. A reddish clay stone from the Coteau de Prairies, west of the Mississippi. (Jackson, Sill. Am. J. xxxv. 388.)

CAT'S EYE. A translucent quartz of beautiful appearance brought from Ceylon. Its colours are green, grey, brown, and red of various shades. Fracture imperfectly conchoïdal. Translucent with vitreous internal lustre. It derives its name from a peculiar play of light (*chatoyant*), arising from fibres interspersed. It scratches quartz, is easily broken, and resists the blowpipe. Specific gravity 2·64. Contains, according to Klaproth, 95 per cent. silica, 1·75 alumina, 1·5 lime, and 0·25 oxide of iron. It is valued for setting as a precious stone. U.

CAULOPHYLLIN. A resinous medicinal preparation obtained in North America from *Caulophyllum Halictroïdes.* (Buchner's N. Repert. vi. 188.)

CAUSTICITY. The quality possessed by strong alkalis, acids, nitrate of silver, &c., of corroding the skin and flesh of animals. In the old language of surgery, caustics were divided into the actual, such as red-hot iron and *moxa*, and the potential, such as the above-mentioned preparations.

CAVOLINITE. See Nephelin.

CAWK. A miner's term for native sulphate of barium.

CEDAR, OIL OF (not to be confounded with *Oleum de cedro*, which is one of the names of oil of citron).—A volatile oil obtained from the wood of the Virginian cedar, *Juniperus Virginiana*, which is used for making pencils, and owes its agreeable odour to this oil. It is a soft semi-solid mass, consisting of a liquid hydrocarbon, cedrene, $C^{15}H^{24}$, and an oxygenated camphor or stearoptene, containing $C^{15}H^{26}O$.

To obtain the camphor, the crude oil is distilled; the distillate is pressed between linen or calico, to free it from the greater portion of the liquid cedrene which adheres to it, and then crystallised from alcohol of ordinary strength, which retains the rest of the cedrene in solution.

Cedar-camphor thus purified is a crystalline mass of great beauty and lustre, having an aromatic odour, like that of pencil-wood, but not much taste. It melts at 74° C. and boils at 282°. Vapour-density = 8·4. It dissolves very sparingly in water, but freely in alcohol, whence it crystallises in needles having a silky lustre. It gives by analysis, 81 per cent. carbon and 11·8 hydrogen, agreeing with the preceding formula; hence it is isomeric with camphor of cubebs (*q. v.*) By distillation with phosphoric anhydride, it is resolved into water and cedrene, $C^{15}H^{26}O = C^{15}H^{24} + H^2O$. With pentachloride of phosphorus, it yields an aromatic substance, which has not yet been analysed. Strong sulphuric acid colours it strongly and separates an amber-coloured oil (Walter, Ann. Ch. Phys. [3] I. 1. 498). According to Bertagnini (Compt. rend. xxxv. 800), oil of cedar combines wth the acid sulphites of the alkali-metals.

CEDRENE. $C^{16}H^{24}$.—This body is produced from the concrete portion of cedar-oil by the action of phosphoric anhydride. It is oily, aromatic, and has a peppery taste. Specific gravity 0·984 at 15° C. Boils at 248°. Vapour-density 7·5 (4 vol.) (Walter, *loc. cit.*)

CEDRIN. See Cedron.

CEDRIRET. One of the products obtained by Reichenbach (J. pr. Chem. i. 1) from the tar of beech-wood; said to crystallise in fine needles. Völckel (Ann. Ch. Pharm. lxxxvi. 331) was not able to find it.

CEDRON. *Simaba Cedron* (Planchon).—A tree which grows in the hottest parts of New Granada, and bears fruits resembling the bean of St. Ignatius; they have a bitter taste, and are used in that country as medicine. Ether extracts from them a neutral crystallisable fat, insoluble in cold alcohol. The fruit, after exhaustion with ether, yields to alcohol a crystallisable substance, cedrin, which Lewy regards as the active principle of the fruit. Cedrin is sparingly soluble in cold water, more soluble in boiling water and in alcohol, and crystallises from the solutions in silky needles. It is neutral, and has an intensely and persistently bitter taste. (Lewy, Compt. rend. xxxii. 510.)

CELESTIN. Syn. with Cœlestin.

CELLULIC ACID. Syn. with Metapectic Acid. (See Pectic Acid.)

CELLULOSE. $C^6H^{10}O^5$. *Lignin, Woody fibre. Ligneux. Zellstoff, Planzenzellstoff, Pflanzenfaserstoff.* (Payen, *Précis de Chimie industrielle*, 4^{me} éd. ii. 11; Gerh. ii. 481; Gm. xv. 123.)—This substance constitutes the essential part of the solid framework of plants. The cell-walls in the early stages of their development are composed entirely of it, but as the plant grows, they become incrusted with colouring matter, resins, and other foreign substances, which in some parts, as in the heart-wood of large trees, fill up the entire cavities. Some tissues, however, consist almost wholly of cellulose, *e. g.* the pith of the rice-paper plant (*Aeschynomene paludosa*), and the horny perisperms of certain seeds, as those of the phytelephas or vegetable ivory, the date-tree, dragon-tree, &c. Several manufactured vegetable fabrics, as cotton, linen, hemp, and unsized white paper, consist of cellulose very nearly pure.

Cellulose has also been said to exist in the animal kingdom, constituting the chief part of the mantle of mollusca, and according to Frémy, of the testa or integument of insects and crustacea; from the analysis of other chemists, however, these substances appear to be nitrogenous (see CHITIN). According to Virchow (Compt. rend. xxxvi. 492, 860), cellulose is found in degenerated human spleen and in certain parts of the brain.

The easiest method of obtaining pure cellulose, is to wash white cotton, unsized paper, old linen, or elder-pith, with a hot solution of caustic potash or soda, then with cold dilute hydrochloric acid, then with ammonia, washing thoroughly with water after the application of each of these reagents, and lastly with alcohol and ether; it is often necessary to repeat this series of operations two or three times. To obtain pure cellulose from wood, it is necessary, after boiling the wood with potash till the liquid is almost dry, to treat it with chlorine-water or with a weak solution of chloride of lime, repeating these successive operations several times, in order to free the cellular tissue from the encrusting matter which is so intimately united with it. The vegetable fibres in the excrements of herbivorous animals furnish a convenient source of cellulose, because the encrusting matter has been already removed or disintegrated to a great extent by the process of digestion, so that the cellular substance which remains is much easier to purify than the tissue of the plant in its natural state.

Cellulose thus purified is white, translucent, of specific gravity about 1·5, insoluble in water, alcohol, ether, and oils, both fixed and volatile. When quite pure, it is unalterable in the air; but as it exists in wood, in contact with azotised and other easily alterable matters, it gradually decomposes in moist air, undergoing a slow combustion, and being converted into a yellow or brown friable substance called *touchwood*.

The state of aggregation of cellulose varies with its origin. In its less compact forms, as in Iceland moss, it is easily disintegrated by boiling with *water*, and converted into a soluble substance, viz. dextrin; but in its ordinary denser form, as in wood, linen, cotton, &c. it resists the action of water, and even of more energetic solvents, for a long time.

Strong *sulphuric* and *phosphoric acid* disintegrate cellulose at ordinary temperatures, and convert it into dextrin, a substance isomeric with cellulose, without colouring it; if water be then added and the mixture boiled, the dextrin is converted into glucose. Thin strips of paper or linen, triturated with strong sulphuric acid added drop by drop, are converted, after some time, into a viscous mass consisting of dextrin, and on boiling this mass with water, it acquires the property of reducing copper-salts in presence of an alkali, and after some hours' boiling is completely converted into glucose.

Unsized paper plunged for a few seconds into sulphuric acid diluted with half to a quarter its bulk of water, and then washed with weak ammonia, undergoes a very remarkable alteration, being converted, without change of composition, into a tough substance very much resembling animal parchment, and applicable to the same purposes. The formation of this remarkable substance was first noticed in 1847, by Messrs. Poumarède and Figuier, who gave to it the name of *Papyrin*. The discovery remained, however, without practical application till the year 1857, when it was again brought into notice and patented in this country by Mr. W. E. Gaine; and the material, called *vegetable parchment*, or *parchment paper*, is now manufactured in large quantity by Messrs. De la Rue and Co. Besides its application to the same purposes as ordinary parchment, it is largely used for covering pots in which preserves and jellies are kept, and for making shirt-collars, imitation lace, &c. &c.; it is also very useful in the laboratory, for connecting pieces of apparatus in distillations, and as an intervening membrane in experiments of diffusion, osmose, &c. That it should have remained so long unnoticed after its first discovery is probably due to the circumstance that Messrs. Poumarède and Figuier, in preparing it, used strong sulphuric acid, of specific gravity 1·842; and it has since been found that the material thus produced, though possessing the general characters above described, is not nearly so tenacious as that obtained with acid diluted to the extent already mentioned. (Hofmann, Ann. Ch. Pharm. cxii. 243.)

Cellulose (linen, for example), boiled for a short time with *moderately dilute sulphuric* or *nitric* acid, is converted into a pulpy mass, which still exhibits the composition of cellulose, and does not dissolve sensibly in water. *Strong boiling hydrochloric acid* converts cellulose into a fine powder, without change of composition. *Moderately strong nitric acid* converts cellulose into a nitro-substitution-product, resembling xyloïdin, $C^6H^9(NO^2)O^5$ (*q. v.*) With *very strong nitric acid*, or a mixture of strong *nitric* and *sulphuric acids*, higher substitution-products are formed, viz. $C^6H^8(NO^2)^2O^5$ and $C^6H^7(NO^2)^3O^5$ called gun-cotton, or pyroxylin (*q. v.*)

Caustic potash or *soda* disintegrates cellulose but slowly, and with the more compact varieties the effect is merely superficial. When equal parts of potash and cellulose, moistened with water, are heated in a closed vessel, hydrogen is evolved, and wood-spirit distils over, while formic, acetic, and carbonic acids are produced, and remain with the alkali. Melted hydrate of potassium converts cellulose into malic acid.

Cellulose in all its forms is immediately blackened by *fluoride of boron.*

When *chlorine gas* is passed into water in which cellulose is suspended, the cellulose is rapidly oxidised, with evolution of carbonic acid; the same effect is produced on gently heating cellulose with the solution of a *hypochlorite:* hence in bleaching cotton or linen fabrics, paper-pulp, with hypochlorites, &c., great care must be taken not to use too strong a solution.

Cellulose in its more compact forms is not coloured by solution of *iodine;* but if previously disintegrated by sulphuric acid or caustic alkalis, it produces a violet-blue colour with iodine. In this manner, cellulose may be detected in vegetable tissues under the microscope. Some lichens and algæ, Iceland moss for example, give the blue colour with iodine after being boiled with water.

Solution of Cellulose.—Cellulose dissolves completely in an *ammoniacal solution of oxide of copper.* This solvent may be prepared by passing air freed from carbonic acid into a bottle filled with copper turnings and half filled with ammonia; or by placing copper turnings which have been oxidised on the surface by heating them in the air and then reduced by dry hydrogen, in a tall glass vessel, and causing ammonia to drop through them into a bottle placed below; or again, by directly dissolving oxide of copper in ammonia. Silver-paper, or thin filtering-paper, dissolves in this liquid after a while, forming a syrupy solution, which may be filtered after dilution with an equal bulk of water. On mixing the liquid thus formed with excess of hydrochloric acid, the cellulose is precipitated in amorphous flakes, which, after washing with water, are colourless and quite free from copper. Even in this finely divided state, cellulose is not coloured blue by iodine, unless it be first subjected to the action of strong sulphuric acid. (Payen.)

Several substances obtained from the solid tissue of plants, and formerly regarded as distinct proximate principles, are now known to be mere modifications of cellulose; *e. g. fungin*, from fungi, *medullin*, from the pith of various trees, &c. *Hordein*, from barley, is a mixture of cellulose with starch and a nitrogenous body.

CELTIS. The fruit of *Celtis orientalis* contains 71 per cent. of fleshy pericarp, and 28·3 seeds, the latter consisting of 67·3 husks, and 32·7 kernel; 100 pts. of the kernels contain 15·2 pts. oil, and 45·6 ash, of which 40·4 pts. consist of carbonate of calcium, and 4·4 of silica.

CEMENT. The term cement is applied to any substance capable of holding together the surfaces of two bodies without mechanical rivets. Cements may be divided into two classes, stony cements, and those of a resinous and glutinous character.

1. The chief stony cements are *common building mortar*, a mixture of lime slaked to a creamy consistence, and sharp sand, which hardens partly by drying, partly by absorption of carbonic acid from the air; and *hydraulic mortar*, or *Roman Cement*, a mixture of slaked lime with *amorphous silica*, which hardens under water to a compact mass of hydrated silicate of calcium. (See Silicates of Calcium.)

The *mastic cement* of London, much employed for giving to brickwork the hardness and appearance of stone, is composed of oolitic limestone, chiefly that of Portland, finely ground, mixed with sand and litharge, and made into a loosely coherent paste with linseed oil, either raw or boiled. The oil is extemporaneously mixed by the workman with the cement powder on a board by a trowel, and plastered thinly and smoothly over bricks, laths, or any surfaces which are to resemble stones. The fine dust produced by sawing stone slabs, is said to answer a like purpose, when mixed with litharge and oil. Analysis shows that the said *mastic* is composed of 35 pts. of siliceous sand, 62 of limestone, and 3 of litharge. These proportions may, however, be somewhat varied without injury. Too much limestone impairs the hardness of the cement; too much sand makes it porous. For every 100 pts. of such a mixture, about 7 of oil are required. As this compost is friable, it may be made more ductile by keeping it compressed in moulds, for a little time before spreading it by the trowel. The surface to which it is to be applied, must be cleaned and oiled beforehand with a brush. It is particularly useful in closing fissures in buildings, and preventing the ingress of moisture through seams.

2. *Resinous* and *glutinous* cements are of many different compositions. Rosin and beeswax melted together, and thickened with more or less fine brickdust, serve for cementing glass and metal works. Asphalt mixed with chalk in due proportion has been used extensively for paving streets and terraces. The bitumen of Seyssel and Lobsann in France, has been largely employed for this purpose. The compost rendered nearly fluid by heat, is applied to bodies dried, and if convenient, previously heated.

Coal tar mixed with sand, forms a bad composition, which becomes friable and porous by exposure to weather.

Seven or eight parts of rosin, and one of wax, melted together and mixed with a small quantity of plaster of Paris, form a very good cement to unite pieces of Derbyshire spar, or other stone. The stone should be made hot enough to melt the cement, and the pieces should be pressed together as closely as possible, so as to leave as little as may be of the cement between them: this is a general rule in cementing, as the thinner the stratum of cement interposed, the firmer it will hold. Melted sulphur used in the same way will answer sufficiently well, if the joining be not required to be very strong.

It sometimes happens, that jewellers, in setting precious stones, break off pieces by accident: in this case they join them, so that it cannot be easily seen, with gum-mastic, the stones being previously made hot enough to melt it. By the same medium, cameos of white enamel or coloured glass are often joined to a real stone as a ground, to produce the appearance of an onyx. Mastic is likewise used to cement false backs or doublets to stones to alter their hue.

The jewellers in Turkey, who are generally Armenians, ornament watch-cases and other trinkets with gems by glueing them on. The stone is set in silver or gold, and the back of the setting made flat to correspond with the part to which it is to be applied. It is then fixed on with the following cement: Isinglass, soaked in water till it swells up and becomes soft, is dissolved in French brandy, or in rum, so as to form a strong glue. Two small bits of gum galbanum, or gum ammoniacum, are dissolved in two ounces of this by trituration; and five or six bits of mastic, as big as pease, being dissolved in as much alcohol as will render them fluid, are to be mixed with this by means of a gentle heat. The cement is to be kept in a phial closely stopped; and when used, it is to be liquefied by immersing the phial in hot water. This cement resists moisture.

A solution of shellac in alcohol, added to a solution of isinglass in proof spirit, makes another cement that will resist moisture.

So does common glue melted without water, with half its weight of rosin, with the addition of a little red ochre to give it a body. This is particularly useful for cementing hones to their frames.

Clay and oxide of iron mixed with oil, are said to form a cement that will harden under water.

A strong cement, insoluble in water, may be made from cheese. The cheese should be that of skimmed milk, cut into slices, throwing away the rind, and boiled till it becomes a strong glue, which, however, does not dissolve in the water. This water being poured off, it is to be washed in cold water, and then kneaded in warm water. This process is to be repeated several times. The glue is then to be put warm on a levigating stone, and kneaded with quick lime. This cement may be used cold, but it is better to warm it; it will join marble, stone, or earthenware, so that the joining is scarcely to be discovered.

Boiled linseed oil, litharge, red lead, and white lead, mixed together to a proper consistence, and applied on each side of a piece of flannel, or even linen or paper, and put between two pieces of metal before they are brought home, or close together, will make a close and durable joint, that will resist boiling water, or even a considerable pressure of steam. The proportions of the ingredients are not material; but the more the red lead predominates, the sooner the cement will dry, and the more the white, the contrary. This cement answers well for joining stones of large dimensions.

The following is an excellent cement for iron, as in time it unites with the metal into one mass:—Take two ounces of sal-ammoniac, one of flour of sulphur, and sixteen of cast-iron filings or borings. Mix them well in a mortar, and keep the powder dry. When the cement is wanted for use, take one part of this mixture, twenty parts of clear iron borings or filings, grind them together in a mortar, mix them with water to a proper consistence, and apply them between the joints.

Powdered quick lime mixed with bullock's blood, is often used by coppersmiths to lay over the rivets and edges of sheets of copper in large boilers, as a security to the junctures, and also to prevent cocks from leaking.

Six parts of clay, one of iron filings, and linseed oil sufficient to form a thick paste, make a good cement for stopping cracks in iron boilers.

Temporary cements are wanted in cutting, grinding, or polishing optical glasses, stones, and various small articles of jewellery, which it is necessary to fix on blocks, or handles, for the purpose. Four ounces of rosin, a quarter of an ounce of wax, and four ounces of whiting made previously red-hot, form a good cement of this kind, as any of the above articles may be fastened to it by heating them, and removed at pleasure in the same manner, though they adhere very firmly to it when cold. Pitch, rosin, and a small quantity of tallow, thickened with brick-dust, is much used at Birmingham for these purposes. Four parts of rosin, one of beeswax, and one of brickdust, likewise make a good cement, which answers extremely well for fixing knives and forks in their hafts; but the manufacturers of cheap articles of this kind too commonly use rosin and brickdust alone. On some occasions, in which a very tough cement is requisite, which will not crack though exposed to repeated blows, as in fastening to a block metallic articles that are to be cut with a hammer and punch, workmen usually mix some tow with the cement, the fibres of which hold its parts together.

Excellent water-proof cements are made from caoutchouc (p. 739).

The following composition is a good cement for electrical apparatus:—Five pounds of rosin, one of beeswax, one of red ochre, and two table spoonfuls of plaster of Paris, all melted together. A cheaper one for cementing voltaic plates into wooden troughs is made with six pounds of rosin, one pound of red ochre, half a pound of plaster of Paris, and a quarter of a pint of linseed oil. The ochre and plaster of Paris should be well dried, and added to the other ingredients in a melted state.—U. (See *Ure's Dictionary of Arts, Manufactures and Mines*, i. 641).

CEMENTATION is the process by which one solid is made to penetrate and combine with another at a high temperature so as to change the properties of one of them, without liquefaction taking place, being an exception to the general chemical rule, that bodies do not mutually act on each other unless when one or more of them is fluid. The conversion of iron into steel by absorption of carbon into its inmost substance, from a mass of ground charcoal in which it lies embedded while exposed to strong ignition, is one of the best examples of this process. A like change takes place on palladium, iridium, and platinum, in contact with charcoal or silica at a high heat. When a compact mass of the oxide of nickel or iron is ignited in a crucible lined and covered with charcoal, the carbon exerts its deoxidating and metallising power to the very centre. The same phenomenon occurs with compact sulphate of potassium or sodium encased and heated to redness in charcoal, these salts being thereby converted into metallic sulphides. These transformations have been ascribed to the progressive production of the gaseous oxide of carbon, and to its absorption by the metals, or its combination with the oxygen of the oxides or acids. U.

CEMENT COPPER, is the metal precipitated from the blue water of copper mines or works by plunging iron plates into them. (See COPPER.)

CENTAURIN. See CNICIN.

CENTRALLASSITE. A hydrated silicate of calcium occurring in kidney-shaped lumps, together with other minerals, at Fundy Bay. These lumps are coated with a greenish crust resembling chlorite; below this crust is a thin layer of cerinite; within this the centrallassite; and the central portion consists of cyanolite. Centrallassite exhibits a lamellated radiating structure; it is white or yellowish, translucent, brittle, of specific gravity 2·45 to 2·46, hardness 3·5, and has an almost waxy lustre. It melts before the blowpipe with intumescence to an opaque glass, and forms clear beads with fluxes. It dissolves in hydrochloric acid without gelatinising. Its analysis is said to agree with the formula $8Ca^2O.15SiO^2 + 5aq$. (H. How, Edinb. N. Phil. J. x. 847.)

CEPHALIS. See IPECACUANHA.

CEPHALOTE. *Ceranocephalote.*—A name applied by Couerbe (J. Chim. Med. x. 524) to a yellow elastic fatty substance, insoluble in alcohol, but soluble in ether, which he obtained from the brain. According to Frémy and J. R. Simon, it is a mixture of the cerebrates of potassium and sodium, with traces of olein and oleophosphoric acid.

CERADIA FUSCATA. A plant indigenous on the coast of Africa, which exudes an amber-brown resin smelling like olibanum.

CERAIC ACID. An acid containing $C^{20}H^{40}O^3$, said by Hess (Ann. Ch. Pharm. xxvii. 3) to be formed by oxidation in beeswax; also supposed to be produced in the preparation of oxalic or saccharic acid by the action of nitric acid on wheat-starch; existing also, according to Oppermann (Ann. Ch. Phys. [2] xlix. 240), in a Brazilian wax. Its existence has not been distinctly proved.

CERAIN. A name applied by Boudet and Boissenot (J. Pharm. xiii. 38) to the portion of beeswax which is sparingly soluble in alcohol, and, according to their statement, is not saponified by potash. It appears to be chiefly impure myricin, inasmuch as that body is not quite insoluble in alcohol.

CERANCEPHALOTE. See CEPHALOTE.

CERANTIC ACID. An acid found by Braconnot (Ann. Ch. Phys. [3] xxi. 484) in the fuel taken out of an antique lamp, probably of the fourth century. This material was partly soluble in boiling alcohol of 36°. The solution on cooling deposited a white flaky substance melting at 64° C., probably *cerin:* and the alcoholic mother-liquor retained a substance, which remained after evaporation, as a white, hard, brittle mass, melting at 51° C.; its alcoholic solution reddened litmus, and by slow evaporation deposited small granular crystals. This more soluble substance Braconnot designated *cerantic acid.* The portion insoluble in boiling alcohol contained myricin.

CERASIN. The gum which exudes from the cherry-tree, plum-tree, and others of the same family is only partly soluble in water. The soluble portion exhibits the characters of arabin; the remaining portion, which is called *cerasin*, merely swells up in water. Cerasin is colourless, semi-transparent, tasteless, and inodorous; easily pulverised, uncrystallisable, insoluble in water and in alcohol, not susceptible of alcoholic fermentation. Treated with nitric acid, it yields 15·5 p. c. mucic acid. According to Gélis (Compt. rend. xliv. 144) ordinary gum arabic is converted into insoluble cerasin by a heat of 150° C. This artificial cerasin is reconverted into a soluble gum by prolonged boiling with water, but again becomes insoluble when heated to 150°.

CERASINE or **CERASITE.** Syn. with Horn Lead.

CERASUS. The wood of *Cerasus avium*, the bird-cherry, contains 0·28 per cent., the bark 10·37 per cent. of ash. The constituents of these ashes are as follows:

	K^2O	Na^2O	Ca^2O	Mg^2O	Fe^4O^3	P^2O^5	SO^3	SiO^2	Cl
Wood . .	25·9	10·4	35·8	11·4	0·1	9·6	4·1	2·5	trace
Bark . .	7·9	15·5	44·7	5·4	0·2	3·5	0·8	21·3	0·4

The unripe fruit of *C. caproniana* contains a large quantity of malic acid.

C. capricida is known in Naples, and *C. virginiana* in North America, as deleterious.

CERATE. A mixture of wax with oil or lard, used by surgeons to screen ulcerated surfaces from the air. Sometimes watery liquids are incorporated with the mass, as subacetate of lead in lead-cerate. U.

CERAUNITE. Syn. with Nephrite.

CEREALIN. A nitrogenous substance closely resembling diastase, obtained by Mège-Mouriès (Compt. rend. xxxvii. 351; xxxviii. 505; xlii. 1122; xlviii. 431; l. 467) from bran. It is contained in the epispermium, the sixth membrane of the seed, reckoning from without, and possesses the power of converting starch into dextrin, sugar, and lactic acid. The brown colour of bread made with flour containing bran appears to be chiefly due to the decomposition of a portion of the flour by the cerealin of the bran (see Bread, pp. 658, 660). Stiff starch-paste is quickly converted into a thin liquid by an infusion of bran at 40° or 50° C.

To isolate cerealin, bran is treated for six hours with dilute alcohol, the residue pressed, and this treatment repeated three times, whereby the bran is freed from sugar and dextrin, while the cerealin remains unaltered and undissolved. On treating the residue with water, the cerealin is dissolved, and the aqueous solution evaporated at 40° C. leaves it in the form of an amorphous albuminoïd substance easily soluble in water, insoluble in alcohol, ether, and oils. The solution coagulates at 75° C., also on addition of alcohol; it is precipitated in flakes by dilute acids, not altered by neutral rennet. Its peculiar action on starch is prevented by the presence of alkalis. Cerealin once coagulated is no longer soluble in acids or alkalis, but still possesses the power of transforming starch, though slowly. Cerealin retains its power of decomposing starch at 70° C., but not at higher temperatures, whereas diastase does not lose this power below 90° C. In other respects the two bodies appear to resemble each other exactly.

According to recent investigation by Mouriès, bran freed from cerealin, especially the *perispermium*, appears to be more active than cerealin itself, and possesses the power of converting starch even at 100° C.

CEREALS. *Cerealia. Getreide.*—This name is applied to the grasses which are cultivated for human food, viz. wheat, barley, rye, oats, maize, and rice. They are for the most part distinguished by the large quantities of starch, nitrogenous compounds, and phosphoric acid contained in their seeds, which constituents it is the object of cultivation to develop as much as possible. The several kinds of cereal grain, excepting rice, contain nearly the same amount of nitrogen; but in wheat-grain, the nitrogenous matter (gluten) possesses a peculiar adhesiveness, arising from the presence of a glutinous substance called *gliadin*, which is wanting in the other cereals. It is this property which renders wheat-flour so peculiarly adapted for the making of bread (p. 657).

From the numerous analyses that have been made of the grain and straw of these plants, we select the following:

Way and Ogston have determined the amount of water and ash in the grain, straw, and chaff of wheat barley, oats, and rye with the following results (Journal of the Royal Agricultural Society, vii. [2] 593—678; Jahresber. f. Chem. 1849, p. 672):

Species and Varieties.	Moisture in 100 pts. of			Specific Gravity of the Grain.	Weight of 1 bushel in lbs.	Ash in 100 pts. of dry			Weight of Straw | Chaff. that of the Grain = 1000.	
	Grain.	Straw.	Chaff.			Grain.	Straw.	Chaff.	Straw	Chaff

‡ Including 73·4 sand.

Way and Ogston deduce from their analyses of the ash of cereals the following general conclusions:

The *amount* of ash is not influenced in any definite manner by the nature of the soil; it appears, however, to be greatest on clay soils, less on calcareous, and least on sandy soils. The strongest straw contains the largest amount of ash. The amount of ash in the chaff varies in proportion to that in the straw, not to that in the grain (see Table I.). The amount of ash in the grain varies between much narrower limits than that of the straw or chaff. It varies as much in different samples of grain grown on the same soil as in samples from different soils, and bears no definite relation either to climate or to variety. But in all cases that were examined, the proportion of ash in the grain was found to vary inversely as the total weight of grain in the crop; whence it would appear that the amount of mineral constituents abstracted from the soil by the grain is the same whatever may be the actual weight of the crop.

Not only the amount, but likewise the composition of the ash appears to be independent of the nature of the soil: the predominance of any constituent, lime or silica, for example, in the soil by no means leads to a predominance of that same constituent in the plant. Neither does it appear that different bases have any tendency to replace one another in plants. An abundance of soda in the soil or the manure does not cause that alkali to take the place of potash in the plant. Other chemists have, however, arrived at different conclusions relating to this point. (See Daubeny, Chem. Soc. Qu. J. v. 9; xiv. 215.—Malaguti and Durocher, Ann. Ch. Phys. [3] liv. 257.)

The difference in the amount of ash in the grain, straw, and chaff relate only to the silica; if this be deducted, the remainders exhibit no perceptible difference.

The ash of the grain of barley and oats differs from that of wheat-grain only in the much larger amount of silica contained in the two former; if this be deducted, all essential differences vanish.

For further details, see the names of the several cereals (BARLEY, under HORDEUM); also the articles SOILS and MANURES.

CEREBRIC ACID. (Frémy, Ann. Ch. Phys. [2] lvi. 168; v. Bibra, *Vergleichende Untersuchungen über das Gehirn der Menschen und der Wirbelthiere*, Mannheim, 1854.)—A fatty acid contained in the brain. It is obtained by cutting brain into thin slices; treating it repeatedly with boiling alcohol to deprive it of water; pressing it; digesting first with cold then with warm ether; distilling off the ether from the solution; and digesting the slimy residue with a much larger quantity of ether. Cerebric acid then remains as a sodium-salt mixed with phosphate of calcium, oleo-phosphoric acid in the form of a sodium and calcium-salt, and brain-albumin. To purify the product, it is digested in boiling absolute alcohol slightly acidulated with sulphuric acid, which leaves the calcium and sodium undissolved as sulphates, while the alcohol takes up the cerebric and oleo-phosphoric acids, and deposits them on cooling. Lastly, the mixture is washed with cold ether, which dissolves the oleo-phosphoric acid and leaves the cerebric acid, which is finally purified by recrystallising it several times from boiling ether.

Cerebric acid has a white, granular, crystalline aspect; it is soluble in boiling alcohol, insoluble in cold ether, easily soluble in boiling ether; in boiling water it swells up, but does not dissolve. It melts at a temperature near that at which it begins to decompose, and when more strongly heated burns with a characteristic odour, leaving a difficultly combustible charcoal with a decided acid reaction. It consists, according to Frémy, of 66·7 per cent. carbon, 10·6 hydrogen, 2·3 nitrogen, 0·9 phosphorus, and 19·5 oxygen. According to Müller and v. Bibra, the phosphorus is not an essential constituent.

Cerebric acid is a weak acid, but nevertheless forms salts with all bases. The *ammonium-*, *potassium-*, and *sodium*-salts are obtained as precipitates, nearly insoluble in alcohol, by placing an alcoholic solution of cerebric acid in contact with the respective alkalis. *Baryta*, *strontia*, and *lime* unite directly with cerebric acid, and deprive it of its property of forming an emulsion with water.

CEREBRIN. This name has been applied to several substances obtained from brain. Fourcroy in 1793 (Ann. Chim. xvi. 283) obtained a substance which was called cerebrin, brain-fat, or phosphoretted bile-fat, and was probably a mixture of Frémy's cerebric acid with the substance which separates after some time from alcohol in which anatomical preparations containing nerves or brain have been preserved. Chevreul applied the same term to a substance obtained from blood-serum, probably a mixture of fats and glycerides containing phosphoric acid. Lastly, Gobley (J. Pharm. [3] xviii. 107) designates as cerebrin, a substance obtained chiefly from carp's eggs, and agreeing essentially in composition and property with Frémy's cerebric acid, excepting that it does not exhibit any tendency to combine with bases.

W. Müller (Ann. Ch. Pharm. cv. 361) has obtained a substance analogous to

Frémy's cerebrin, by triturating brain to a thin pulp with water, heating the mixture to the boiling point, and treating the separated coagulum with boiling alcohol. The alcoholic extract filtered at the boiling heat deposits a mixture of cholesterin and cerebrin, together with other substances; and on treating this mixture with cold ether, cerebrin remains behind, and may be purified by repeated crystallisation from boiling alcohol. It then forms a snow-white powder composed of microscopic spherules, agreeing with Frémy's cerebric acid in most of its properties, especially in swelling up in water like starch, and forming an emulsion. It contains 68·45 per cent. carbon, 11·20 hydrogen, 4·51 nitrogen, and 15·66 oxygen, whence Müller deduces the empirical formula $C^{17}H^{33}NO^{3}$. It does not dissolve in alkalis or in dilute acids, but is decomposed at the boiling heat by hydrochloric, sulphuric, and nitric acid. The product of its decomposition by nitric acid is a non-azotised white waxy body, soluble in alcohol and ether. Treated with strong sulphuric acid in the cold, it dissolves with dark purple-red colour, and the solution mixed with a large quantity of water becomes colourless, and deposits a yellowish, tenacious, flocculent substance.

It is most probable that the cerebrin of Gobley and Müller, the cerebrote of Couerbe, and the cerebric acid of Frémy and v. Bibra contain, as their essential constituent, one and the same substance, which is likewise present in cephalote and stearoconote. (Handw. d. Chem. 2te Aufl. ii. [2] 888.)

CEREBROL (Berzelius). *Eleene-cerebrol* (Couerbe).—An oily reddish substance, insoluble in water, soluble in alcohol and ether, obtained by Couerbe (J. Chim. méd. ii. 765; x. 524) from brain. According to Frémy, it is a mixture of olein, oleo-phosphoric acid, cholesterin, and cerebric acid.

CEREBRO-SPINAL FLUID. A serous fluid contained in the sub-arachnoïdal cavities, and forming a liquid atmosphere round the brain and spinal marrow. It belongs to the class of serous transudates, and is generally distinguished by its very small amount of solid constituents, especially of organic matter. These constituents are albumin, traces of fat, extractive matter, and the inorganic salts of blood-serum. It contains also a substance which reduces cupric salts, but differs from glucose in not being resolved into alcohol and carbonic acid by fermentation. According to F. Hoppe (Chem. Centralbl. 1860, p. 42) this substance is soluble in water and in absolute alcohol, does not crystallise, either *per se* or with chloride of sodium, is not precipitated either by neutral or basic acetate of lead alone, but yields a precipitate with the latter in presence of ammonia. It is decomposed by putrefaction.

Hoppe and Schwaberg analysed the cerebro-spinal fluid obtained by puncturing, in two cases of *Spina bifida* and two of *Hydrocephalus internus*, with the following results:—

	Spina bifida.		Hydrocephalus.	
	I. Puncture.	II. Puncture.	I. Puncture.	II. Puncture.
Water	989·33	989·80	979·01	989·53
Soiled matter	10·67	10·20	20·99	10·47
Albumin	0·25	0·55	11·79	0·70
Extractive matter	2·30	2·00	1·32	1·57
Soluble salts	7·67	7·20	7·54	7·67
Insoluble salts	0·45	0·45	0·35	0·53

The fluids from the *Spina bifida* were strongly alkaline and perfectly transparent. The first reduced cupric oxide, the second did not. The second hydrocephalic liquid also exhibited the reducing action. The greater amount of albumin in the first hydrocephalic liquid was due to previous inflammation of the transudent vessels. (Handw. d. Chem. ii. [2] 891.)

CEREBROTE. (Couerbe, Ann. Ch. Phys. [2] lvi. 164.) *Brain-wax*, *Hirnwachs* (L. Gmelin), *Markpulver*, *Myelocone* (Kühn.)—A substance containing sulphur and phosphorus, which Couerbe obtained by treating the deposit which separates from the alcoholic and ethereal extracts of the brain with ether; cholesterin then dissolves, and the so-called cerebrote remains. According to Frémy, it is merely a mixture of cerebric acid with small quantities of cerebrate of potassium and brain-albumin.

CERIC ACID. An acid obtained by treating cerin, the waxy matter of cork, with nitric acid, washing with water, dissolving in alcohol, filtering and evaporating. It is a brownish diaphanous waxy mass, which softens at a gentle heat, and melts below the boiling point of water. Dissolves readily in alkalis. Yields empyreumatic products when heated. Contains 64·2 per cent. carbon, 8·8 hydrogen, and 27·0 oxygen. With acetate of *lead* it forms a white precipitate containing 51·1 C, 6·9 H, 19·2 $Pb^{2}O$, and 22·8 O. (Döpping, Ann. Ch. Pharm. xlv. 289.)

CERIN. A waxy substance extracted by alcohol or ether from grated cork, previously freed from the outer crust. It separates from the solution in yellowish needles, which may be obtained colourless by recrystallisation. Contains 74·95 carbon, 10·55 hydrogen, and 14·5 oxygen, agreeing nearly with the empirical formula $C^{23}H^{40}O^{3}$. Cerin softens in boiling water and falls to the bottom. It is not attacked by boiling potash. Thrown on glowing coals, it volatilises like beeswax, giving off white fumes. By dry distillation it yields a little acid and a large quantity of an oil which solidifies on cooling; it leaves but little charcoal. Treated with hot nitric acid it yields ceric acid, together with oxalic and carbonic acids. Cork contains from 1·8 to 2·5 per cent. of waxy matter. (Chevreul, Ann. Chim. xcvi. 170; Döpping, *loc. cit.*)

The name *cerin* was also applied by John to the portion of beeswax which is soluble in alcohol; but according to Brodie, the substance thus designated is merely impure cerotic acid (*q. v.*)

CERINE or ALLANITE. See ORTHITE.

CERININ. A waxy fat obtained from the lignite of Gerstewitz near Merseberg, of which it forms about 18 per cent. Contains 76·7 to 78·1 C, and 11·1 to 12·3 H. Plastic at common temperatures; melts at 100° C.; sparingly soluble in alcohol; not saponifiable; yields a crystalline product by distillation. (Wackenroder, Ann. Ch. Pharm. lxxii. 315.)

CERITE. A hydrated silicate of cerium, containing also lanthanum and didymium. It is the chief source of cerium, and is the mineral from which that metal was first obtained. It is found only in an abandoned copper mine at Riddarhytta in Westmanland, Sweden, occurring in compact fine-grained masses of indistinct blackish red colour; also in short six-sided prisms. Specific gravity 4·93. Hardness 5·5. Before the blowpipe it gives off water, but does not melt. It is completely decomposed by hydrochloric acid, leaving a residue of silica. According to Kjerulf (Ann. Ch. Pharm. lxxxvii. 12) it does not give off a trace of chlorine when treated with hydrochloric acid, and consequently the cerium exists in it wholly as cerous oxide. Kjerulf found it to contain:

SiO^{2}	$Ce^{2}O$	$La^{2}O$ $Di^{2}O$	$Fe^{2}O$	$Ca^{2}O$	$H^{2}O$	MoS	BiS	
20·40	56·07	8·12	4·77	1·17	5·29	3·27	0·18	= 99·27

whence may be deduced the formula $2M^{2}O.SiO^{2}$ + aq. or $M^{4}SiO^{4}$ + aq. It generally also contains a small quantity of yttria.

CERIUM. *Symbol* Ce. *Atomic Weight* 46.—This metal, which was discovered in 1803, simultaneously by Klaproth and by Hisinger and Berzelius, exists, together with lanthanum and didymium, in cerite, allanite, orthite, yttro-cerite, and a few other minerals, all of somewhat rare occurrence. The most abundant of them is cerite (*vid. sup.*) To extract the oxides of the three metals, the cerite is finely pounded and boiled for some hours with strong hydrochloric acid, or aqua-regia, which dissolves the metallic oxides, leaving nothing but silica. The filtered solution is then treated with a slight excess of ammonia, which precipitates everything but the lime; the precipitate is redissolved in hydrochloric acid, and the solution treated with excess of oxalic acid. A white or faintly rose-coloured precipitate is then obtained, consisting of the oxalates of cerium, lanthanum, and didymium: it is curdy at first, but in a few minutes becomes crystalline, and easily settles down. When dried and ignited, it yields a red-brown powder, containing the three metals in the state of oxide. The finely pounded cerite may also be mixed with strong sulphuric acid to the consistence of a thick paste, the mixture gently heated till it is converted into a dry white powder. and this powder heated somewhat below redness in an earthen crucible. The three metals are thus brought to the state of basic sulphates, which dissolve completely when very gradually added to cold water; and the solution treated with oxalic acid yields a precipitate of the mixed oxalates, which may be ignited as before.

From the red-brown mixture of the oxides of cerium, lanthanum, and didymium thus obtained, a pure oxide of cerium may be prepared by either of the following processes:—1. The mixed oxides are heated with strong hydrochloric acid, which dissolves the whole, with evolution of chlorine; the solution is precipitated with excess of caustic potash; and chlorine gas passed through the liquid with the precipitate suspended in it. The cerium is thereby brought to the state of ceroso-ceric oxide, which is left undissolved in the form of a bright yellow precipitate, while the lanthanum and didymium remain in the state of protoxides, and dissolve. To ensure complete separation, the passage of the chlorine must be continued till the liquid is completely saturated with it, and the solution, together with the precipitate, left for several hours in a stoppered bottle, and agitated now and then. The liquid is then filtered, the washed precipitate treated with strong boiling hydrochloric acid, which dissolves it with evolution of chlorine, and forms a colourless solution of protochloride of cerium; and this, when treated with oxalic acid or oxalate of ammonia, yields a perfectly white precipitate of oxalate of cerium, which may be converted into oxide by ignition (Mosander).—2. The red-brown mixture of the three oxides is treated with very dilute nitric acid (1 pt. of nitric acid of ordinary strength to between 50 and 100 pts. of water), which dissolves the greater part of the oxides of lanthanum and didymium, and leaves the oxide of cerium; and by treating the residue with very strong nitric acid, the last traces of lanthanum and didymium may be extracted (Mosander, Marignac).—3. The red-brown mixture of the three oxides is boiled for several hours in a strong solution of chloride of ammonium. The oxides of lanthanum and didymium then dissolve, with evolution of ammonia, and sesquioxide of cerium is left in a state of purity. It must be collected on a filter and washed with a solution of sal-ammoniac, because, when washed with pure water, it first runs through the filter, and then stops it up (Watts, Chem. Soc. Qu. J. ii. 147).—4. Oxalate of cerium obtained as above is mixed with half its weight of pure magnesia, and made up into a stiff paste with water; and this mixture when dry is heated to low redness in a porcelain basin, with constant stirring. The product is a cinnamon-coloured powder, containing the whole of the cerium as ceric (? ceroso-ceric) oxide, in combination with magnesia, oxide of lanthanum, and other protoxides. It dissolves completely, with aid of heat, in strong nitric acid, forming a deep brown solution of a double salt, which appears to consist of ceric nitrate in combination with cerous nitrate and the nitrates of lanthanum, didymium, and magnesium, sometimes also a small quantity of nitrate of yttrium. This double salt separates in splendid rhombohedral crystals having nearly the colour of acid chromate of potassium. The solution, if diluted with water before these crystals have separated, does not yield any precipitate, either in the cold or in boiling; but if the crystallisation be allowed to go on till lighter-coloured laminated crystals separate containing magnesium and lanthanum with very little cerium, the mother-liquor then deposits, on dilution and boiling, a basic salt of cerium free from all other metals. The precipitate is not formed so long as the red double salt remains dissolved in the liquid; indeed it redissolves on adding to the liquid a solution of that salt. The liquid from which the cerium precipitate has separated still retains cerium, which may be separated by repetition of the treatment.

To separate the cerium from the solution of the red salt, it is diluted with a large quantity of water, then boiled, and sulphuric acid added in small quantity as long as the resulting precipitate is thereby increased. The cerium is then precipitated as a yellowish-white, flocculent basic salt, containing both nitric and sulphuric acids, but free from all other metals, which is difficult to wash on a filter, but is easily washed by decantation with water slightly acidulated with sulphuric acid. This salt dissolves readily in strong sulphuric acid, and the solution, after reduction with sulphurous acid, yields, with oxalic acid, a white precipitate of pure cerous oxalate.

If it be desired to obtain a basic nitrate of cerium free from sulphuric acid, as is often desirable for other preparations, the red solution of the double nitrate must be evaporated to a syrup, and then poured into a large excess of boiling water slightly acidulated with nitric acid. The precipitate thereby formed is washed by decantation with water containing a little nitric acid, and the mother-liquor, together with the wash-water, is again evaporated to a syrup and treated as before, till nearly all the cerium is extracted. The addition of nitric acid to the wash-water is essential, as the basic nitrate dissolves somewhat readily in pure water. It is best to preserve the precipitated salt under acidulated water, since it becomes insoluble in acids when dried and ignited. (Bunsen, Ann. Ch. Pharm. cv. 40.)

Metallic cerium is obtained by heating the pure anhydrous protochloride with potassium or sodium. It is a grey powder, which acquires the metallic lustre by pressure. It oxidises readily, decomposes water slowly at ordinary temperatures, quickly at the boiling heat, and dissolves rapidly in dilute acids, with evolution of hydrogen, forming a solution of a cerous salt.

Cerium forms three classes of compounds, viz. the *cerous compounds*, or *proto-compounds*, *e.g.* the protochloride, CeCl, the protoxide Ce^2O; the *sesqui-compounds*, or *ceric compounds*, *e.g.* Ce^2Cl^3, and Ce^4O^3, and the *ceroso-ceric* compounds, which may be regarded as compounds of the other two; *e.g.* ceroso-ceric oxide, $Ce^3O^2 = Ce^2O.C^4O^3$.

CERIUM, BROMIDE OF. Not known in the anhydrous state. A solution of ceric oxide in hydrobromic acid yields by evaporation, small crystals of a hydrated bromide, which gives off hydrobromic acid when heated and leaves an oxybromide.

CERIUM, CHLORIDES OF. Cerium burns vividly when heated in chlorine gas, and forms the *protochloride* CeCl. The anhydrous chloride may be prepared by igniting the sulphide, or the residue obtained by evaporating to dryness a solution of the chloride mixed with sal-ammoniac, in a current of chlorine gas. If the air is not completely excluded, an oxychloride is also produced. The anhydrous chloride is a white porous mass, fusible at a red heat, and perfectly soluble in water. A *hydrated* *chloride* is obtained in colourless four-sided prisms, by dissolving the hydrated oxide or the carbonate in hydrochloric acid, and evaporating to a syrup. The solution when exposed to the air, turns yellow, from formation of a ceroso-ceric salt.

Protochloride of cerium forms with *dichloride of platinum*, an orange-coloured crystalline double salt, $2CeCl.PtCl^2.4H^2O$, easily soluble in water and alcohol, insoluble in ether. It also combines with *iodide of zinc*. (Holzmann, Phil. Mag. [4] xxii. 219.)

Ceroso-ceric chloride.—Hydrated ceroso-ceric oxide dissolves in cold hydrochloric acid, forming a red solution, which, however, soon gives off chlorine, and is reduced, more or less completely, to protochloride.

CERIUM, DETECTION AND ESTIMATION OF. 1. *Reactions.*—All compounds of cerium, ignited with *borax* or *microcosmic salt* in the outer blowpipe flame, yield a glass which is deep red while hot, but becomes colourless on cooling. In the inner flame, a colourless bead is formed with a small quantity of the cerium compound; but a yellow enamel with a larger quantity.

Cerous salts in solution are colourless, have a sweet astringent taste, and redden litmus, even when the acid is perfectly saturated. They are distinguished by the following reactions: *Sulphydric acid* produces no precipitate. *Sulphide of ammonium* throws down the hydrated protoxide. *Caustic potash* or *soda* produces a white precipitate of the hydrated protoxide, which is insoluble in excess, and is converted into the yellow hydrated sesquioxide by the action of chlorine-water or hypochlorous acid. *Ammonia* precipitates a basic salt. *Alkaline carbonates* form a white precipitate of cerous carbonate insoluble in excess. *Oxalic acid* or *oxalate of ammonia* produces a white precipitate of cerous oxalate, gelatinous at first, but quickly assuming the crystalline character, and converted by ignition in an open vessel into a yellowish-white powder consisting of ceroso-ceric oxide. *Ferrocyanide of potassium* produces a white pulverulent precipitate; ferricyanide of potassium none. *Sulphate of potassium* produces a white crystalline precipitate of potassio-cerous sulphate, nearly insoluble in pure water, and quite insoluble in excess of sulphate of potassium. With dilute solutions the precipitate takes some time to form. This character, together with the behaviour of the oxalate and the yellow coloration of the hydrated protoxide by hypochlorous acid, serves to distinguish cerium from all other metals.

2. *Quantitative Estimation.*—Cerium is precipitated from neutral solutions of cerous salts by carbonate of ammonium, as cerous carbonate, or by oxalate of ammonium as cerous oxalate; and either of these compounds is converted by ignition in an open vessel, into ceroso-ceric oxide, which, according to Bunsen, corresponds, *within the limits of experimental error*, to the formula Ce^3O^4, and contains 81·18 per cent. of metallic cerium, or 95·04 per cent. of the protoxide. Another method is to dissolve the precipitated carbonate in dilute sulphuric acid, evaporate, and heat the residue to commencing redness, whereby it is converted into the anhydrous sulphate, Ce^2SO^4, containing 48·95 per cent. of the metal, or 57·45 per cent. of the protoxide.

3. *Separation from other Elements.*—Sulphydric acid serves to separate cerium from all metals which are precipitated by that reagent from their acid solutions. From *manganese*, *iron*, *cobalt*, *nickel*, *zinc*, *titanium*, *chromium*, *vanadium*, and *tungsten*, cerium may be separated by means of a saturated solution of sulphate of potassium.

From *aluminium* it may be separated by carbonate of barium, which precipitates alumina and not cerous oxide; from *glucinum* by sulphate of potassium. From *yttrium*, with which it is often associated in minerals, it may be separated by a saturated solution of sulphate of potassium, added in excess, the sulphate of yttrium and potassium being soluble in excess of sulphate of potassium, while the cerous double salt remains undissolved. From *zirconium*, cerium is separated by treating the boiling acid solution with sulphate of potassium, whereby the greater part of the zirconia is precipitated as basic sulphate, while the cerium remains dissolved; to complete the precipitation, a small quantity of ammonia must be added, but not sufficient to saturate the acid (H. Rose). From *magnesium* also cerium may be separated by sulphate of potassium; from *barium*, *strontium*, and *calcium*, it is separated by ammonia added in slight excess; or from barium by sulphuric acid, and from strontium and calcium by sulphuric acid and alcohol; and from the *alkali-metals* by precipitation with oxalate of ammonia. Bunsen's method of precipitation already described, affords however the the best means of separating cerium from all the metals with which it is found associated, especially from *lanthanum*, *didymium*, and *yttrium*.

4. *Atomic Weight of Cerium.*—The older statements respecting the atomic weight of this metal, all refer to cerium containing lanthanum and didymium. For this impure metal, Hisinger, in 1814, found the number 45·65 ($H = 1$), and Otto found 46·8. After the method of removing the lanthanum and didymium had been pointed out by Mosander, Beringer (Ann. Ch. Pharm. lii. 134), from the analysis of the proto-

chloride CeCl, deduced the number 47·8, and from that of the sulphate the number 46·2.

Hermann, from an analysis of cerous sulphate, in which the sulphuric acid was precipitated as sulphate of barium, found for cerium the number 46.

Marignac (Ann. Ch. Pharm. lxviii. 215), by precipitating cerous sulphate with a graduated solution of chloride of barium, obtained, as a mean of seven experiments, Ce = 47·26. Afterwards, however (Ann. Ch. Phys. [3] xxxviii. 148), he rejected this number, and adopted that previously found by Hermann, viz. 46, attributing the excess of his former determination to the circumstance, that a portion of the cerous sulphate had been carried down undecomposed by the barium precipitate, whence the quantity of chloride of barium required to precipitate the sulphate came out too low.

Lastly, Bunsen has determined the atomic weight of cerium by the analysis of the sulphate. Pure basic ceric sulphate, obtained as above described (p. 832), was dissolved in sulphuric acid, reduced to cerous sulphate by sulphurous acid, the salt evaporated and ignited till all the excess of acid was expelled, and the residue twice crystallised from water. A solution of this salt was precipitated by oxalic acid; the precipitated oxalate converted into ceroso-ceric oxide by ignition in an open vessel; and the sulphuric acid precipitated from the filtrate by chloride of barium. The ceroso-ceric oxide was then heated in a sealed flask containing very little air, with pure hydrochloric acid and iodide of potassium, whereby it was reduced to cerous oxide, and a quantity of iodine set free equivalent to the oxygen separated from the ceroso-ceric oxide. This free iodine was estimated by Bunsen's volumetric method (ANALYSIS, VOLUMETRIC, p. 266), and the corresponding amount of oxygen estimated by the formula $x = \frac{O}{2I}\ a\ (nt - t')$. In this manner, 100 pts. of the ceroso-ceric oxide were found to contain 95·04 cerous oxide and 4·96 oxygen. From this, the quantity of cerous oxide in the ignited ceroso-ceric oxide (that is to say, in the original quantity of cerous sulphate), was calculated, and the amount of sulphuric acid (SO^3) being likewise found from the precipitated sulphate of barium, the composition of the cerous sulphate was found to be $57·49\ Ce^2O + 42·51\ SO^3 = 100$, whence the atomic weight of cerous oxide was found from the proportion $42·51 : 57·49 = 80 : x$, giving $Ce^2O = 108·1$, and therefore $Ce = 46·1$. Two other experiments gave $Ce = 46·02$ and $46·05$.

In accordance with the preceding results, the whole number 46 is generally adopted as the true atomic weight of cerium.

CERIUM, FLUORIDES OF. The protofluoride CeF, is obtained as a white precipitate, by adding an alkaline fluoride to a cerous salt. It is but partially reduced by the action of hydrogen gas and potassium vapour at a red heat. (Mosander.)

The *sesquifluoride*, Ce^2F^3, prepared in like manner, is a yellow precipitate. It also occurs native as *fluocerite*, in brick-red or nearly yellow six-sided prisms and plates, with very distinct basal cleavage; also massive; specific gravity 4·7. Hardness 4·5. It gives off fluorine when strongly heated in a glass tube. It occurs at Finbo and Broddbo, near Fahlun, in Sweden. Sesquifluoride of cerium also occurs with the fluorides of calcium and yttrium, as *yttrocerite* (*q. v.*)

A *hydrated ceric oxyfluoride*, $Ce^6F^6O^3 + 3H^2O$, occurs at Finbo as *fluocerine*, in yellow crystals with vitreous lustre, supposed to belong to the regular system (Gm. iii. 271). A mineral from Bastnäs in Sweden, analysed by Hisinger, yielded numbers corresponding to the formula $Ce^6F^6O^3 + 4H^2O$; one from Finbo, analysed by Berzelius, was found to consist of $Ce^{16}F^6O^9 + 3H^2O$, or $2Ce^2F^3.3(Ce^4O^3.H^2O)$. (Dana, ii. 96.)

CERIUM, OXIDES OF. The *Protoxide*, or *Cerous oxide*, Ce^2O, is obtained by heating the carbonate or oxalate in a current of dry hydrogen perfectly free from air. It is a greyish-blue powder, which on exposure to the air quickly becomes very hot, and is converted into yellowish-white ceroso-ceric oxide. *Cerous hydrate* precipitated from the solution of a cerous salt by a caustic alkali, is white, but when exposed to the air, quickly changes to a yellow mixture of cerous carbonate and ceroso-ceric hydrate (Rammelsberg, Pogg. Ann. cviii. 40). The hydrate dissolves readily in sulphuric, nitric, hydrochloric, and acetic acid, the solutions giving the characters described at p. 833.

Ceroso-ceric Oxide, Ce^3O^2.—This oxide, which may be regarded as a compound of cerous and ceric oxide: $2Ce^3O^2 = Ce^2O.Ce^4O^3$, is produced when cerous hydrate, carbonate, oxalate, or nitrate, is ignited in an open vessel. It is yellowish-white, acquires a deep orange-red colour when heated, but recovers its original tint on cooling (Bunsen, Rammelsberg). Ignited in hydrogen gas, it assumes an olive-green colour, but does not diminish perceptibly in weight (Bunsen). It is not raised to a higher state of oxidation by heating in oxygen gas, or even by fusion with chlorate or hydrate of potassium (Rammelsberg). Nitric and hydrochloric acid have but little action upon it, even at the boiling heat, unless it be mixed with the oxides of lanthanum and didymium, in which case it dissolves readily in hot hydrochloric acid, with evolution of chlorine. Heated with a mixture of iodide of potassium and hydrochloric acid, it dissolves completely, with separation of iodine,—a property which has been made available by Bunsen for determining its composition. Strong sulphuric acid at the boiling heat, converts it into an orange-red salt, which becomes light yellow on cooling, and dissolves with yellow colour in water.

Marignac did not obtain ceroso-ceric oxide of constant composition, but supposed it to have, for the most part, the composition $3Ce^2O.2Ce^4O^3$, or $Ce^{14}O^9$. Rammelsberg, by decomposing the ceroso-ceric sulphate, $3Ce^2SO^4.Ce^4(SO^4)^3$ with potash, obtained a reddish-grey precipitate which contained $3Ce^2O.Ce^4O^3$, but was quickly converted into Ce^3O^3, on exposure to the air.

Ceroso-ceric Hydrate, $2Ce\,O^2.3H^2O$, obtained by passing chlorine into aqueous potash in which cerous hydrate is suspended (p. 831), is a bright yellow precipitate, which dissolves readily in sulphuric and nitric acid, forming yellow solutions of ceroso-ceric salts; in hydrochloric acid, with evolution of chlorine, forming colourless cerous chloride.

Ceric Oxide, Ce^4O^3, does not appear to exist in the free state, inasmuch as ceroso-ceric oxide is not brought to a higher state of oxidation, even by ignition with powerful oxidising agents (*vid. sup.*)

CERIUM, OXYGEN-SALTS OF. The *cerous salts* are produced by dissolving cerous oxide or carbonate in acids, also by the action of sulphurous acid and other reducing agents on ceric or ceroso-ceric salts. (For their properties and reactions see p. 833.) Cerous silicate exists in nature as *Cerite;* the phosphate as *Monazite*, *Erdwardsite*, *Cryptolite*, and *Phosphocerite:* the carbonate, together with fluoride of calcium, in *Parisite.*

Cerous sulphate forms sparingly soluble double salts with the sulphates of ammonium, potassium, and sodium. The potassium-salt, $KCeSO^4$, is the least soluble in water, and quite insoluble in solution of sulphate of potassium.

The *ceroso-ceric* salts are obtained by dissolving the corresponding oxide or hydrate in acids. The solution of the sulphate yields by spontaneous evaporation, first brown-red crystals, composed of $3Ce^2SO^4.Ce^4.(SO^4)^3 + 18\,aq.$, and afterwards a yellow, indistinctly crystalline salt, containing $Ce^2SO^4.Ce^4(SO^4)^3 + 8\,aq.$ By substituting *cericum*, $ce = 30\frac{2}{3}$ for *cerosum*, $Ce = 46$, in the sesquisulphate, these formulæ may be reduced to $\left.\begin{matrix}(SO^2)''\\ Ce\,.\,ce\end{matrix}\right\}O + 6\,aq.$ and $\left.\begin{matrix}(S^2O^4)^{iv}\\ Ce.ce^3\end{matrix}\right\}O^4 + 4\,aq.$, respectively. Both salts are decomposed by water, with separation of a basic salt, containing $5Ce^2O^2.3\left(\left.\begin{matrix}S^2O^4\\ Ce\,.\,ce\end{matrix}\right\}O^4\right)$ $+ 12\,aq.$, but dissolve on addition of sulphuric or nitric acid. The solution of either salt yields, with sulphate of potassium, a mixture of at least two double salts, in which potassium and cerosum may be regarded as replacing one another isomorphously: similarly with sulphate of ammonium: the ammonium double salts, when ignited, leave pure ceroso-ceric oxide.

The rhombohedral nitrate of cerium and magnesium obtained by Bunsen (p. 832), is, when purified, a ceroso-cerico-magnesic salt, containing $Mg^2Ce(NO^3)^3.(Ce^2)'''(NO^3)^3$ $+ 8\,aq.$, or $\left.\begin{matrix}(NO^2)^6\\ Mg^2\,Ce\,ce^3\end{matrix}\right\}O^6 + 8\,aq.$ [As originally obtained, it contains lanthanum and didymium, replacing cerium isomorphously.] Double salts of similar composition are obtained by mixing a solution of this nitrate with the nitrates of potassium and zinc; with nitrate of nickel, a basic salt containing $\left.\begin{matrix}(NO^2)^6\\ Ni^2\,Ce\,ce^3\end{matrix}\right\}O^6.NiHO + 12H^2O$. (Holzmann, J. pr. Chem. lxxv. 321.)

The existence of pure *ceric* salts is by no means certain. Bunsen speaks of a basic ceric sulphate, precipitated by boiling the solution of the magnesian ceroso-ceric salt just mentioned, with sulphuric acid; but he has not given an analysis of it: indeed, *no analysis of a pure ceric salt has yet been published.* The so-called basic ceric sulphate just mentioned, yields, by digestion with caustic potash, not ceric, but ceroso-ceric hydrate (Holzmann). [For further details respecting the oxygen-salts of cerium, see the several acids.]

CERIUM, PHOSPHIDE OF. Said to be obtained, together with phosphate, by passing phosphoretted hydrogen over white-hot ceroso-ceric oxide. (Mosander.)

CERIUM, SELENIDE OF. Produced by decomposing cerous selenite with hydrogen at a red heat. It is a brownish powder, which dissolves in acids, with evolution of selenhydric acid. Cerous salts give with alkaline selenides a pale red precipitate, probably consisting of hydrated selenide of cerium.

CERIUM, SULPHIDES OF. *Cerous sulphide*, Ce^2S, is obtained by igniting the carbonate in vapour of sulphide of carbon, or by heating an oxide of cerium with sulphide of potassium. The first process yields a light powder of the colour of red lead; the second, a product resembling mosaic gold (Mosander). *Ceric sulphide* is not known in the free state, but is said to combine with other metallic sulphides.

CEROLEIN. A substance obtained from beeswax (in which it is said to exist to the amount of 4 or 5 per cent.) by treating the wax with boiling alcohol, leaving the cerotic acid to deposit on cooling, and evaporating the filtered solution. It is very soft, melts a 28·5° C., dissolves readily in cold alcohol and ether; is acid to litmus; gives by analysis 78·74 per cent. C, 12·51 H, and 8·75 O (Lewy, Ann. Ch. Phys. [3] xiii. 438). It is probably a mixture.

CEROLITE or **KEROLITE** (from κηρος wax, and λιθος stone).—This name is applied to two or three minerals or mixtures, consisting chiefly of hydrated silicate of magnesium more or less mixed with silicate of aluminium. They are all massive, reniform, compact or lamellar, transparent or translucent, white or grey, with vitreous or resinous lustre, and greasy to the touch.

Analyses.—*a.* From Frankenstein in Silesia by Kühn; *b.* from an unknown locality by Delesse; *c.* from Zöblitz in Saxony by Melling:

	SiO^2	Al^4O^3	Mg^2O	Fe^2O	H^2O	
a . .	46·96	—	31 26	—	21·22	= 99·44
b . .	53·5	0·9	28·6	—	16·4	= 99·4
c . .	47·13	2·57	36·13	2·92	11·50	= 100·25

The first agrees nearly with the formula $Mg^4SiO^4 + 3aq.$ (*Rammelsberg's Mineralchemie*, p. 862.)

CEROPIC ACID. An acid obtained by Kawalier (Ann. Ch. Pharm. lxxxviii. 360) from the needles of the Scotch fir (*Pinus sylvestris*). The needles are boiled with alcohol of 40 per cent., the alcohol is distilled off, and the residue is mixed with water, whereby it is separated into a yellowish resin and a somewhat turbid liquid. The resinous mass is redissolved in alcohol of 40 per cent., the solution precipitated with acetate of lead, and the precipitate suspended in alcohol is decomposed by sulphuretted hydrogen. The solution filtered hot deposits ceropic acid in yellowish-white flocks, which, by boiling with alcohol and animal charcoal and repeated crystallisation from alcohol, may be obtained in white, friable, microscopic crystals, melting at 100° C., and solidifying in a waxy mass. The crystals dried in vacuo gave by analysis 74·24 per cent. carbon and 12·17 hydrogen, whence Kawalier deduces the improbable formula $C^{36}H^{34}O^{5}$. The barium-salt gave 65·50 carbon, 10·33 hydrogen, 12·65 oxygen, and 11·52 baryta, represented by the formula $BaO.C^{36}H^{34}O^{5}$.

CEROSIC ACID. $C^{48}H^{96}O^{2}$.—Obtained by heating cerosin (sugar-cane wax) with potash-lime, and purified by saponifying with baryta, dissolving the soap in alcohol, decomposing it with hydrochloric acid, and dissolving the precipitate in rock-oil, whence it crystallises on cooling. It melts at 93°C.; dissolves sparingly in boiling alcohol and ether. (Lewy, Ann. Ch. Phys. [3] xiii. 438.)

CEROSIN. *Cerosie.*—The wax of the sugar-cane, obtained by rasping the bark of the cane, especially of the violet variety, and purified by recrystallising several times from boiling alcohol. It then forms delicate white nacreous laminæ, which do not stain paper. Gives by analysis 81·0 to 81·7 C and 13·6 to 14·2 H, agreeing nearly with the formula $C^{48}H^{96}O^{2}$, which represents it as a kind of aldehyde or ether. It melts at 82° C., is insoluble in cold ether and alcohol, very soluble in boiling alcohol. It is very hard and easily pulverised. (Avequin, Ann. Ch. Phys. lxxv. 218; Dumas, *ibid.* lxxv. 222; Lewy, *loc. cit.*)

CEROTENE. $C^{27}H^{54}$.—A hydrocarbon homologous with ethylene, first obtained by Brodie (Phil. Mag. [3] xxxiii. 378; Ann. Ch. Pharm. lxvii. 199) as a product of the dry distillation of Chinese wax. The distillate consists of two parts, cerotic acid passing over first, and afterwards cerotene mixed with a certain quantity of oily matter, which may be removed by pressure. It is purified by crystallisation, first from a mixture of alcohol and naphtha, then from ether. It is crystalline, melts between 57° and 58° C., and exhibits the characters of the substances which have been confounded under the name of *Paraffin* (*q. v.*) When distilled several times, it is completely transformed into a mixture of liquid hydrocarbons, whose boiling points vary from 75° to 260° C.

Chlorinated derivatives of Cerotene.—When moist chlorine is passed over melted cerotene, the latter assumes a waxy aspect, then becomes gummy, and is ultimately converted into a transparent resin, becoming harder as it absorbs more chlorine. The reaction takes several weeks to complete, and at different stages of it the following compounds are formed:—$C^{27}H^{36}Cl^{18}$; $C^{27}H^{33}Cl^{21}$; $Cl^{27}H^{32}Cl^{22}$. (Brodie.)

CEROTIC ACID. $C^{27}H^{54}O^{2} = C^{27}H^{53}O.H.O.$ *Cerin of Beeswax.* (John, *Chemische Schriften*, iv. 38; Boudet and Boissenot, J. Pharm. xiii. 38; Ettling, Ann.

Ch. Pharm. ii. 267; Hess, *ibid.* xxvii. 3; Gerhardt, Rev. scient. xix. 5; Lewy, Ann. Ch. Phys. [3] xiii. 438; Brodie, Ann. Ch. Pharm. lxvii. 180.)—This acid is the essential constituent of that portion of beeswax which is soluble in boiling alcohol. It is prepared by treating beeswax several times in succession with boiling alcohol, till the deposit which forms on cooling melts at 70° or 72° C. The acid thus obtained is not yet pure. It is, therefore, to be dissolved in a large quantity of boiling alcohol and the solution precipitated by acetate of lead. The precipitate, after being exhausted with the aid of heat by alcohol and ether, is decomposed by concentrated acetic acid, and the product crystallised from alcohol yields pure cerotic acid. Cerotic acid may also be obtained very nearly pure by crystallising several times from ether, the crude product which melts at 72° C. The mother-liquors retain a small quantity of another fatty acid.— Cerotic acid is likewise produced by the dry distillation of Chinese wax, and by melting that substance with potash.

Pure cerotic acid crystallises on cooling from its solutions in small grains, melting at 78° C. The melted mass assumes on cooling a highly crystalline character.

The pure acid distils without alteration, but the impure acid is decomposed by distillation, yielding principally oily hydrocarbons of very variable boiling point, and containing in solution small quantities of a fatty acid and other oxygenised products. Chlorine transforms cerotic acid into *chlorocerotic acid*, $C^{27}H^{42}Cl^{12}O^2$.

Cerotates.—Cerotic acid is monobasic, the formula of its neutral salts being $C^{27}H^{53}M.O^2$. The *lead-salt*, $C^{27}H^{53}PbO^2$, is obtained as a white bulky precipitate on mixing a solution of cerotic acid in boiling alcohol with alcoholic acetate of lead. The *silver-salt*, $C^{27}H^{53}AgO^2$, is obtained by precipitating an alcoholic and ammoniacal solution of cerotic acid with nitrate of silver at the boiling heat.

CHLOROCEROTIC ACID. $C^{27}H^{42}Cl^{12}O^2$.—Produced by exposing melted cerotic acid to the action of chlorine for several days, as long indeed as fumes of hydrochloric acid are perceptible. The product is a thick transparent gum of a pale yellow colour.

Chlorocerotate of sodium is nearly insoluble in water.

Chlorocerotate of ethyl, $C^{29}H^{46}Cl^{12}O^2 = C^{27}H^{41}Cl^{12}O^2.C^2H^5$, is prepared similarly to the cerotate. It has the aspect of chlorocerotic acid.

CEROTIC ETHERS. *Cerotate of ethyl*, $C^{29}H^{58}O^2 = C^{27}H^{53}O^2.C^2H^5$, is easily produced by passing hydrochloric acid gas into solution of cerotic acid in absolute alcohol. It has the aspect of beeswax, and melts at 59°—60° C.

Cerotate of Ceryl. Chinese Wax. $C^{54}H^{108}O^2 = \left.\begin{matrix}C^{27}H^{53}O\\C^{27}H^{55}\end{matrix}\right\}O$. — This is a peculiar waxy substance obtained from China, where it is produced on certain trees by the puncture of a species of *coccus*. It is crystalline, and of a dazzling whiteness, like spermaceti, but more brittle and of a more fibrous texture. It melts at 82° C. It is purified by crystallisation from a mixture of alcohol and naphtha, then washed with ether, treated with boiling water, and recrystallised from absolute alcohol, which dissolves it in small quantity only. Chinese wax is not saponified completely by boiling with aqueous potash, but decomposes readily when fused with potash, yielding cerotate of potassium and hydrate of ceryl. By dry distillation it yields cerotic acid and cerotene. Almost all the wax gathered in China is used there for making candles. It is also employed by the Chinese as a medicine.

CEROTIN. Syn. of CERYLIC ALCOHOL or HYDRATE OF CERYL (p. 838).

CEROTINONE. The acetone of cerotic acid, obtained by careful distillation of cerotate of lead. (Bruckner, J. pr. Chem. lvii. 1.)

CEROXYLIN or *Palm wax* is the produce of the *Ceroxylon Andicola*, and is obtained by rasping the epidermis of the tree and boiling the raspings in water. The wax floats on the surface in a soft state, while the impurities sink to the bottom. It may be further purified by repeated boiling with alcohol. In its natural state it is a greyish-white powder; after purification, yellowish-white. It is nearly insoluble in alcohol, and melts at 72° C. It has been analysed by Boussingault (Ann. Ch. Phys. xxix. 333), Lewy (Ann. Ch. Phys. [3] xiii. 458), and Teschemacher (Ann. Ch. Pharm. lx. 270) with the following results:—

	Boussingault.	Lewy.	Teschemacher.
Carbon	80·48	80·73	80·28
Hydrogen	13·29	13·30	13·20
Oxygen	6·23	5·97	6·42
	100·00	100·00	100·00

CERUMEN OF THE EAR. A yellow secretion which lines the external auditory canal, rendered viscid and concrete by exposure to air. It has a bitter taste, melts at a low heat, and evolves a slightly aromatic odour. On ignited coals it gives out a white smoke, similar to that of burning fat, swells, emits a fetid ammoniacal odour, and is converted into a light charcoal. Alcohol dissolves ⅝ of it, and on evaporation leaves a substance resembling the resin of bile. The ⅜ which remain are albumin mixed with oil, which by incineration leave carbonate of sodium and phosphate of calcium. U.

CERUSE or *White lead.* See CARBONATES (p. 786).

CERUSITE. Native carbonate of lead (p. 786).

CERVANTITE. Native tetroxide of antimony, SbO^2 or $Sb^2O^3.Sb^2O^5$, found at Cervantes in Spain and at Pereta in Tuscany (p. 324).

CERYL, HYDRATE OF. *Cerylic Alcohol, Cerotin.* $C^{27}H^{56}O = \left.\begin{matrix}C^{27}H^{55}\\H\end{matrix}\right\}O.$ — Produced by fusing Chinese wax (cerotate of ceryl) with potash, digesting the fused mass in boiling water, whereby a solution of cerotate of potassium is obtained holding cerylic alcohol in suspension; precipitating the cerotic acid with chloride of barium; and dissolving out the hydrate of ceryl with alcohol, ether, or coal-tar oil. The hydrate of ceryl, purified by several crystallisations from ether or alcohol, forms a waxy substance melting at 97° C. Heated with potash-lime, it gives off hydrogen, and is converted into cerotate of potassium:

$$C^{27}H^{56}O + KHO = C^{27}H^{53}KO^2 + 4H.$$

At a very high temperature it distils partly undecomposed, partly resolved into water and cerotene, $C^{27}H^{54} + H^2O$. Chlorine acts upon hydrate of ceryl, producing a transparent pale-yellow substitution-product, *chlorcerotal*, containing 37·62 to 37·89 C, 4·76 to 4·78 H, and 55·11 to 55·07 Cl, numbers which correspond to the formula $C^{27}H^{42\frac{1}{2}}Cl^{13\frac{1}{2}}O$. The action of the chlorine was probably not complete. The product has the appearance of a gum-resin, and becomes electrical by friction. (Brodie, Ann. Ch. Pharm. lxvii. 120.)

Hydrate of ceryl treated with excess of sulphuric yields a product which, when washed with cold water, dried in vacuo, and crystallised from ether, has the composition of *neutral sulphate of ceryl with* 1 *at. water*, $(C^{27}H^{55})^2SO^4 + H^2O$. When pure it is perfectly soluble in water, especially if a little alcohol is added; the solution evaporated at a low temperature leaves the substance in the form of a soft wax. (Brodie.)

CETENE or *Cetylene*, $C^{16}H^{32}$. (Dumas and Péligot, Ann. Ch. Phys. [2] lxii. 4; Smith, *ibid.* [3] vi. 40.)—A hydrocarbon homologous with ethylene, obtained by distilling cetylic alcohol with phosphoric anhydride, also by distilling cetin (palmitate of cetyl), and treating the product with potash to saponify the fatty acids which have passed over in the distillation, the cetene then floating on the surface of the liquid.

Cetene is a colourless oily liquid, which stains paper. It boils at 275° C., distilling without alteration. Vapour-density 8·007. It is insoluble in water, easily soluble in alcohol and ether, neutral to test-paper. It has no particular taste. When set on fire, it burns with a very pure white flame, like the fat oils.

Cetene unites with hydrobromic and hydrochloric acids, slowly at ordinary temperatures, somewhat more quickly at 100° C. The compound is decomposed by distillation. (Berthelot, Ann. Ch. Phys. [3] li. 81.)

The ethylosulphates (sulphovinates) yield by dry distillation an oily liquid (*heavy* oil of wine), from which water separates an oily hydrocarbon (*light oil of wine*), which boils at nearly the same temperature as cetene; and this oil, when exposed to a very low temperature deposits crystals (*camphor* or *stearoptene of wine-oil*), having the same composition.

CETIC ACID. $C^{15}H^{30}O^2$?—Produced, according to Heintz, in very small quantity in the saponification of spermaceti (p. 840). Crystallises in nacreous scales grouped in stars, melting at 53·5° C. Benic acid obtained from oil of ben, and stillistearic acid, from the fruit of *Stillingia sebifera*, have the same composition.

CETIN, $C^{32}H^{64}O^2$. (Chevreul, *Recherches sur les Corps gras*, p. 171; Smith, Ann. Ch. Pharm. xlii. 247; Stenhouse, J. pr. Chem. xxvii. 253; Radcliff, Ann. Ch. Phys. [3] vi. 50.)—A fatty crystalline substance constituting the essential part of spermaceti, the substance which, in the state of solution in an oil, fills the cavities in the head of the cacholot, or spermaceti whale, and other cetaceous animals. To obtain it in a state of purity, spermaceti is treated with cold alcohol, which removes the oil, and the residue is crystallised from boiling alcohol.

Cetin melts at 49° C., and solidifies on cooling in a translucent mass, which serves for the manufacture of candles. Heated to 360°, out of contact with the air, it volatilises without alteration; but if heated quickly and in considerable quantities, it is completely decomposed into a solid fatty acid (palmitic acid), and a liquid hydrocarbon (cetene), accompanied, chiefly towards the end of the distillation, by secondary products, such as water, carbonic anhydride, carbonic oxide, and olefiant gas. Cetin is insoluble in water. 100 pts. of *alcohol* of 0·821 dissolve 2·5 pts. of it; *absolute alcohol* and *ether* dissolve it in larger quantities, and deposit it on cooling in brilliant laminæ. *Nitric acid* attacks it slowly, and converts it into a mixture of œnanthylic, adipic, and pimelic acids.

Cetin boiled with caustic alkalis is transformed into hydrate of cetyl and a palmitate of the alkali-metal (Smith):

$$C^{32}H^{64}O^2 + KHO = \underset{\substack{\text{Hydrate of}\\ \text{cetyl.}}}{C^{16}H^{34}O} + \underset{\substack{\text{Palmitate of}\\ \text{potassium.}}}{C^{16}H^{31}KO^2}.$$

It must be observed, however, that the statements of different chemists regarding the fatty acids resulting from the saponification of cetin do not quite agree. Chevreul obtained margaric and oleic acid. Heintz (Pogg. Ann. lxxxiv. 232) obtained a mixture of stearic, palmitic, myristic, cocinic, and cetic acids, which he separated by the different solubility of the acids themselves, and of their barium-salts, in alcohol. He therefore regards cetin, not as a simple proximate principle, but as a mixture of the cetyl-salts of the acids just mentioned. By repeatedly crystallising spermaceti from ether, he obtained at last a small quantity of a fatty substance, which melted at 53·5° C., but in other respects exhibited the characters of cetin, and also its composition, viz. 80·03 C, 13·25 H, and 6·72 O.

CETRARIA. See LICHENS.

CETRARIC ACID. *Cetrarin.* $C^{18}H^{16}O^8$. (Berzelius, Schw. J. vii. 317; Ann. Chim. xc. 277.—Herberger, Ann. Ch. Pharm. xxi. 137.—Knop and Schnedermann, *ibid.* lv. 144.)—Contained, together with lichenostearic acid, in Iceland moss (*Cetraria islandica*). To obtain the two acids, the lichen is treated for about a quarter of an hour with a boiling mixture of strong alcohol and carbonate of potassium (15 grm. of the carbonate to each kilogramme of alcohol), whereby the acids are dissolved as potassium-salts. The filtered liquid mixed with hydrochloric acid, deposits the two acids mixed with a green substance; and by treating this mixture with 8 or 10 times its weight of boiling dilute alcohol, the lichenostearic acid is dissolved, while the cetraric acid and the green substance remain undissolved.

To isolate the cetraric acid, which forms the greater part of the residue, this residue is washed several times with a mixture of ether and an essential oil, for the purpose of removing the green matter; it is then boiled with strong alcohol, which dissolves the cetraric acid, and on cooling deposits it in slender needles, which are purified by boiling them with animal charcoal, then dissolving them in potash, and decomposing the potassium-salt with hydrochloric acid. (Knop and Schnedermann.)

Cetraric acid crystallises in extremely fine capillary needles, of dazzling whiteness. It has a pure bitter taste, is nearly insoluble in water, sparingly soluble in ether, very soluble in boiling alcohol. The crystals are anhydrous.

Cetraric acid turns brown when boiled with water; the alcoholic solution also turns brown on boiling: this change is much accelerated by the presence of an alkali. *Sulphuric acid* colours cetraric acid, first yellow, afterwards red: the mass becomes glutinous and dissolves: and water added to the solution throws down ulmic acid. *Hydrochloric acid* dissolves a small quantity of cetraric acid, the undissolved portion assuming a deep blue colour. This blue compound is dissolved with red colour by strong sulphuric acid, and reprecipitated blue by water. This blue precipitate dissolves in a mixture of dichloride and tetrachloride of tin, and alkalis added to the solution throw down a blue lake (Herberger). Cetraric acid is oxidised by *nitric acid*, yielding oxalic acid and a yellow resin. Chlorine and bromine do not appear to act upon it.

Cetraric acid decomposes carbonates, and forms yellow salts, soluble in water and alcohol, and having an intolerably bitter taste. It has a great tendency to form acid salts. The neutral salts cannot be evaporated, even in vacuo, without decomposing and turning brown. The acid salts are precipitated in a gelatinous form, by mixing the neutral salts with half the quantity of hydrochloric acid necessary to saturate the base. They are difficult to wash, but may be evaporated in the air without turning brown.

An alcoholic solution of acid cetrarate of potassium, forms a deep red precipitate with *ferric* chloride, the liquid at the same time assuming a blood-red colour.

Cetrarate of ammonium is obtained as a yellow powder, by treating the acid with gaseous ammonia, of which it absorbs 10·2 per cent. The *lead*-salt, $C^{18}H^{14}Pb^2O^8$, is obtained as a yellow flocculent precipitate, by mixing acetate of lead with cetrarate of ammonium. The *silver*-salt is a yellow precipitate, which rapidly turns brown. (Knop and Schnedermann.)

CETYL. $C^{16}H^{33}$.—A monotomic alcohol-radicle not yet isolated, but supposed to exist in a series of compounds homologous with the ethyl-compounds, and derived from spermaceti. The cetyl-compounds at present known are:

Type H.H.O.

Hydrate of cetyl (cetylic alcohol)	$C^{16}H^{33}.H.O$
Oxide of cetyl (cetylic ether)	$(C^{16}H^{33})^2O$
Oxide of cetyl and sodium	$C^{16}H^{33}.Na.O$
Oxide of cetyl and ethyl	$C^{16}H^{33}.C^2H^5.O$
Oxide of cetyl and amyl	$C^{16}H^{33}.C^5H^{11}.O$
Acetate of cetyl	$C^2H^3O.C^{16}H^{33}.O$
Benzoate of cetyl	$C^7H^5O.C^{16}H^{33}.O$
Butyrate of cetyl	$C^4H^7O.C^{16}H^{33}.O$
Stearate of cetyl	$C^{18}H^{35}.O.C^{16}H^{33}.O$
Succinate of cetyl	$(C^4H^4O^2)''.(C^{16}H^{33})^2.O^2$
Sulphate of cetyl and hydrogen	$(SO^2)''.C^{16}H^{33}.H.O^2$
Sulphydrate of cetyl	$C^{16}H^{33}.H.S$
Sulphide of cetyl	$(C^{16}H^{33})^2S$
Cetyl-xanthic acid	$(CO)''.C^{16}H^{33}.H.S^2$

Type HH.

Bromide of cetyl	$C^{16}H^{33}Br$
Chloride of cetyl	$C^{16}H^{33}Cl$
Iodide of cetyl	$C^{16}H^{33}I$
Cyanide of cetyl	$C^{16}H^{33}Cy$

Type NH³.

Nitride of cetyl, or tricetylamine	$N.(C^{16}H^{33})^3$
Cetylphenylamine	$N\left\{\begin{matrix}C^{16}H^{33}\\C^6H^5\\H\end{matrix}\right.$
Dicetylphenylamine	$N\left\{\begin{matrix}C^{16}H^{33}\\C^{16}H^{33}\\C^6H^5\end{matrix}\right.$

CETYL, ACETATE OF. $C^{18}H^{36}O^2 = C^2H^3O.C^{16}H^{33}.O$, is produced by treating cetylic alcohol with acetic and hydrochloric or sulphuric acid, precipitating by water, dissolving in ether, and evaporating, as an oily liquid, which at a low temperature solidifies, after a while, in a mass of needle-shaped crystals, fusible at 18·5° C. (Becker, Ann. Ch. Pharm. cii. 219.)

CETYL, BENZOATE OF. $C^{23}H^{38}O^2 = C^7H^5O.C^{16}H^{33}.O$.—Obtained by heating chloride of benzoyl with cetylic alcohol in equivalent proportion, dissolving the residue in ether, and precipitating with alcohol. It forms crystalline scales, which melt at 30° C., dissolve readily in ether, and sparingly in alcohol. (Becker, *loc. cit.*)

CETYL, BROMIDE OF. $C^{16}H^{33}Br$.—Produced by the action of bromine and phosphorus on cetylic alcohol. It is a colourless solid body, heavier than water in the melted state, insoluble in water, very soluble in alcohol and ether; melts at 15° C. When distilled, it gives off hydrobromic acid. (Fridau, Ann. Ch. Pharm. lxxxiii. 15.)

CETYL, BUTYRATE OF. $C^{20}H^{40}O^2 = C^4H^7O.C^{16}H^{33}.O$.—Obtained by slowly heating a mixture of cetylic alcohol and butyric acid to 200° C., and proceeding as with the benzoate. It is white, neutral, miscible with ether but not with alcohol, melts more easily than cetylic alcohol, and when cautiously heated in small quantity, volatilises without decomposition. (Handw. d. Chem. 2te Aufl. ii. [2] 929.)

CETYL, CHLORIDE OF. $C^{16}H^{33}Cl$. *Hydrochlorate of Cetene.*—Obtained by the action of pentachloride of phosphorus on cetylic alcohol. The two bodies mixed in fragments in a retort, become heated, melt, and act violently on each other, giving off large quantities of hydrochloric acid. On subsequently distilling the product, oxychloride of phosphorus passes over, and then chloride of cetyl, which may be purified by redistillation with a small quantity of pentachloride of phosphorus, washing with boiling water, and drying in vacuo at about 120° C. If it still contains hydrochloric acid, it must be distilled with lime recently ignited. (Dumas and Péligot, Ann. Ch. Phys. lxxii. 4.)

Chloride of cetyl is a limpid oily liquid of specific gravity 0·8412 at 12° C., insoluble in water and in alcohol, but soluble in ether, whence it may be precipitated by weak alcohol. It distils above 200° C., with partial decomposition, and by prolonged ebullition the whole of the chlorine may be expelled as hydrochloric acid, leaving cetene (p. 838). It is not acted upon by nitric acid, but strong sulphuric acid decomposes it, eliminating hydrochloric acid and forming cetyl-sulphuric acid. It does not absorb ammonia. (Tütscheff, Rép. Chim. pure, ii. 463.)

CETYL, CYANIDE OF. $C^{16}H^{33}.CN$.—Obtained in an impure state, by heating cetylsulphate of potassium with cyanide of potassium, and extracting with ether

(Köhler, Zeitschr. d. gesammt. Naturw. vii. 252; Jahresber. 1856, 579.—Heintz, Pogg. Ann. cii. 257; Jahresber. 1857, 445). According to Köhler, it is a solid crystalline substance, melting at 53° C., easily soluble in ether and in hot alcohol; according to Heintz, it is liquid at ordinary temperatures, but its formation is accompanied by that of a crystalline solid, which melts at 55·1°, and is probably a mixture of cetylic ether with palmitic aldehyde. Heated with potash it appears to yield margaric acid, $C^{17}H^{34}O^2$. (Köhler.)

CETYL, HYDRATE OF. $C^{16}H^{34}O = C^{16}H^{33}.H.O$. *Cetylic Alcohol, Ethal.* (Chevreul, *Recherches sur les Corps gras*, p. 171.—Dumas and Péligot, Ann. Ch. Phys. [2] lxii. 4; Smith, *ibid.* [3] vi. 40; also, Ann. Ch. Pharm. xlii. 247.—Heintz, Pogg. Ann. lxxxiv. 232; lxxxvii. 553.)—This compound is prepared by saponifying spermaceti with an alkali, the cetin, or palmitate of cetyl contained in that substance being then resolved into an alkaline palmitate and hydrate of cetyl, which latter is dissolved out by alcohol or ether. Dumas and Péligot add 1 pt. of solid hydrate of potassium, by small portions and with constant agitation, to 2 pts. of melted spermaceti, treat the resulting soapy mass with water, and then with a slight excess of hydrochloric acid. On boiling the liquid, the ethal and the fatty acids of the soap rise to the surface, in the form of an oily layer, which is separated by decantation, and saponified a second time in the same manner, to decompose a small remaining quantity of spermaceti; the fatty acids are again separated by means of hydrochloric acid, and saponified with slaked lime added in excess. A mixture of lime-soap and hydrate of cetyl is thus obtained, from which the latter is dissolved out by alcohol. Lastly, the alcohol is distilled off, and the cetylic alcohol which remains is purified by crystallisation from ether. Heintz boils spermaceti with an alcoholic solution of potash; precipitates the boiling liquor with a concentrated aqueous solution of chloride of barium; and dissolves out the ethal from the precipitate with alcohol. As the alcohol also dissolves small quantities of barium-salts, it is removed by distillation, and the ethal which remains is dissolved in cold ether, and finally purified by several crystallisations from ether.

Cetylic alcohol or ethal is a white solid crystalline mass, which melts at a temperature above 48° C., but solidifies at 48° (Chevreul). It melts in water at 50° C., and when it solidifies, the temperature rises to 51·5°; when melted alone, it solidifies at 49° or 49·5° (Heintz). When slowly cooled, it crystallises in shining laminæ: it also crystallises on cooling from solution in alcohol. It is without taste or smell, and distils without alteration, passing over even with vapour of water. It is insoluble in water, but mixes in all proportions with alcohol and ether.

Ethal does not give off water when heated with *oxide of lead.* It is not dissolved by *aqueous alkalis;* but when strongly heated with *potash-lime,* it gives off hydrogen, and is converted into a potassium-salt, probably palmitate or ethalate (Dumas and Stas, Ann. Ch. Phys. [2] lxxiii. 124):

$$C^{16}H^{34}O + KHO = C^{16}H^{31}KO^2 + 4H.$$

Ethal is decomposed by *sodium,* yielding *cetylate of sodium,* $C^{16}H^{33}KO$. With *potash* and *sulphide of carbon* it forms cetyl-xanthate of potassium, $C^{16}H^{33}.K.COS^2$. Distilled with *pentachloride of phosphorus,* it forms chloride of cetyl, oxychloride of phosphorus, and hydrochloric acid:

$$C^{16}H^{33}.H.O + PCl^3.Cl^2 = C^{16}H^{33}Cl + PCl^3O + HCl.$$

With *iodine* and *phosphorus,* it yields iodide of cetyl. With strong *sulphuric acid,* it forms cetyl-sulphuric acid, $C^{16}H^{33}.H.SO^4$.

Heintz (*loc. cit.*) regards ethal, not as a simple alcohol, but as a mixture of cetylic and stearic alcohols, $C^{16}H^{34}O$, and $C^{18}H^{38}O$: because, according to his experiments, the *ethalic* acid of Dumas and Stas, is a mixture of palmitic and stearic acids, separable by solution in boiling alcohol and precipitation by acetate of barium.

CETYL, IODIDE OF, $C^{16}H^{33}I$. (Fridau, Ann. Ch. Pharm. lxxxiii. 9).—Prepared by introducing phosphorus into cetylic alcohol heated to 120° C. in an oil-bath, and adding an excess of iodine by small portions at a time, while the mixture is continually stirred. Hydriodic acid is then given off, together with phosphorous acid, while iodide of phosphorus crystallises out, and iodide of cetyl remains in the liquid state. When the reaction is complete, the iodide of cetyl is decanted, washed with cold water, which causes it to solidify, and then crystallised from alcohol. It crystallises in colourless interlaced laminæ, insoluble in water, easily soluble in ether, more soluble in boiling than in cold alcohol. Melts at 22° C., and solidifies on cooling in rosettes having a fatty aspect. Burns with a clear flame, giving off free iodine.

It does not distil without alteration, but decomposes quickly at 250° C., giving off copious vapours of iodine and hydriodic acid, together with an oily hydrocarbon. It is violently attacked by *mercuric* oxide at 200°, yielding an oil (cetene?) together with iodide of mercury and metallic mercury, and leaving a crystallisable solid fusible at 50°. With oxide of silver recently precipitated, and still moist, it forms the same compound, melting at 50°. With cetylate of sodium it yields iodide of sodium and oxide of cetyl·

$$C^{16}H^{33}.K.O + C^{16}H^{33}.I = KI + (C^{16}H^{33})^2O.$$

Ammonia in solution does not act on iodide of cetyl, but gaseous ammonia converts it into tricetylamine, $N(C^{16}H^{33})^3$. With phenylamine it forms cetyl-phenylamine and dicetyl-phenylamine. (Fridau).

CETYL, NITRIDE OF. See CETYLAMINE.

CETYL, OXIDE OF. *Cetylic ether.* $(C^{16}H^{33})^2O$.—Obtained by treating cetylate of sodium, $C^{16}H^{33}KO$, with iodide of cetyl at 110° C., washing the product with boiling water to remove iodide of potassium, and crystallising from alcohol or ether. It crystallises in shining scales. Melts at 55° C., and solidifies between 53° and 54° in a radiated mass; distils at 300° for the most part without decomposition. It is not attacked by hydrochloric or nitro-hydrochloric acid at the boiling heat. but strong sulphuric acid destroys it. (Fridau, Ann. Ch. Pharm. lxxxiii. 20.)

Cetyl-ethyl-oxide or *cetylate of ethyl*, $C^2H^5.C^{16}H^{33}.O$, and *cetyl-amyl-oxide* or *cetylate of amyl*, $C^5H^{11}.C^{16}H^{33}.O$, are obtained in like manner by treating cetylate of sodium with iodide of ethyl or amyl. They both crystallise in laminæ, soluble in alcohol or ether: the ethyl-compound melts at 20° C., the amyl-compound at 30°. (G. Becker, Ann. Ch. Pharm. cii. 220.)

Cetyl-sodium-oxide or *cetylate of sodium*, $C^{16}H^{33}NaO$, obtained by the action of sodium or cetylic alcohol, is a greyish-yellow solid which begins to melt at 100° C. and is perfectly fluid and transparent at 110°. It is not decomposed by boiling water, but hydrochloric acid separates cetylic alcohol from it. (Fridau.)

CETYL, STEARATE OF. $C^{34}H^{68}O^2 = C^{18}H^{35}O.C^{16}H^{33}.O$.—Prepared like the butyrate. Thin white shining laminæ, sparingly soluble in boiling alcohol and in cold ether, easily in boiling ether. Melts at 55°—60° C., and forms a crystalline mass on cooling. Volatilises with partial decomposition when heated in a tube. (Handw.)

CETYL, SUCCINATE OF. $C^{36}H^{70}O^4 = (C^4H^4O^2)''.(C^{16}H^{33})^2.O^2$.—Prepared by heating 1 at. succinic acid with 2 at. cetylic alcohol in an air-bath, neutralising with carbonate of sodium and recrystallising from ether. White laminæ, sparingly soluble in alcohol, more freely in ether-alcohol, still more in pure ether. (Tütscheff, *loc. cit.*)
